- This release also fixes an issue where the deployment of the AXService would fail in slower environments due to a hard-coded timeout.

What's new in local agent 2.3.0

- Local agent 2.3.0 enables the execution of custom pre- and post- deployment scripts.
- It fixes the problem introduced in 2.2.0 with regard to deploying older platform updates.
- This release removes the monitoring agent and introduces a new service called LBDTelemetry, which will be used to install the ETWManifests.

> **IMPORTANT**
> This release requires that a new local agent configuration file be downloaded from LCS. Refer to the Troubleshoot on-premises deployments topic if you encounter problems.

What's new in local agent 2.1.0

- Local agent 2.1.0 enables the two-phased servicing where **Environment preparation** and **Environment update** are two distinct steps and explicit actions. This reduces the total downtime customers must take when applying updates to their on-premises environments by preparing upfront and allowing users to use

the environment during preparation and then communicating the downtime when the actual update environment action is triggered.

What's new in local agent 2.0.0

- Local agent 2.0.0 can deploy Platform update 12.
- It enables the Reconfigure feature until the first deployment of Platform update 12 succeeds.
- It disables the Reconfigure feature on the first successful deployment of Platform update 12. After deployment succeeds, you can use the regular update experience to update the environment.

> **NOTE**
>
> Local agent 2.0.0 **cannot** deploy Platform update 8 and Platform update 11. You must have version 1.1.0 to deploy those platform updates.

Download the latest local agent and configuration from LCS

> **NOTE**
>
> If you require an older version of the local agent for your current deployments, download it from the Asset library in Microsoft Dynamics Lifecycle Services (LCS). To download Local agent version 1.1.0, go to **Shared Asset Library -> Model** and click on Dynamics 365 for Finance and Operations on-premises - Local agent v1.1.0**.
>
> You must have version 2.0.0 or later to deploy Platform update 12 and complete update flows.

1. In LCS, select **Project settings** > **On-prem connectors**.
2. Select the connector to your environment, and then select **Edit**.
3. On the menu on the left side of the page, select **Setup host infrastructure**, and then select **Download agent installer**.

   You must now verify that the zip file that is downloaded and unblocked.
4. Go to the zip file, right-click it, and then select **Properties**.
5. In the **Properties** dialog box, select **Unblock**, and then select **Apply**.
6. On the **Configure agent** tab, select **Download configurations** to download the localagent-config.json configuration file.

Update the local agent

1. Copy the zip file and the localagent-config.json file into one of the **Orchestrator** nodes, such as **c:\DynamicsAgent** in the **Orch1** virtual machine (VM).
2. Unzip the agent installer to C:\DynamicsAgent\LocalAgent.
3. Copy the localagent-config.json file to C:\DynamicsAgent\LocalAgent.
4. In a **Command Prompt** window, go to C:\DynamicsAgent\LocalAgent, and run the following command.

```
LocalAgentCLI.exe Cleanup <path of localagent-config.json>
```

> **NOTE**
>
> You must use the current agent's binaries to clean up the agent. If you don't have the current agent's binaries, you can delete the local agent application from Service Fabric Explorer.

5. Press any key to exit the cleanup operation.
6. Verify that the local agent has been successfully cleaned up by looking in Service Fabric Explorer and making sure that there are no apps in the **Deployed Applications** section in the **Orchestrator** nodes.
7. After the local agent is successfully cleaned up, run the following command.

```
LocalAgentCLI.exe Install <path of localagent-config.json>
```

8. After the local agent is successfully installed, go back to your on-premises connector in LCS.
9. On the **Validate setup** tab, select **Message agent** to test LCS connectivity to your new local agent.

Troubleshoot on-premises deployments

2/18/2021 • 51 minutes to read • Edit Online

This topic provides troubleshooting information for deployments of Microsoft Dynamics 365 Finance + Operations (on-premises).

Access Service Fabric Explorer

You can access Service Fabric Explorer in a web browser by using the default address, `https://sf.d365ffo.onprem.contoso.com:19080`.

To verify the address, note the value that was used in the "Create DNS zones and add A records" section of the appropriate setup and deployment topic for your environment:

- Platform update 12
- Platform update 8 and Platform update 11

You can access the site only if the client certificate is in cert:\CurrentUser\My on the machine that you're accessing the site on. (In Certificate Manger, go to **Certificates - Current User** > **Personal** > **Certificates**.) When you access the site, select the client certificate when you're prompted.

Monitor the deployment

Identify the primary orchestrator

To determine the machine that is the primary instance for stateful services such as a local agent, in Service Fabric Explorer, expand **Cluster** > **Applications** > **<*intended application example*> LocalAgentType** > **fabric:/LocalAgent/OrchestrationService** > **(GUID)**.

The primary node is shown. For stateless services or the remaining applications, you must check all the nodes.

Note the following points:

- OrchestrationService orchestrates the deployment and servicing actions for Finance + Operations.
- ArtifactsManager downloads files from Microsoft Azure cloud storage to the local agent file share. It also unzips the files into the required format.

Review the orchestrator event logs

From the primary OrchestrationService orchestrator machine, in Event Viewer, go to **Applications and Services Logs** > **Microsoft** > **Dynamics** > **AX-LocalAgent**.

> **NOTE**
>
> To view the full error message, you must select the **Details** tab.

The following modules must be installed:

- Common
- ReportingServices
- AOS
- FinancialReporting

The following commands must be run:

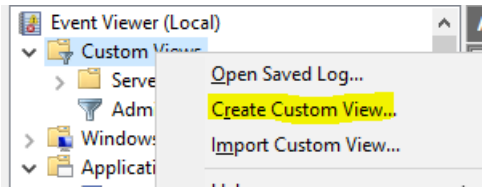
- **Setup**
- **Dvt** – This command runs a deployment verification test.
- **Cleanup** – This command is used to service and delete an environment.

The following folders contain additional information:

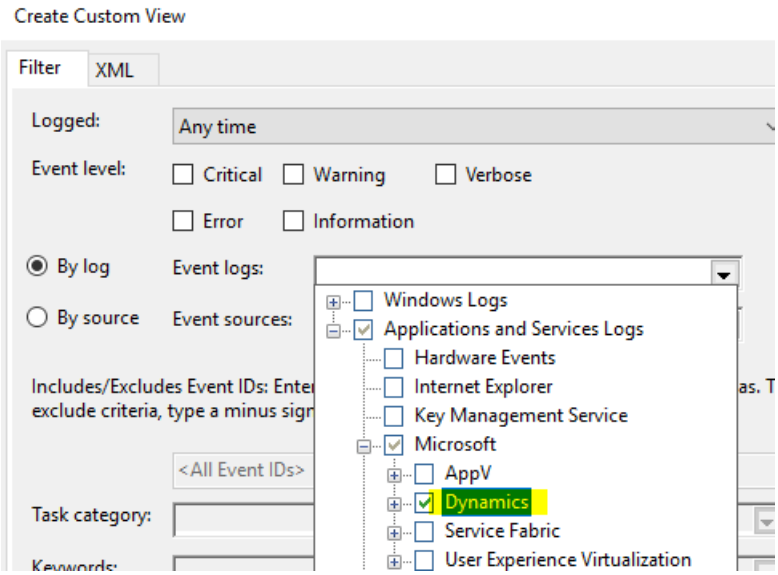
- AX-SetupModuleEvents
- AX-SetupInfrastructureEvents
- AX-BridgeService

To review Microsoft Dynamics entries in Event Viewer, follow these steps.

1. In Event Viewer, right-click **Custom Views**, and then select **Create Custom View**.



2. In the **Event logs** field, select **Dynamics**.



> **NOTE**
> Also look at **Administrative Events** in **Custom Views**.

Service Fabric Explorer

Note the state of the cluster, application, and nodes. For information about how to access Service Fabric Explorer, see Access Service Fabric Explorer.

Error: "Partition is below target replica or instance count"

You might receive the following error:

```
Partition is below target replica or instance count
```

This error isn't a root error. It indicates that the status of each node isn't ready. For AXSFType (AOS), the status might still be **InBuild**.

On the machines that are related to the error message, use Event Viewer to view the latest activity.

AXSFType

If a status of **InBuild** is shown for AXSFType (AOS), review the DB Sync status and other events from Application Object Server (AOS) machines.

To diagnose errors, use Event Viewer to review the following event logs:

- Applications and Services Logs > Microsoft > Dynamics > AX-DatabaseSynchronize
- Custom Views > Administrative Events

Error: "'ExtractInstallerService failed to extract' C:\Users\dynuser.CONTOSO\AppData\Local\Temp\1blssblh.w0n\FabricInstallerService.Code\FabricClient.dll"

You might receive the following error:

> "ExtractInstallerService failed to extract" C:\Users\dynuser.CONTOSO\AppData\Local\Temp\1blssblh.w0n\FabricInstallerService.Code\FabricClient.dll.

If you receive this error, download the latest version of Azure Service Fabric. Note that the user name and path in the error message vary, depending on your environment.

Service Fabric logs

You can find more details about Service Fabric applications in the log files at C:\ProgramData\SF\<OrchestratorMachineName>\Fabric\work\Applications\LocalAgentType_App<N>\log.

Lifecycle Services

Note the current deployment status for the environment in Microsoft Dynamics Lifecycle Services (LCS).

A time-out error occurs when a Service Fabric cluster is created

Run Test-D365FOConfiguration.ps1 as noted in the "Set up a standalone Service Fabric cluster" section of the appropriate setup and deployment topic for your environment. Note any errors.

- Platform update 12
- Platform update 8 and Platform update 11

Be sure to complete these steps:

- Verify that the Service Fabric Server client certificate exists in the LocalMachine store on all Service Fabric nodes.
- Verify that the Service Fabric Server certificate has the access control list (ACL) for Network Service on all Service Fabric nodes.
- Review the antivirus exclusions that are noted in Environment setup.

A time-out error occurs while you're waiting for Installer Service to be completed for machine x.x.x.x

Only one node type is supported for each Internet Protocol (IP) address (that is, for each machine). Check whether the nodes are being reused on the same machine. For example, AOS and ORCH must not be on the same machine, and ConfigTemplate.xml must be correctly defined.

Remove a specific application

We recommend that you use LCS to remove or clean up deployments. However, you can also use Service Fabric Explorer to remove an application as you require.

In Service Fabric Explorer, go to **Application node** > **Applications** > **MonitoringAgentAppType-Agent**. Select the ellipsis button (...) next to **fabric:/Agent-Monitoring**, and delete the application. Enter the full name of the application to confirm the deletion of the application.

You can also remove MonitoringAgentAppType-Agent by selecting the ellipsis button and then selecting **Unprovision Type**. Enter the full name to confirm the removal of the application.

Remove all applications from Service Fabric

The following script removes and unprovisions all Service Fabric applications except LocalAgent and the monitoring agent for LocalAgent. You must run this script on an orchestrator virtual machine (VM).

```
$applicationNamesToIgnore = @('fabric:/LocalAgent', 'fabric:/Agent-Monitoring', 'fabric:/Agent-
LBDTelemetry')
$applicationTypeNamesToIgnore = @('MonitoringAgentAppType-Agent', 'LocalAgentType', 'LBDTelemetryType-
Agent')

Get-ServiceFabricApplication | `
    Where-Object { $_.ApplicationName -notin $applicationNamesToIgnore } | `
    Remove-ServiceFabricApplication -Force

Get-ServiceFabricApplicationType | `
    Where-Object { $_.ApplicationTypeName -notin $applicationTypeNamesToIgnore } | `
    Unregister-ServiceFabricApplicationType -Force
```

Remove Service Fabric

To completely remove the Service Fabric cluster, follow these steps.

1. Run the following command.

   ```
   .\RemoveServiceFabricCluster.ps1 -ClusterConfigFilePath .\ClusterConfig.json
   ```

2. If an error occurs, remove a specific node on the cluster by using the **CleanFabric.ps1** command. You can find this command in C:\Program Files\Microsoft Service Fabric\bin\fabric\fabric.code.

3. Remove the **C:\ProgramData\SF** folder, if you're using the default location. Otherwise, remove the specified folder.

   If you receive an "Access denied" error, restart Microsoft Windows PowerShell or the machine.

Clean up an existing environment and redeploy

To clean up an existing environment and redeploy, follow these steps.

1. In LCS, open the project, and then, in the **Environments** section, delete the deployment.

   The applications should start to disappear from Service Fabric Explorer in the environment. This process will take one to two minutes.

2. Access the orchestrator machine that contains LocalAgentCLI.exe, and follow these steps:

   a. Run the local agent cleanup.

      ```
      .\LocalAgentCLI.exe Cleanup '<path of localagent-config.json>'
      ```

   b. Remove Service Fabric.

```
.\RemoveServiceFabricCluster.ps1 -ClusterConfigFilePath '<path of ClusterConfig.json>'
```

c. If any nodes fail, run the **CleanFabric.ps1** command. You can find this command in C:\Program Files\Microsoft Service Fabric\bin\fabric\fabric.code.

d. Remove the **C:\ProgramData\SF** folder on all Service Fabric nodes.

If you receive an "Access denied" error, restart the machine, and try again.

3. Remove or update certificates as required.

Remove old certificates from all AOS, BI, ORCH, and DC nodes.

- The certificates exist in the following certificate stores: Cert:\CurrentUser\My\, Cert:\LocalMachine\My, and Cert:\LocalMachine\Root.
- If the setup of Microsoft SQL Server will be modified, remove the SQL Server certificates.
- If the settings for Active Directory Federation Services (AD FS) will be modified, remove the AD FS certificate.

4. Update the following configuration files as required:

- ConfigTemplate.xml
- ClusterConfig.json

For information about how to correctly fill in the fields in the templates, see the appropriate setup and deployment topic for your environment:

- Platform update 12
- Platform update 8 and Platform update 11

5. In LCS, open the project, and update the LCS on-premises connector as required.

a. Re-create the LCS on-premises connector for the environment, or edit the settings of an existing connector.

To obtain easy-to-copy values for LCS, use the .\Get-AgentConfiguration.ps1 script.

b. Download the latest local agent configuration, localagent-config.json.

6. Deploy again by following the instructions in the appropriate setup and deployment topic for the environment:

- Platform update 12
- Platform update 8 and Platform update 11.

Find the local agent values that are used

You can find local agent values in Service Fabric Explorer. Go to **Cluster** > **Applications** > **LocalAgentType** > **fabric:/LocalAgent**, and then select **Details**.

Alternatively, run the following Windows PowerShell command.

```
.\Get-AgentConfiguration.ps1 -ConfigurationFilePath .\ConfigTemplate.xml
```

Install, upgrade, or uninstall a local agent

For information about how to update the local agent, see Update the local agent.

You can also use the following upgrade and uninstallation commands:

```
LocalAgentCLI.exe Install <path of localagent-config.json>
LocalAgentCLI.exe Cleanup <path of localagent-config.json>
```

> **NOTE**
>
> The **Cleanup** command doesn't remove any files that were put in the file share. The file share can be reused.

An error occurs when local agent services are started

When local agent services are started, you might receive the following error:

> Could not load file or assembly 'Lcs.DeploymentAgent.Proxy.Contract, Version=1.0.0.0, Culture=neutral, PublicKeyToken=31bf3856ad364e35' or one of its dependencies.

This error means that strong name verification is turned on. You can turn off this verification by using Configure-PreReqs.ps1. To validate that strong name verification is no longer turned on, run Test-D365FOConfiguration.ps1.

A "Validation in progress" message is shown for several minutes in LCS

Follow these steps to troubleshoot general issues with local agent validation.

1. Run **Configure-PreReqs.ps1** on all orchestrator machines to configure the machines correctly.
2. Verify that the Test-D365FOConfiguration.ps1 script passes on all the orchestrator machines.
3. Verify that the installation of LocalAgentCLI.exe is successfully completed.
4. In Service Fabric Explorer, verify that all the applications are healthy.
5. If the applications aren't healthy, find the primary node for the service that is failing. In Event Viewer, look for events in the following locations:
   - Custom Views > Administrative Events
   - Applications and Services Log > Microsoft > Dynamics > AX-LocalAgent

Local agent errors

Issue

Error: When you install the local agent, you receive the following error.

```
LocalAgentCLI.exe Error: 0 : Exception System.InvalidOperationException: unable to get settings for
telemetry setup component
    at LBDTelemetryCommon.LBDTelemetrySetupManager.GetComponentSettings()
    at LBDTelemetryCommon.LBDTelemetrySetupManager.ApplyParameters()
    at LocalAgentCLI.Program.Main(String[] args)
Press any key to exit
```

Reason: You're trying to install local agent version 2.3.0 or later, but the localagent-config.json file that you're using isn't up to date.

Steps: Get the new version of the localagent-config.json file from LCS by following the instructions in the "Configure a connector and install an on-premises local agent" section of Set up and deploy on-premises

environments.

You can also manually add the following values in the **components** section of the localagent-config.json file.

```
{
    "name": "LBDTelemetry",
    "placementCriteria": "(IsOrchestratorEnabled == True)",
    "parameters": {
        "applicationPackagePath": {
            "value": "Applications\\LBDTelemetry"
        }
    }
},
```

Issue

Error: You might receive the following errors:

> Unable to process commands

> Unable to get the channel information

> RunAsync failed due to an unhandled exception causing the host process to crash:
> System.ArgumentNullException: Value cannot be null. Parameter name: certificate

Reason: These errors can occur because the certificate that is specified for the OnPremLocalAgent certificate either isn't valid or isn't correctly configured for the tenant.

Steps: Follow these steps to resolve the error.

1. Run **Test-D365FOConfiguration.ps1** on all orchestrator nodes to make sure that all checks pass.
2. Verify that the certificate that is specified in the local agent configuration is correct.
   - Make sure that the thumbprint that you specify in LCS and in the ConfigTemplate.xml file has no special characters.
   - The certificate should be the same certificate that is specified in the following section in infrastructure\ConfigTemplate.xml.

     ```
     <Certificate type="Orchestrator" exportable="true" generateSelfSignedCert="true">
         <Name>OnPremLocalAgent</Name>
         <Thumbprint></Thumbprint>
         <ProtectTo></ProtectTo>
     </Certificate>
     ```
3. Make sure that the same certificate that is specified in the local agent configuration in LCS was used to complete the steps in the "Configure LCS connectivity for the tenant" section of the appropriate setup and deployment topic for your environment:
   - Platform update 12
   - Platform update 8 and Platform update 11
4. Uninstall the local agent.
5. Specify the correct certificate in the local agent configuration, and download the configuration file again.
6. Install the local agent again by using the new configuration file.

Error

Error: During servicing, you receive an "Unable to download asset" error, and the details state, "The credentials supplied to the package were not recognized."

Reason: The ACL wasn't correctly defined on certificates.

Steps:

Check whether ACL was removed from client certificate on orchestrator machines. Run the .\Test-D365FOConfiguration.ps1 script on orchestrator machines, and verify the ACL.

To resolve the error, run the .\Set-CertificateAcls.ps1 script to reset the ACLs.

Error

Error:

> Access to the path '\...\agent\assets\StandAloneSetup-76308-1.zip' is denied.

Reason: The file share that is specified in the local agent configuration isn't valid.

Steps: Follow these steps to resolve the error.

1. Verify that the specified share exists.
2. Verify that the local agent user has full permission on the share. The local agent user is the Domain Name System (DNS) name that is specified in the following section in ConfigTemplate.xml.

   ```
   <ADServiceAccount type="gMSA" name="svc-LocalAgent$" refName="gmsaLocalAgent">
       <DNSHostName>svc-LocalAgent.d365ffo.onprem.contoso.com</DNSHostName>
   </ADServiceAccount>
   ```

3. Make sure that the "Set up file storage" section of the appropriate setup and deployment topic for your environment is completed:
   - Platform update 12
   - Platform update 8 and Platform update 11
4. Uninstall the local agent.
5. Specify the correct file share in the local agent configuration, and download the configuration file again.
6. Install the local agent again by using the new configuration file.

Error

Error: When you do a servicing operation, you receive the following error:

> Unable to get extract setup folder for command

Reason: The file share has been removed or changed.

Steps: To see what the file share is set to, open Microsoft SQL Server Management Studio, and run the following query on the orchestrator database:

```
select * from OrchestratorCommandArtifact where CommandId = 'xxx'
```

Error

Error:

> Login failed for user 'D365\svc-LocalAgent$'. Reason: Could not find a login matching the name provided. [CLIENT: 10.0.2.23]

Reason: The local agent user can't connect to the orchestrator database. This issue can occur because users have been deleted and then re-created in Active Directory Domain Services (AD DS). Therefore, the security identifier (SID) of the user has changed, and any access that was given to the user for the SQL Server instance or the database no longer works.

Steps: Follow these steps to resolve the error.

1. Run the following script on the SQL Server instance.

   ```
   .\Initialize-Database.ps1 -ConfigurationFilePath .\ConfigTemplate.xml -ComponentName Orchestrator
   ```

   This script creates an empty orchestrator database, if an empty database doesn't already exist. It then adds the local agent user to the database and gives it db_owner permission.

   After the correct permissions are provided, the application should automatically go to a healthy state.

2. If any settings, such as the fully qualified domain name (FQDN) of the SQL Server instance, the database name, or the local agent user, were provided incorrectly in LCS, change the settings, and then reinstall the local agent.

If the preceding steps don't resolve the error, manually remove the local agent user from the SQL Server instance and the database, and then rerun the Initialize-Database script.

If you re-create a user in AD DS, remember that the SID will change. In this case, remove the previous SID for the user, and add a new SID.

Error

Error:

> Unable to migrate database

Steps:

- Verify that you have access to the SQL Server listener.
- If you're doing testing, you can start over and use an empty orchestrator database.

Issue

When you performing the Configure the databases procedure, if the SQL Server instance is a named instance, use the **-DatabaseServer [FQDN/Instancename]** parameter.

Issue

The local agent user can't connect to the SQL Server instance or the database.

Steps: Follow these steps to resolve the error.

1. Delete the svc-LocalAgent user from the SQL Server primary node databases, and then remove the login from both servers.

2. Run the following scripts.

   ```
   .\Initialize-Database.ps1 -ConfigurationFilePath .\ConfigTemplate.xml -ComponentName Orchestrator
   .\Configure-Database.ps1 -ConfigurationFilePath .\ConfigTemplate.xml -ComponentName Orchestrator
   ```

> **IMPORTANT**
>
> These scripts don't work when an **always-on** setup is used. The database must first be created in the primary node and then replicated.

Error

Error:

> RunAsync failed due to an unhandled exception causing the host process to crash:
> System.Net.Http.HttpRequestException: An error occurred while sending the request. --->
> System.Net.WebException: The remote name could not be resolved: 'lcsapi.lcs.dynamics.com'

Reason: The local agent machines can't connect to lcsapi.lcs.dynamics.com. Review the AX-BridgeService event log for "The remote name could not be resolved: 'lcsapi.lcs.dynamics.com'."

Steps: Follow these steps to resolve the error.

1. Run **psping lcsapi.lcs.dynamics.com:80**.
2. If you don't receive a response from the preceding command, contact the IT department at your organization. Either the firewall is blocking access to lcsapi, or proxy issues are occurring.

```
lcsapi.lcs.dynamics.com:443
login.windows.net:443
uswelcs1lcm.queue.core.windows.net:443
www.office.com:443
login.microsoftonline.com:443
dc.services.visualstudio.com:443
uswelcs1lcm.blob.core.windows.net:443
uswedpl1catalog.blob.core.windows.net:443
```

Infrastructure scripts errors

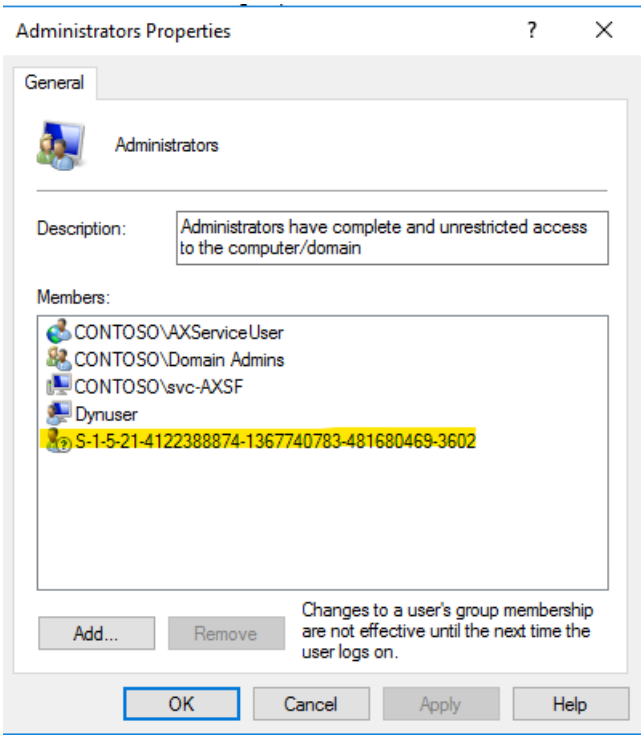
Issue

Error: When you run Test-D365FOConfiguration.ps1 or Test-D365FOConfiguration-AllVMs.ps1, you receive the message:

```
"Get-LocalGroupMember : Failed to compare two elements in the array.
At C:\Infrastructure\Scripts\Test-D365FOConfiguration.ps1:79 char:9
+         Get-LocalGroupMember -Group 'Administrators' | `
+         ~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~~
    + CategoryInfo          : NotSpecified: (:) [Get-LocalGroupMember], InvalidOperationException
    + FullyQualifiedErrorId : An unspecified error
occurred.,Microsoft.PowerShell.Commands.GetLocalGroupMemberCommand"
```

Reason: There is a bug in the PowerShell commandlet, Get-LocalGroupMember, which causes it to fail when there are entries that not valid.

Steps: On the machine where the script is failing, open **local users and groups**. Go to the administrators group and remove any entries that have an entry like the one highlighted in the following image.



Do this on all of the machines that receive this error. After the changes are complete, try running the script again.

Restart applications (such as AOS)

In Service Fabric, expand **Nodes** > **AOSx** > **fabric:/AXSF** > **AXSF** > **Code Packages** > **Code**. Select the ellipsis button (...), and then select **Restart**. When you're prompted, enter the code.

Upgrade Service Fabric

Service Fabric Explorer will show a message that resembles the following message:

> Unhealthy event: SourceId='System.UpgradeOrchestrationService', Property='ClusterVersionSupport', HealthState='Warning', ConsiderWarningAsError=false. The current cluster version 6.1.467.9494 support ends 5/30/2018 12:00:00 AM. Please view available upgrades using Get-ServiceFabricRegisteredClusterCodeVersion and upgrade using Start-ServiceFabricClusterUpgrade.

Because the minimum requirement is one Microsoft SQL Server Reporting Services (SSRS) node and one Management Reporter node, you must pass in a parameter to skip PreUpgradeSafetyCheck.

Follow these steps to upgrade Service Fabric in Windows PowerShell.

1. Connect to the Service Fabric cluster. In the following command, replace **123** with the server/star thumbprint, and use the appropriate IP address.

   ```
   Connect-ServiceFabricCluster -connectionEndpoint 10.0.0.12:19000 -X509Credential -FindType
   FindByThumbprint -FindValue 123 -ServerCertThumbprint 123
   ```

2. Get the latest version that was downloaded.

   ```
   Get-ServiceFabricRegisteredClusterCodeVersion
   ```

3. Start the upgrade. For **-CodePackageVersion**, enter the latest version.

> **NOTE**
>
> **-UpgradeReplicaSetCheckTimeout** is used to skip PreUpgradeSafetyCheck for SSRS and Management Reporter. For more information, see Service Fabric service upgrade not working. You might also want to use **-UpgradeDomainTimeoutSec 600 -UpgradeTimeoutSec 1800**. For more information, see Application upgrade parameters.

```
Start-ServiceFabricClusterUpgrade -Code -CodePackageVersion 6.1.472.9494 -Monitored -FailureAction
Rollback -UpgradeReplicaSetCheckTimeout 30
```

4. Get the upgrade status.

```
Get-ServiceFabricClusterUpgrade
```

For more information, see Troubleshoot application upgrades.

To learn when a new Service Fabric release comes out, see the Azure Service Fabric team blog.

If you receive a warning in Service Fabric Explorer after you upgrade, make a note of the node, and then restart by expanding **Nodes** > **AOSx** > **fabric:/AXSF** > **AXSF** > **Code Packages** > **Code**. Select the ellipsis button (...), and then select **Restart**.

Error: "Unable to load DLL 'FabricClient.dll'"

If you receive an error that states, "Unable to load DLL 'FabricClient.dll'," close and restart Windows PowerShell. If the error persists, restart the machine.

What cluster ID should be used in the agent configuration?

The cluster ID can be any globally unique identifier (GUID). This GUID is used for tracking purposes.

Encryption errors

Some examples of encryption errors include "AXBootstrapperAppType," "Bootstrapper," "AXDiagnostics," "RTGatewayAppType," "Gateway potential failure related," and "Microsoft.D365.Gateways.ClusterGateway.exe."

You might receive one of these errors if the data encipherment certificate that was used to encrypt the AOS account password wasn't installed on the machine. This certificate might be in the certificates (local computer), or the provider type might be incorrect.

To resolve the error, validate the credentials.json file. Verify that the text is correctly decrypted by entering the following command (on AOS1).

```
Invoke-ServiceFabricDecryptText -CipherText 'longstring' -StoreLocation LocalMachine | Set-Clipboard
```

This error can also occur if the '' parameter isn't defined in the ApplicationManifest file. To determine whether this parameter is defined, in Event Viewer, go to **Custom Views** > **Administrative Events**, and verify the following information:

- The encrypt credentials for the credentials.json file have the correct layout/structure. For more information, see the "Encrypt credentials" section of the appropriate setup and deployment topic for your environment:

    - Platform update 12
    - Platform update 8 and Platform update 11
- A closing quotation mark appears at the end of the line or on the next line.

In Event Viewer, under **Custom Views** > **Administrative Events**, note any errors in the **Microsoft-Service Fabric** source category.

Properties to create a DataEncryption certificate

Use the following properties to create the DataEncryption certificate:

- **Is self-signed certificate** – Enable this parameter only when you're using self-signed certificates.
- **Certificate purposes** – Enable all purposes for this certificate.
- **Signature algorithm** – Specify **sha256RSA**.
- **Signature hash algorithm** – Specify **sha256**.
- **Issuer** – Specify **CN = DataEncryptionCertificate**.
- **Public Key** – Specify **RSA (2048 bits)**.
- **Thumbprint algorithm** – Specify **sha1**.

> **WARNING**
> Don't use self-signed certificates in production environments. Instead, use certificates that are issued by certificate authorities.

The certificate and private key that should be used for decryption can't be found (0x8009200C)

If you're missing a certificate and ACL, or if you have the wrong thumbprint entry, check for special characters, and look for thumbprints in C:\ProgramData\SF\<AOSMachineName>\Fabric\work\Applications\AXBootstrapperAppType_App<N>\log\ConfigureCertificates-<timestamp>.txt.

You can also validate the encrypted text by using the following command.

```
Invoke-ServiceFabricDecryptText -CipherText 'longstring' -StoreLocation LocalMachine | Set-Clipboard
```

If you receive the message, "Cannot find the certificate and private key to use for decryption," verify the axdataenciphermentcert and svc-AXSF$ AXServiceUser ACLs.

If the credentials.json file has changed, the action you should take depends on the status of the environment in LCS.

- If your environment appears to be deployed in LCS, do the following:
    1. Go to your environment page and select **Maintain**.
    2. Select **Update settings**.
    3. Do not change any settings. Select **Prepare**.
    4. After a few minutes your environment will be prepared and you can select **Deploy**.
- If your environment is in a failed state in LCS, do the following:
    1. Select **Retry**. The new Credentials.json file will be used during the retry operation.

If none of the preceding solutions work, follow these steps.

1. Verify that the domain name and Active Directory account names that are specified in the ConfigTemplate.xml file are correct.
2. Verify that the thumbprints that are specified in the ConfigTemplate.xml file are correct if the certificate wasn't generated by using the scripts that are provided.
3. Verify that the certificate thumbprints that are specified in LCS are correct, and that they match the thumbprints that are specified in ConfigTemplate.xml. Make sure that there are no special characters. You can run **.\Get-DeploymentSettings.ps1** to obtain the thumbprints in an easy-to-copy manner.
4. If the certificates aren't self-generated, make sure that the provider names match for the following certificate types:
   - **ServiceFabricEncryption type:** Microsoft Enhanced Cryptographic Provider v1.0
   - **All other certificate types:** Microsoft Enhanced RSA and AES Cryptographic Provider
5. Verify that the Set-CertificateAcls.ps1 and Test-D365FOConfiguration.ps1 scripts were successfully run on all Service Fabric machines.
6. Verify that the credentials.json file exists, and that the entries are decrypted to correct values.

   On one of the AOS machines, run the following command to verify that the data encryption certificate is correct.

   ```
   Invoke-ServiceFabricDecryptText '<encrypted string>' -StoreLocation LocalMachine
   ```
7. If any of the certificates must be changed, or if the configuration was incorrect, follow these steps:
   a. Edit the **ConfigTemplate.xml** file so that it has the correct values.
   b. Run all the setup scripts and the **Test-D365FOConfiguration** script.
8. In LCS, reconfigure the environment.

Gateway fails to deploy

Issue: You receive the following error in the event viewer logs.

```
Message Module aos failed Detail System.InvalidOperationException: Gateway app and Bootstrapper app are not
healthy at AOSSetupHybridCloud.Program.Main(String[] args)
at System.AppDomain._nExecuteAssembly(RuntimeAssembly assembly, String[] args)
at System.AppDomain.ExecuteAssembly(String assemblyFile, String[] args)
at System.AppDomain.ExecuteAssembly(String assemblyFile, String[] args)
at SetupCore.SetupManager.LaunchProcessInAppDomain(String startupExe, String workingDir, String
currentFolder, String[] moduleArgs)
at SetupCore.SetupManager.<>c__DisplayClass12_1.<InvokeModules>b__6()
```

You also receive the following error message in the SFExplorer for the Gateway application.

```
'System.RA' reported Warning for property 'ReplicaOpenStatus'.
Replica had multiple failures during open on AOS_13. API call: IStatelessServiceInstance.Open(); Error =
System.InvalidOperationException (-2146233079)
Category does not exist.
   at System.Diagnostics.PerformanceCounterLib.CounterExists(String machine, String category, String
counter)
   at System.Diagnostics.PerformanceCounter.InitializeImpl()
   at System.Diagnostics.PerformanceCounter..ctor(String categoryName, String counterName, String
instanceName, Boolean readOnly)
   at System.Diagnostics.PerformanceCounter..ctor(String categoryName, String counterName, String
instanceName)
   at Microsoft.Dynamics.LBD.Gateways.ClusterGateway.Helpers.CpuPerfCounter..ctor()
   at Microsoft.Dynamics.LBD.Gateways.ClusterGateway.GzipContentDelegatingHandler..ctor()
   at Microsoft.Dynamics.LBD.Gateways.ClusterGateway.ClusterGateway.ConfigureApp(IAppBuilder appBuilder)
   at Microsoft.Owin.Hosting.Engine.HostingEngine.Start(StartContext context)
   at Microsoft.Dynamics.LBD.Gateways.Common.OwinCommunicationListener.b__9_0()
   at Microsoft.D365.ServicePlatform.Context.ServiceContext.Activity.d__10`2.MoveNext()
```

Reason: The pointers to the performance counter that the gateway needs may be corrupt.

Resolution: Run **lodctr /R** in a Command Prompt window that you open as administrator in all AOS nodes where the gateway is unhealthy. If you receive an error message that states that the performance counters can't be rebuilt, try to run the command again.

Management Reporter

Additional logging can be done by registering providers. Download ETWManifest.zip to the **primary** orchestrator machine, and then run the following commands. To determine which machine is the primary instance, in Service Fabric Explorer, expand **Cluster** > **Applications** > **LocalAgentType** > **fabric:/LocalAgent/OrchestrationService** > **(GUID)**.

> **NOTE**
>
> If results in Event Viewer don't appear correct (for example, if words are truncated), get the latest manifest and .dll files. To get the latest manifest and .dll files, go to the WP folder in the agent file share. This share was created in the "Set up file storage" section of the appropriate setup and deployment topic for your environment:
>
> - Platform update 12
> - Platform update 8 and Platform update 11
>
> **Example:** [*Agent Share*]\wp\[*Deployment name*]\StandaloneSetup-...\Apps\ETWManifests

```
.\RegisterETW.ps1 -ManifestsAndDll @{"C:\Files\ETWManifest\Microsoft.Dynamics.Reporting.Instrumentation.man"
= "C:\Files\ETWManifest\Microsoft.Dynamics.Reporting.Instrumentation.dll"}
```

If you must unregister providers, use the following command.

```
.\RegisterETW.ps1 -ManifestsAndDll @{"C:\Files\ETWManifest\Microsoft.Dynamics.Reporting.Instrumentation.man"
= "C:\Files\ETWManifest\Microsoft.Dynamics.Reporting.Instrumentation.dll"} -Unregister
```

After providers are registered, additional details about the new deployment are logged in Event Viewer, at **Applications and Services Logs** > **Microsoft** > **Dynamics**. The following folders will be shown:

- MR-Logger
- MR-Sql

To see the new folders, you must close and reopen Event Viewer. To see additional details, you must deploy an

environment again.

Could not load file or assembly EntityFramework

Issue: You are running Local Agent version 2.3.1 or later and you received the following stacktrace in the event logs while deploying a package that contains Platform update 29 or earlier:

```
System.Reflection.TargetInvocationException: Exception has been thrown by the target of an invocation. --->
System.Reflection.TargetInvocationException: Exception has been thrown by the target of an invocation. --->
System.IO.FileNotFoundException: Could not load file or assembly 'EntityFramework, Version=6.0.0.0,
Culture=neutral, PublicKeyToken=b77a5c561934e089' or one of its dependencies. The system cannot find the
file
specified. at Microsoft.Dynamics.Integration.Service.Utility.AdapterProvider.RefreshAdapters()
--- End of inner exception stack trace ---
```

Resolution: Use TSG_UpdateFRDeployerConfig.ps1. For more information, see TSG_UpdateFRDeployerConfig.ps1.

Unable to deploy Financial Reporting Service

Issue: You are unable to finish deployment of Platform update 26 and later for Financial Reporting because the following error is in the application log for Service Fabric.

```
Application: FinancialReportingDeployer.exe Framework Version: v4.0.30319
Description: The process was terminated due to an unhandled exception.

Microsoft.Dynamics.Performance.Logger.IfxLoggerProvider.CreateLogger(System.String)  at
Microsoft.Extensions.Logging.Logger..ctor(Microsoft.Extensions.Logging.LoggerFactory,  System.String) at
```

Reason: The Microsoft Visual C++ Redistributable Package for Visual Studio 2013 was not correctly installed or is corrupt in some or all of the MR nodes.

Steps: Re-run the installation of the Microsoft Visual C++ Redistributable Package for Visual Studio 2013.

An error occurs while AddAXDatabaseChangeTracking is running

If you receive an error while you run AddAXDatabaseChangeTracking at Microsoft.Dynamics.Performance.Deployment.FinancialReportingDeployer.Utility.InvokeCmdletAndValidateSuccess(DeploymentCmdlet cmdlet), verify that the full path is correct. An example of a full path is **ax.d365ffo.onprem.contoso.com**.

The error might also occur because of an issue with the star certificate. For example, the remote certificate CN=*.d365ffo.onprem.contoso.com has a name that isn't valid or that doesn't match the host, ax.d365ffo.onprem.contoso.com.

Run the initialize database script, and validate that databases have correct users

If you receive only the AddAXDatabaseChangeTracking event, try to reach the MetadataService service for Finance + Operations by going to `https://ax.d365ffo.contoso.com/namespaces/AXSF/services/MetadataService`.

Next, check the certificates of the service in the wif.config file. To find the file, sign in to one of the AOS machines, and then, in Task Manager, find **AxService.exe**. Right-click, and select **Open file location**. In the wif.config file, you should see three thumbprints. Note the following requirements for these thumbprints:

- They must be different.
- They must be in this order:
    1. Financialreporting thumbprint
    2. ReportingService thumbprint
    3. SessionAuthentication thumbprint

If the thumbprints don't meet both these requirements, you must redeploy from LCS by using correct thumbprints.

The remote name can't be resolved

Error:

> The remote name could not be resolved: 'x.d365fo.onprem.contoso.com' / There was no endpoint listening at `https://x.d365fo.onprem.contoso.com/namespaces/AXSF/services/MetadataService` that could accept the message.

Reason: This issue is often caused by an incorrect address or SOAP action.

Steps: Verify that the address can be reached, by manually opening the URL. For more details, see the "InnerException" text in the Event Viewer, if it's present.

Error on ImportDefaultReports

If Management Reporter reports are checked out during deployment, the deployment will fail. To see whether reports are checked out, run the following **select** statements on the FinancialReporting database.

```
select checkedoutto, * from Reporting.ControlReport where checkedoutto is not null
select checkedoutto, * from Reporting.ControlRowMaster where checkedoutto is not null
select checkedoutto, * from Reporting.ControlColumnMaster where checkedoutto is not null
```

To learn which user has objects checked out, you can run the following **select** statement.

```
select * from Reporting.SecurityUser where UserID = ''
```

To resolve this issue manually, update the following tables, and set **checkedoutto** to **null** by using the following commands.

```
update Reporting.ControlReport set checkedoutto = null where checkedoutto is not null
update Reporting.ControlRowMaster set checkedoutto = null where checkedoutto is not null
update Reporting.ControlColumnMaster set checkedoutto = null where checkedoutto is not null
```

axdbadmin can't connect to the database server SQL-LS.contoso.com

Reason: The user doesn't have permission to connect to the AXDB database.

Steps:

1. Remove the axdbadmin user from the database, if it already exists.
2. In the **ConfigTemplate.xml** file, specify the user name that must be added to the AXDB database.

```
<Security>
    <User refName="axdbadmin" type="SqlUser" userName="axdbadmin" />
</Security>
```

3. Run the initialize database script again to add the axdbadmin user.

Unable to resolve the xPath value

In the expected behavior, the following **xPath** value can't be resolved:

[TopologyInstance/CustomizationGroup[@name='ServiceConfiguration']/Group[@name='AOSServicePrincipalUser']/Customizations/Customization[@fieldName='PrincipalUserAccountPassword']/@selectedValue

Therefore, the fact that the **xPath** value can't be resolved isn't an issue. The **xPath** value looks for AOS runtime user information. However, because of integrated security, that information isn't required. The fact that the **xPath** value can't be resolved is communicated in case the failure must be investigated for another reason.

AD FS

The sign-in page doesn't redirect you

The sign-in page might not redirect you but continues to prompt for credentials. Alternatively, you might be redirected but receive the following message:

> An error occurred. Contact your administrator for more information.

In these cases, you can follow these steps to resolve the issue:

- Add the AD FS link to the list of trusted sites.
- Add the Dynamics 365 link to the list of trusted sites.
- Add a trailing slash (/), and see whether the behavior changes.

Verify the AD FS Manager by going to **ADFS** > **Application groups**. Double-click **Microsoft Dynamics 365 for Operations on-premises**. Then, under **Native application**, double-click **Microsoft Dynamics 365 for Operations on-premises - Native application**.

Note the **Redirect URI** value. It should match the DNS forward lookup zone for Finance + Operations.

Error: "Could not establish trust relationship for the SSL/TLS secure channel"

If you receive an error that states, "Could not establish trust relationship for the SSL/TLS secure channel," follow these steps.

1. In Service Fabric, go to **Cluster** > **Applications** > **AXSFType** > **fabric:/AXSF**, and then, on the **Details** tab, scroll down and note the URLs for **Aad_AADMetadataLocationFormat** and **Aad_FederationMetadataLocation**.
2. Browse to those URLs from AOS.
3. On the AOS machine, in Event Viewer, go to **Applications and Services Logs** > **Microsoft** > **Dynamics** > **AX-SystemRuntime** for details.
4. Verify that the AD FS certificate is trusted:
    a. Verify the AD FS certificate. On the AD FS machine, in Server Manager, go to **Tools** > **AD FS Management**.
    b. Expand **AD FS** > **Service** > **Certificates**, and make a note of the certificates. For example, one certificate might be dc1.contoso.com.

c. On the AOS machine, in the Microsoft Management Console Certificates snap-in, go to **Certificates (Local Computer)** > **Trusted Root Certification Authorities** > **Certificates**, and verify that the AD FS certificate is listed.

If you receive a message that states that the site isn't secure, you haven't added your Secure Sockets Layer (SSL) certificate for AD FS to the Trusted Root Certification Authorities store.

You can't connect to the remote server in some locations

You might not be able to connect to the remote server at the following places:

- System.Net.HttpWebRequest.GetResponse()
- System.Xml.XmlDownloadManager.GetNonFileStream(Uri uri, ICredentials credentials, IWebProxy proxy, RequestCachePolicy cachePolicy)
- System.Xml.XmlUrlResolver.GetEntity(Uri absoluteUri, String role, Type ofObjectToReturn)

In this case, go to the C:\ProgramData\SF\AOS_1\Fabric\work\Applications\AXSFType_App35\log folder where you receive the error, and note the out file. The out file contains the following information:

> System.Net.WebException: Unable to connect to the remote server --->
>
> System.Net.Sockets.SocketException: A connection attempt failed because the connected party did not properly respond after a period of time, or established connection failed because connected host has failed to respond x.x.x.x:443

You can also use Psping to try to reach the remote server. For information about Psping, see Psping.

Redirect sign-in questions and issues

If you're having issues when you sign-in, in Service Fabric Explorer, verify that the **Provisioning_AdminPrincipalName** and **Provisioning_AdminIdentityProvider** values are valid. Here is an example:

- **Provisioning_AdminPrincipalName**: `AXServiceUser@contoso.com`
- **Provisioning_AdminIdentityProvider**: `https://DC1.contoso.com/adfs`

If the values aren't valid, you won't be able to proceed, and you must redeploy from LCS.

If you used Reset-DatabaseUsers.ps1, you must restart the Dynamics Service before your changes take effect. If you still have sign-in issues, in the USERINFO table, note the **NETWORKDOMAIN** and **NETWORKALIAS** values. Here is an example:

- **NETWORKDOMAIN:** `https://DC1.contoso.com/adfs`
- **NETWORKALIAS:** `AXServiceUser@contoso.com`
- **IDENTITYPROVIDER:** This should match the **NETWORKDOMAIN** value.

On the AD FS machine, in Server Manager, go to **Tools** > **AD FS Management** > **Service**. Right-click **Service and Edit Federation Service Properties**. The **Federation Service identifier** value should match the **USERINFO.NETWORKDOMAIN** value, and it should have **https** in the URL (for example, `https://DC1.contoso.com/adfs`).

On the AD FS machine, in Event Viewer, go to **Applications and Services Logs** > **AD FS** > **Admin**, and make a note of any errors.

Fiddler

Fiddler can be used for additional debugging. For in-depth information about Fiddler, see AD FS 2.0: How to Use Fiddler Web Debugger to Analyze a WS-Federation Passive Sign-In and Cracking the AD FS Token from another AD FS Claims Provider.

The following sections provide focused debugging steps for claims that are returned to Microsoft Dynamics.

Repo/capture

1. Open Fiddler, go to **Tools** > **Options** > **HTTPS**, and select **Decrypt HTTPS traffic**.
2. Start to capture traffic (the shortcut key is F12). You can verify that that traffic is being captured by looking at the lower left of the tool.
3. Open an InPrivate instance of Internet Explorer or an Incognito instance of Chrome.
4. Open Finance + Operations (for example, `https://ax.d365ffo.onprem.contoso.com/namespaces/AXSF/`).
5. Sign in by using the USERINFO.NETWORKALIAS account and password.
6. After you're signed in, stop Fiddler from capturing traffic.

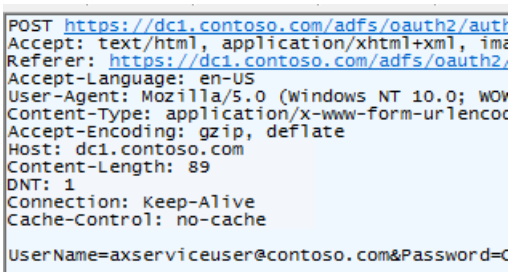
Analyze

In the right pane of Fiddler, notice that a horizontal divider separates the request from the response. Unlike a network trace, where you typically get one frame for a request and another frame for a response, Fiddler provides one frame that contains both the request and the response.

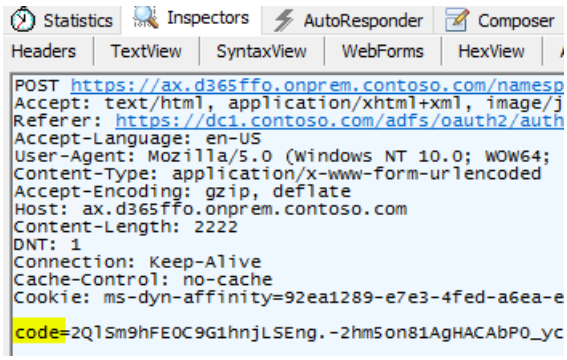
1. In Fiddler, in the upper-right corner, select **Inspectors** > **Raw**.
2. In the lower-right corner, select **Cookies**.
3. Do a search for **MSISAuth**.
4. Select the row that has a result of **200** for the AD FS host.
5. Look above the row that you just selected to find a row that has a result of **302**. Select the row.

   You should see the AD FS URL, host, user name, and password.

   > **IMPORTANT**
   >
   > For privacy, you might have to scrub personally identifiable information.



6. Select the next row that has a result of **302**. The URL should be **.../namespaces/AXSF/**.
7. Find the code line that is shown on that row.



8. Copy the value of code line after the equal sign (=).
9. Go to https://www.base64decode.org/, and paste the code that you just copied.

10. In the **Source charset** field, select **ASCII**.
11. Select **Decode**.
12. Copy the results, and follow these steps:
    - Make sure that the **upn** value matches the user name.
    - Make sure that the **unique_name** value is the Active Directory user that is being tested.
    - Go to **Active Directory Users and Computers** > **domain** > **Users**, and make sure that this user is being tested.

Sign-in issues

If you or other users experience sign-in issues, in Service Fabric Explorer, verify that the **Provisioning_AdminPrincipalName** and **Provisioning_AdminIdentityProvider** values are valid. If the values are valid, run the following command on the primary SQL Server machine.

```
.\Reset-DatabaseUsers.ps1
```

On each AOS machine, in Task Manager, select **AXService.exe**, and then select **End task**.

To verify that a user has been reset, run the following **select** query in the AXDB SQL database.

```
select SID, NETWORKDOMAIN, NETWORKALIAS, * from AXDB.dbo.USERINFO where id = 'admin'
```

> **NOTE**
> In an Azure Active Directory (Azure AD) environment (that is, an online environment), the SID is a hash of a network alias and a network domain. In an AD DS environment (that is, an on-premises environment), the SID is a hash of a network alias and an identify provider.

In some cases, you still might not be able to sign in, and you might receive the following error:

> You are not authorized to login with your current credentials. You will be redirected to the login page in a few seconds.

If this error occurs, follow these steps.

1. On the AD FS machine, go to **Server Manager** > **Tools** > **AD FS Management**.
2. Right-click **AD FS**, and then select **Edit Federation Service Properties**.
3. Make sure that the **Federation Service Identifier** value matches the **Userinfo.NetworkDomain** and **UserInfo.IdentityProvider** values.
4. On the AD FS machine, open Windows PowerShell, and run **Get-AdfsProperties**.
5. Make sure that the **IdTokenIssuer** value matches the **Federation Service Identifier** value from step 3, and also the **Provisioning_AdminIdentityProvider** value on the **fabric:/AXSF Details** tab at **Service Fabric Explorer** > **Cluster** > **Applications** > **AXSFType**.
6. In Service Fabric Explorer, verify that the **Provisioning_AdminPrincipalName** and **Provisioning_AdminIdentityProvider** values are valid.

If the preceding steps don't resolve the issue, see the AD FS section of this topic.

System.Data.SqlClient.SqlException (0x80131904) and

System.ComponentModel.Win32Exception (0x80004005)

You might receive one of the following errors:

> System.Data.SqlClient.SqlException (0x80131904): A connection was successfully established with the server, but then an error occurred during the sign-in process. (provider: SSL Provider, error: 0 - The certificate chain was issued by an authority that is not trusted.)

> System.ComponentModel.Win32Exception (0x80004005): The certificate chain was issued by an authority that is not trusted

In this case, either the certificates haven't been installed, or they haven't given access to the correct users. To resolve this error, add the public key SQL Server certificate to all the Service Fabric nodes.

Keyset doesn't exist

If you find that the keyset doesn't exist, scripts weren't run on all machines. Review and complete the "Set up VMs" section of the appropriate setup and deployment topic for your environment:

- Platform update 12
- Platform update 8 and Platform update 11

Copy the scripts in each folder to the VMs that correspond to the folder name.

Additionally, check the .csv file to verify that the correct domain is used.

Error: "RunAsync failed due to an unhandled FabricException causing replica to fault"

You might receive the following error:

> RunAsync failed due to an unhandled FabricException causing replica to fault: System.Fabric.FabricException: The first Fabric upgrade must specify both the code and config versions. Requested value: 0.0.0.0:

In this case, in the ClusterConfig.json file, change **diagnosticsStore** from a network share to a local path. For example, change **\\server\path** to a default value of **C:\ProgramData\SF\DiagnosticsStore**.

Service Fabric AOS node error during build: The execution time-out expired

Error:

> The timeout period elapsed prior to completion of the operation or the server is not responding.
> The statement has been terminated.

Only one AOS machine can run DB Sync at a time. You can safely ignore this error, because it means that one of the AOS VMs is running DB Sync. Therefore, the other VMs produce a warning that they can't run it. To verify that DB Sync is running, on the AOS VM that isn't producing warnings, in Event Viewer, go to **Applications and Services Log** > **Microsoft** > **Dynamics** > **AX-DatabaseSynchronize/Operational**.

Error: "RequireNonce is 'true' (default) but validationContext.Nonce is null"

You might receive the following error:

> RequireNonce is 'true' (default) but validationContext.Nonce is null

This error also appears as an HTTP error 500 in Internet Explorer after you sign in to the client. The nonce that is issued can't be validated if Internet Explorer is in Enhanced Security Configuration.

To sign in to the client, disable Enhanced Security Configuration for Internet Explorer via Server Manager.

Error: "Invalid algorithm specified / Cryptography"

If you receive an "Invalid algorithm specified / Cryptography" error, you must use the Microsoft Enhanced RSA and AES Cryptographic Provider. For more information, see the certificate requirements. Additionally, verify that the structure of the credentials.json file is correct.

If you must re-create the certificate by using the correct provider, follow these steps.

1. Create the certificate again by using the correct provider.
2. Change the **ConfigTemplate.xml** file.
3. Run the infrastructure scripts on all machines in the cluster, and make sure that the **Test-D365FOConfiguration.ps1** script passes.
4. Reconfigure the environment from LCS.

An "Unable to find certificate" error occurs when you run Test-D365FOConfiguration.ps1

If you receive an "Unable to find certificate" error when you run Test-D365FOConfiguration.ps1, check whether certificates or thumbprints are being combined for multiple purposes. For example, you will receive this error if the client certificate and the SessionAuthentication certificate are combined. We recommend that you not combine certificates. For more information, see the certificate requirements, and check the acl.csv file for **domain.com\user** versus **domain\user** (for example, NETBIOS structure).

The client and server can't communicate because they don't have a common algorithm

If the client and server can't communicate because they don't have a common algorithm, verify that the certificates that are created use the specified provider, as explained in the "Plan and acquire your certificates" section of the appropriate setup and deployment topic for your environment:

- Platform update 12
- Platform update 8 and Platform update 11

Find a list of group managed service accounts

To find a list of all groups and hosts, run the following command.

```
Get-ADServiceAccount -Identity svc-LocalAgent$ -Properties PrincipalsAllowedToRetrieveManagedPassword
```

AddCertToServicePrincipal script fails on Import-Module

Error:

> AddCertToServicePrincipal script failing on Import-Module : Could not load file or assembly

> 'Commands.Common.Graph.RBAC, Version=1.0.0.0, Culture=neutral, PublicKeyToken=31bf3856ad364e35' or one of its dependencies. Strong name validation failed. (Exception from HRESULT: 0x8013141A) may have multiple versions of the same module installed.

Steps: To resolve this issue, follow these steps.

1. Run the following command in Windows PowerShell.

```
Uninstall-Module -Name AzureRM
Install-Module AzureRM
```

2. Close the Windows PowerShell window, and try to run the script again.

ReportingServicesSetup.exe error

Error:

> ReportingServicesSetup.exe Error: 0 : Application fabric:/ReportingService is not OK after 10 minutes
> Application: ReportingServicesBootstrapper.exe
> Framework Version: v4.0.30319
> Description: The process was terminated due to an unhandled exception.

Reason: If you receive this error, strong name validation is enabled in the Reporting server, but it should not be enabled.

Steps: To resolve this issue, run the **config-PreReq** script on the Reporting server machine.

The requested operation requires elevation

This issue occurs because AOS users aren't in the local administrator group, and User Account Control (UAC) hasn't been disabled correctly. To resolve the issue, follow these steps.

1. Add AOS users as local admins, as described in the "Join VMs to the domain" section of the appropriate setup and deployment topic for your environment:
   - Platform update 12
   - Platform update 8 and Platform update 11
2. Run the **Config-PreReq** script on all the AOS machines.
3. Make sure that the **Test-Configuration** script passes.
4. If UAC was changed, you must restart the machine before the changes take effect.

Files in use errors

If these "Files in use" errors occur, set up the exclusion rules that Service Fabric advises. For information, see Environment setup.

Apply deployable packages during deployment

Package deployment fails because of a "path too long" exception

Because of a 260-character limit in Microsoft Windows, deployment will fail if a package has a longer name, or if the on-premises share has the full FQDN path. If the character limit is exceeded, you receive the following error:

> System.IO.PathTooLongException: The specified path, file name, or both are too long. The fully qualified file

> name must be less than 260 characters, and the directory name must be less than 248 characters. at System.IO.PathHelper.GetFullPathName

To work around this issue, shorten the package name, and then apply the package again. Alternatively, shorten the overall length of the share path for the on-premises assets.

Package deployment fails because of a serialization error

During package deployment, you might receive the following error:

> Serialization version mismatch detect, make sure the runtime DLLs are in sync with the deployed metadata. Version of file 'XXX'. Version of DLL 'XXX'

In this case, the version of the environment where the package was developed might differ from the version of the environment that the package is being deployed in.

To work around this issue, keep the development or build environments on the same version as the deployed on-premises environment. You can confirm the package version by looking in the **Additional details** section in the Asset library where the package is uploaded. To fix the error, generate the package on a version that is the same as or earlier than the version that is deployed in the on-premises environment.

Package deployment fails because of dependencies on missing modules

If you try to apply a package that is missing dependent modules, package application will fail, and you will receive a message that resembles the following message:

> Package [dynamicsax-My_commonextension.7.0.4679.35176.nupkg has missing dependencies: [dynamicsax-demodatasuite;dynamicsax-financialreportingadaptors;dynamicsax-fleetmanagement;dynamicsax-fleetmanagementextension;dynamicsax-publicsectorformadaptor]]
>
> Package [dynamicsax-My_coreextension.7.0.4679.35176.nupkg has missing dependencies: [dynamicsax-demodatasuite;dynamicsax-financialreportingadaptors;dynamicsax-fiscalbooksformadaptor;dynamicsax-fleetmanagement;dynamicsax-fleetmanagementextension;dynamicsax-fleetmanagementunittests;dynamicsax-generalledgerformadaptor;dynamicsax-publicsectorformadaptor;dynamicsax-retailformadaptor]]
>
> Package [dynamicsax-My_uiextension.7.0.4679.35176.nupkg has missing dependencies: [dynamicsax-demodatasuite;dynamicsax-financialreportingadaptors;dynamicsax-fiscalbooksformadaptor;dynamicsax-fleetmanagement;dynamicsax-fleetmanagementextension;dynamicsax-fleetmanagementunittests]]

To confirm the issue and find the missing dependencies, in Event Viewer, open **Application and Services**, and then go to **Microsoft** > **Dynamics** > **AX-SetupModuleEvents** to view events that have missing modules. For example, one of the modules that is typically missing is ApplicationFoundationFormAdaptor.

To fix this issue and successfully apply the package, either add dependent modules, or remove modules that require dependent modules. To add dependent modules, you must include the dependencies when you build the package. To remove modules, you can use ModelUtil.exe to delete a module. For more information, see Export and import models.

Package deployment works in a one-box environment but not in the sandbox environment

A one-box environment might have all the modules installed, whereas the sandbox environment might have only the modules that are required in order to run your production environment. If the package that was built in the dev environment has a dependency on modules that are present in the one-box environment but not in the sandbox environment, the package won't work in the sandbox environment.

To resolve this issue, look at all the modules that you're dependent on, and make sure that you don't pull any farm adapter or any other module that isn't required in the production environment. The best practice is to take

the package from the build box.

An error occurs when you sign in to on-premises environments

- **Platform update 12:** Turn off the Skype integration by going to **System administration** > **Setup** > **Client performance options**. When you go to the app, append **?debug=true** to the URL, as shown in the following example: `https://ax.d365ffo.onprem.contoso.com/namespaces/AXSF/?debug=true`
- **Platform update 8 and Platform update 11:** A known issue for the Skype application programming interface (API) affects the ability to sign in to on-premises environments. Microsoft is investigating a resolution for this issue. To work around this issue, you can add **?debug=true** to the end of the URL, as shown in the following example: `https://ax.d365ffo.onprem.contoso.com/namespaces/AXSF/?debug=true`

The local agent stops working after the tenant for the project from LCS is changed

Follow these steps to configure the local agent with the updated tenant.

1. Uninstall the local agent.

   ```
   .\LocalAgentCLI.exe Cleanup <path of localagent-config.json>
   ```

2. Follow the steps in the "Configure LCS connectivity for the tenant" section of the appropriate setup and deployment topic for your environment:

   - Platform update 12
   - Platform update 8 and Platform update 11

3. Create a new LCS connector in the new tenant.

4. Download the **local-agent.config** file.

5. Install the local agent.

   ```
   .\LocalAgentCLI.exe Install <path of localagent-config.json>
   ```

Additional deployments (for example, two sandbox deployments, or a sandbox and production deployment)

You will receive the following error when you deploy an additional environment:

> .\Publish-ADFSApplicationGroup.ps1 -HostUrl `https://ax.d365ffo.onprem.contoso.com` New-AdfsApplicationGroup : MSIS9908: The application group identifier must be unique in AD FS configuration.

You can skip or modify the following sections in the deployment instructions.

Plan and acquire your certificates (as documented for Platform update 12 or Platform update 8 and Platform update 11)

- You must use the same on-premises local agent certificate.
- You can use same star certificates (AOS SSL and Service Fabric).
- The remaining certificates should probably differ from the certificates for the existing environment.

Download setup scripts from LCS (as documented for Platform update 12 or Platform update 8 and Platform update 11)

- The scripts that are downloaded should be copied into a new folder.

Set up a standalone Service Fabric cluster (as documented for Platform update 12 or Platform update 8 and Platform update 11)

- The scripts that are downloaded should be copied into a new folder.

Configure LCS connectivity for the tenant (as documented for Platform update 12 or Platform update 8 and Platform update 11)

- You must complete this task only one time for the tenant.

Configure AD FS (as documented for Platform update 12 or Platform update 8 and Platform update 11)

- Configure AD FS according to the Reuse the same AD FS instance for multiple environments guide.

Redeploy SSRS reports

Version 10.0.13 or later

Run the following command against your business data database (AXDB):

```
 UPDATE SF.synclog SET STATE=5, SyncStepName = 'ReportSyncstarted' WHERE CODEPACKAGEVERSION in (SELECT
TOP(1) CODEPACKAGEVERSION from SF.SYNCLOG ORDER BY CREATIONDATE DESC)
```

Version 10.0.12 or earlier

Run the following command against your business data database (AXDB):

```
    DELETE FROM SF.synclog WHERE CODEPACKAGEVERSION in (SELECT TOP(1) CODEPACKAGEVERSION from SF.SYNCLOG
ORDER BY CODEPACKAGEVERSION DESC)
```

> **NOTE**
>
> If you are using version 10.0.12 or earlier, a full database synchronization will be executed.

After running the command, restart one of your AOS nodes through Service Fabric Explorer or restart the VM that the node is running on.

Add axdbadmin to tempdb after a SQL Server restart via a stored procedure

When SQL Server is restarted, the tempdb database is re-created. Therefore, there will be missing permissions. Run the following script to create a stored procedure on the master database.

```
\-----
USE [master]
GO
CREATE procedure [dbo].[CREATETEMPDBPERMISSIONS] as begin exec ('USE tempdb; declare @dbaccesscount int;
select @dbaccesscount = COUNT(*) from master..syslogins where name = ''axdbadmin''; if (@dbaccesscount <> 0)
exec sp_grantdbaccess ''axdbadmin''; ALTER USER [axdbadmin] WITH DEFAULT_SCHEMA=dbo; EXEC sp_addrolemember
N''db_datareader'', N''axdbadmin''; EXEC sp_addrolemember N''db_datawriter'', N''axdbadmin''; EXEC
sp_addrolemember N''db_ddladmin'', N''axdbadmin''; exec sp_grantdbaccess ''contoso\svc-AXSF$''; ALTER USER
[contoso\svc-AXSF$] WITH DEFAULT_SCHEMA=dbo; EXEC sp_addrolemember N''db_datareader'', N''contoso\svc-
AXSF$''; EXEC sp_addrolemember N''db_datawriter'', N''contoso\svc-AXSF$''; EXEC sp_addrolemember
N''db_ddladmin'', N''contoso\svc-AXSF$'';') end
GO
EXEC sp_procoption N'[dbo].[CREATETEMPDBPERMISSIONS]', 'startup', '1'
\-----
```

Error: "Updates to existing credential with KeyId '<key>' is not allowed"

You might receive the following error:

> Updates to existing credential with KeyId '<key>' is not allowed

The steps to resolve this issue depend on whether you have only an on-premises project, or whether you have both an online project and an on-premises project.

If have only an on-premises project

If have only an on-premises project, you can't update the existing credential with KeyId '<key>'.

```
New-AzureRmADSpCredential : Update to existing credential with KeyId '<key>' is not allowed.
At C:\InfrastructureScripts\Add-CertToServicePrincipal.ps1:62 char:1
New-AzureRmADSpCredential -ObjectId $servicePrincipal.Id -CertValue $ ...
CategoryInfo : InvalidOperation: (:) [New-AzureRmADSpCredential], Exception
FullyQualifiedErrorId : Microsoft.Azure.Commands.ActiveDirectory.NewAzureADSpCredentialCommand
```

Run the following PowerShell command to resolve the issue.

```
Remove-AzureRmADSpCredential -ServicePrincipalName "00000015-0000-0000-c000-000000000000" -KeyId <key>
```

If you have both an online project and an on-premises project

If you have both an online project and an on-premises project, follow these steps.

1. Verify that the Microsoft .NET Framework version 4.7.2 is installed.
2. Run the following Windows PowerShell script to install the Azure PowerShell module.

   ```
   Install-Module -Name Az
   ```

3. Run the following Windows PowerShell script to upload the new certificate.

```
Import-Module -Name Az.Accounts
Import-Module -Name Az.Resources

Connect-AzAccount

$servicePrincipalName = "00000015-0000-0000-c000-000000000000";
$CertificateThumbprint = <Thumbprint of Agent Certificate>
$cert = Get-ChildItem -path Cert:\CurrentUser\my | Where-Object { $_.Thumbprint -eq
$CertificateThumbprint }
if (!$cert)
{
    $cert = Get-ChildItem -path Cert:\LocalMachine\my | Where-Object { $_.Thumbprint -eq
$CertificateThumbprint }
    if (!$cert)
    {
        throw "Unable to find the certificate in the Local machine or Current User store"
    }
}

$keyValue = [System.Convert]::ToBase64String($cert.GetRawCertData())
$servicePrincipal = Get-AzADServicePrincipal -ServicePrincipalName $servicePrincipalName
if (!$servicePrincipal)
{
    throw "Unable to find the service principal"
}
New-AzADSpCredential -ObjectId $servicePrincipal.Id -CertValue $keyValue -EndDate $cert.NotAfter -
StartDate $cert.NotBefore
Get-AzADSpCredential -ObjectId $servicePrincipal.Id
```

4. Run the following command to remove the duplicate certificate, if more than one certificate exists.

```
Remove-AzADSpCredential -ServicePrincipalName "00000015-0000-0000-c000-000000000000" -KeyId <key>
```

ODBC driver 17 is required for platform updates

The latest platform binary update uses Open Database Connectivity (ODBC) driver 17. This upgrade resolves stability issues that are linked to older ODBC drivers. The Setup perquisites documentation has been updated to reflect the change in which ODBC driver 17 must be installed on each AOS server. If you don't install ODBC driver 17, you will receive DB Sync errors during servicing of the environment.

Here are some examples of errors:

- In Service Fabric:

> Unhealthy event: SourceId='System.RA', Property='ReplicaOpenStatus', HealthState='Warning', ConsiderWarningAsError=false.
> Replica had multiple failures during open on AOS3. API call: IStatelessServiceInstance.Open(); Error = System.Exception (-2146233088)
> **DB sync failed.**

- On AOS machines:
  - Event Viewer > Custom Views > Administrative Events:

> Application: Microsoft.Dynamics.AX.Deployment.Setup.exe Framework Version: v4.0.30319
> Description: The process was terminated due to an unhandled exception. Exception Info: System.IO.FileNotFoundException at Microsoft.Dynamics.AX.Deployment.Setup.Program.Main(System.String[])

- C:\ProgramData\SF\AOSx\Fabric\work\Applications\AXSFType_Appxx\log:

> Microsoft.Dynamics.AX.Deployment.Setup.exe -bindir "C:\ProgramData\SF\AOS1\Fabric\work\Applications\AXSFType_App18\AXSF.Code.1.0.20180831174152\Packages" -metadatadir "C:\ProgramData\SF\AOS1\Fabric\work\Applications\AXSFType_App18\AXSF.Code.1.0.20180831174152\Packages" -sqluser "axdbadmin" -sqlserver "SQL-LS.contoso.com" -sqldatabase "AXDB" -setupmode servicesync -syncmode fullall -onprem
>
> Unhandled Exception: System.IO.FileNotFoundException: **Could not load file or assembly 'aoskernel.dll' or one of its dependencies. The specified module could not be found.** at Microsoft.Dynamics.AX.Deployment.Setup.Program.Main(String[] args)
>
> **DB sync failed.**

A "No subscription found in the context" error occurs when you run Add-CertToServicePrincipal

Recent versions of Windows PowerShell might cause a "No subscription found in the context" error. To resolve this issue, install and load an older version of Windows PowerShell, such as version 5.7.0.

```
# Install version 5.7.0 of Azure PowerShell
Install-Module -Name AzureRM -RequiredVersion 5.7.0

# Load version 5.7.0 of Azure PowerShell
Import-Module -Name AzureRM -RequiredVersion 5.7.0
```

Service Fabric Explorer warnings occur after you restart a machine

Error:

> Error event: SourceId='MonitoringAgentService', Property='ServiceState'. System.Management.Automation.RuntimeException: Error: **The GUID passed was not recognized as valid by a WMI data provider.** (Exception from HRESULT: 0x80071068). Stack trace:

Steps: To resolve this issue, restart the application package that generated the warning message. For more information, see Restart applications (such as AOS).

The internal time zone version number that is stored in the database is higher than the version that is supported by the kernel (13/12)

This database synchronization error can cause an old platform build (Platform update 12) to be deployed on top of a database that had a newer build (Platform update 15).

To resolve this issue, note the **SYSTIMEZONESVERSION** value.

```
select * from SQLSYSTEMVARIABLES where parm = 'SYSTIMEZONESVERSION'
```

Update the value to the version that was returned in the error message.

```
update SQLSYSTEMVARIABLES set VALUE = 12 where parm = 'SYSTIMEZONESVERSION'
```

Printing randomly stops

Make sure that all network printers that have been installed on the AOS server are running as the Windows service account that the AXService.EXE process is running as.

For more information about how to configure network printers in on-premises environments, see Install network printer devices in on-premises environments.

Ax-DatabaseSynchronize isn't populated with events

In Platform update 20 and later, there is database synchronization log issue where the synchronization logs aren't written under **Ax-DatabaseSynchronize** in Event Viewer.

To resolve this issue, go to <SF-dir>\AOS_<x>\Fabric\work\Applications\AXSFType_App<X>\log. For example, go to C:\ProgramData\SF\AOS_11\Fabric\work\Applications\AXSFType_App183\log. Here, you can see the output from DatabaseSynchronize in the Code_AXSF_M_<X>.out files. Troubleshoot any issues that pertain to this component.

You can't access Finance + Operations: "AADSTS50058: A silent sign-in request was sent but no user is signed in"

After a user enters credentials to sign in to Finance + Operations, the browser briefly shows the application layout. However, it then tries to redirect outside Finance + Operations, but fails with the following error:

> AADSTS50058: A silent sign-in request was sent but no user is signed in.

The cookies that represent the user's session weren't sent in the request to Azure AD. This issue can occur if the user is using Internet Explorer or Microsoft Edge, and if the web app that sends the silent sign-in request is in a different IE security zone than the Azure AD endpoint (login.microsoftonline.com).

This issue occurs because there was a change in the Skype Presence API, and on-premises environments connect to this API by default.

To resolve the issue, run the following SQL Server query.

```
update [AXDB].[dbo].[SYSCLIENTPERF] set SkypeEnabled = 0
```

Alternatively, turn off the **Skype presence enabled** option on the **Client performance options** page (**System administration** > **Setup** > **Client performance options**). To use this approach, you must be able to sign in to Finance + Operations. Therefore, you must first block redirection in the browser. After you disable the Skype presence, you can unblock redirection again.

The Google Chrome browser blocks redirection by default.

Error: "There was an error during CodePackage activation. Service host failed to activate. Error:0x8007052e"

You might receive the following error during a new installation:

> Error event: SourceId='System.Hosting', Property='CodePackageActivation:Code:EntryPoint'. There was an error during CodePackage activation.Service host failed to activate. Error:0x8007052e

This error will cause the AXSF service to fail with the same error.

To resolve this issue, follow these steps.

1. In the agent share path, find the **netstandard.dll** file. For example, this file might be at \wp\<name>\StandaloneSetup-<ver>\Apps\AOS\AXServiceApp\AXSF\Code\bin\netstandard.dll.
2. On each AOS server, open a Command Prompt window as an administrator, and run the following command.

   ```
   "C:\Program Files (x86)\Microsoft SDKs\Windows\v8.1A\bin\NETFX 4.5.1 Tools\gacutil.exe" -i <path from step 1.>\netstandard.dll /f
   ```

3. Delete **AXBootstrapperApp** from Service Fabric.
   a. Delete the **fabric:/Bootstrapper/AXBootstrapper** service.
   b. Delete the **fabric:/Bootstrapper** application.
   c. Unprovision the **AXBootstrapperAppType** type.
4. Redeploy the environment from LCS.

SQL Server 2016 service pack 2 is recommended for Reporting Services instances

When you go through LCS servicing operations, you might receive the following error:

> The process cannot access the file 'C:\Program Files\Microsoft SQL Server\MSRS13.MSSQLSERVER\Reporting Services\ReportServer\bin\Microsoft.Dynamics.AX.Framework.Services.Platform.Client.dll' because it is being used by another process.

This issue occurs because Reporting Services has a lock on a Microsoft Dynamics .dll file. We currently recommend that you have SQL Server 2016 service pack 2 installed on Reporting Services instances.

> **NOTE**
> You must have service pack 2 installed, and no additional cumulative updates or hotfixes must be installed.

SysClassRunner doesn't run successfully

Issue: When you try to run SysClassRunner on Platform update 29 through Platform update 31, you get the following exception:

```
Microsoft.Dynamics.Ax.Xpp.ClrErrorException: TypeInitializationExeption --->
System.TypeInitializationException: The type initializer for
'Microsoft.Dynamics.Ax.Metadata.XppCompiler.CompilerTracer' threw an exception. --->
System.TypeInitializationException: The type initializer for
'Microsoft.Dynamics.Ax.DesignTime.Telemetry.OneDS' threw an exception. --->
System.IO.FileLoedAxception: Could not load file or assembly 'Microsoft.Diagnostics.Tracing.TraceEvent,
Version=2.0.43.0, Culture=neutral, PublicKeyToken=b03f5f7f11d50a3a' or one of its dependencies.
The located assembly's manifest definition does not match the assembly reference. (Exception from HRESULT:
0x80131040) at Microsoft.Dynamics.Ax.DesignTime.Telemetry.OneDS.cctor()
--- End of inner exception stack trace ---
```

Reason: There is a .dll mismatch between the runtime and the application.

Resolution: Use TSG_SysClassRunner.ps1. For more information, see TSG_SysClassRunner.ps1.

DBSync fails with PEAP APP version 10.0.9 Platform update 33

Issue: During deployment of the APP 10.0.9 PU33 PEAP-package, the deployment fails with the AXSF applications staying in "InBuild" status in Service Fabric explorer. When reviewing the logs on the AXSF nodes's work directories, the following DBSync error can be found.

Error message from DBSync:

```
Microsoft.Dynamics.AX.Deployment.Setup.exe -bindir
"C:\ProgramData\SF\LBDEN08FS1AOS03\Fabric\work\Applications\AXSFType_App398\AXSF.Code.1.0.20200123151456\Pac
kages" -metadatadir
"C:\ProgramData\SF\LBDEN08FS1AOS03\Fabric\work\Applications\AXSFType_App398\AXSF.Code.1.0.20200123151456\Pac
kages" -sqluser "" -sqlserver "" -sqldatabase "" -setupmode servicesync -syncmode fullall -onprem

   at Microsoft.Dynamics.AX.Framework.Database.Tools.SyncEngine.RunSync()
   at Microsoft.Dynamics.AX.Framework.Database.Tools.SyncEngine.Run(String metadataDirectory, String
sqlConnectionString, SyncOptions options)
```

Reason: This issue may occur because the SQL password contains special characters.

Resolution: Update the password of the SQL user and remove the special characters. Then, update the Credentials.json file with the new password and retry the deployment from LCS.

DBSync fails with PEAP and first release APP version 10.0.14 Platform update 38

Issue: During deployment, the deployment fails with the AXSF applications staying in "InBuild" status in Service Fabric explorer. When reviewing the logs on the AXSF nodes's work directories, the following DBSync error is present multiple times.

```
10/01/2020 14:49:25: Failed when creating deadlock capture session event System.Data.SqlClient.SqlException
(0x80131904): User does not have permission to perform this action.
   at System.Data.SqlClient.SqlConnection.OnError(SqlException exception, Boolean breakConnection, Action`1
wrapCloseInAction)
   at System.Data.SqlClient.TdsParser.ThrowExceptionAndWarning(TdsParserStateObject stateObj, Boolean
callerHasConnectionLock, Boolean asyncClose)
   at System.Data.SqlClient.TdsParser.TryRun(RunBehavior runBehavior, SqlCommand cmdHandler, SqlDataReader
dataStream, BulkCopySimpleResultSet bulkCopyHandler, TdsParserStateObject stateObj, Boolean& dataReady)
   at System.Data.SqlClient.SqlCommand.RunExecuteNonQueryTds(String methodName, Boolean async, Int32
timeout, Boolean asyncWrite)
   at System.Data.SqlClient.SqlCommand.InternalExecuteNonQuery(TaskCompletionSource`1 completion, String
methodName, Boolean sendToPipe, Int32 timeout, Boolean& usedCache, Boolean asyncWrite, Boolean inRetry)
   at System.Data.SqlClient.SqlCommand.ExecuteNonQuery()
   at Microsoft.Dynamics.AX.Framework.Database.Monitor.DeadlockMonitor.CreateDeadlockTrackingSystemEvent()
```

Reason: This issue occurs because the SQL Server account used by Finance + Operations does not have sufficient permissions to execute the operation.

Resolution: Execute the following command in your SQL Server:

```
use master
GRANT ALTER ANY EVENT SESSION to axdbadmin;
```

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Scripts for resolving issues in on-premises environments

2/18/2021 • 4 minutes to read • Edit Online

This topic will serve as a central repository for scripts that you can use to fix issues in on-premises environments. These scripts must usually be run as pre-deployment or post-deployment scripts.

For more information about how to resolve issues in on-premises environments, see Troubleshoot on-premises deployments.

Prepare your environment for script execution

1. Configure the execution of pre-deployment and post-deployment scripts. For more information, see Local agent pre-deployment and post-deployment scripts.
2. Add the following code to your Predeployment.ps1 script.

```
# This has to be filled out
# $agentShare = '<Agent-share path>' # E.g '\\LBDContosoShare\agent''

$agentShare = '\\servername\D365FFOAgent'
Write-Output "AgentShare is set to $agentShare"

# The scripts make the assumption that the wp folder only contains one folder for the environment
name.
# If you have multiple folders in there from older deployments, then please remove those.
# It is not recommended to use the same agent share for multiple environments.

#& $agentShare\scripts\TSG_UpdateFRDeployerConfig.ps1 -agentShare $agentShare

#& $agentShare\scripts\TSG_WindowsAzureStorage.ps1 -agentShare $agentShare

#& $agentShare\scripts\TSG_SysClassRunner.ps1 -agentShare $agentShare

#& $agentShare\scripts\TSG_RemoveFilesFromZip.ps1 -agentShare $agentShare -filesToRemove
'Packages\TaxEngine\bin\Microsoft.Dynamics365.ElectronicReportingMapping.dll','Packages\TaxEngine\bin
\Microsoft.Dynamics365.ElectronicReportingMapping.pdb','Packages\TaxEngine\bin\Microsoft.Dynamics365.
ElectronicReportingServiceContracts.dll','Packages\TaxEngine\bin\Microsoft.Dynamics365.ElectronicRepo
rtingServiceContracts.pdb','Packages\TaxEngine\bin\Microsoft.Dynamics.ElectronicReporting.Instrumenta
tion.dll','Packages\TaxEngine\bin\Microsoft.Dynamics.ElectronicReporting.Instrumentation.pdb','Packag
es\TaxEngine\bin\Microsoft.Dynamics365.LocalizationFrameworkCore.dll','Packages\TaxEngine\bin\Microso
ft.Dynamics365.LocalizationFrameworkCore.pdb','Packages\TaxEngine\bin\Microsoft.Dynamics365.Localizat
ionFrameworkForAx.dll','Packages\TaxEngine\bin\Microsoft.Dynamics365.LocalizationFrameworkForAx.pdb'
```

3. From the relevant section of this topic, copy the code that you require to fix your issue, and paste it into a new file. Save this file in the same folder where your Predeployment.ps1 script is stored. The file name must match the title of the section that you copied the code from. Repeat this step for other issues that you must fix.
4. In the Predeployment.ps1 script, in the code that you added earlier, uncomment the lines that invoke the scripts that you want to use.

TSG_SysClassRunner.ps1

The following script is used to fix an issue that occurs when SysClassRunner is run in some versions of the

platform. For more information about this issue, see SysClassRunner doesn't run successfully.

```
param (
    [Parameter(Mandatory=$true)]
    [string]
    $agentShare = ''
)

$delete = @("Microsoft.Diagnostics.Tracing.TraceEvent.dll", "Microsoft.AI.Agent.Intercept.dll",

The survey will take about seven minutes. No personal data is collected (privacy statement).

Create deployable packages of models

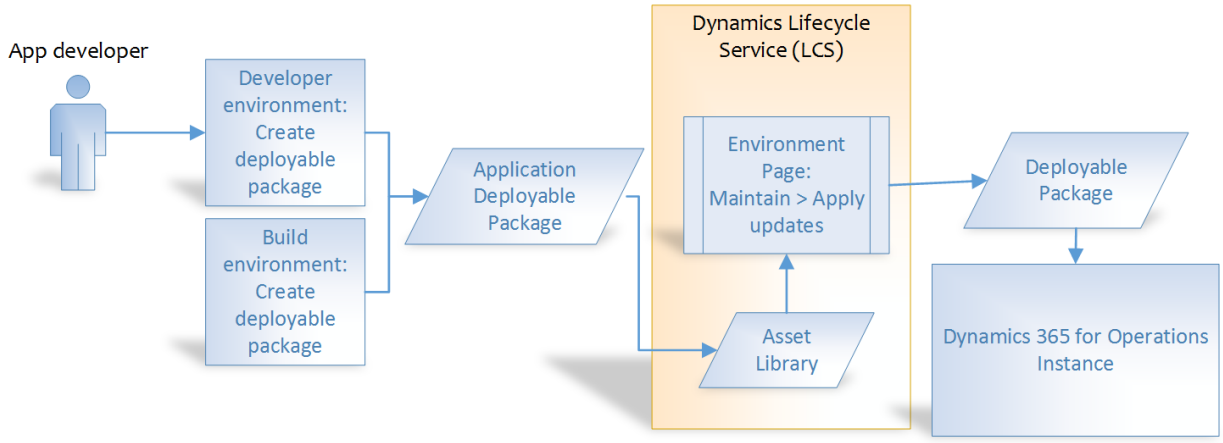
2/18/2021 • 2 minutes to read • Edit Online

An AOT package is a deployment and compilation unit of one or more models that can be applied to an environment. It includes model metadata, binaries, reports and other associated resources. One or more AOT packages can be packaged into a deployable package, which is the vehicle used for deployment of code (and customizations) on demo, sandbox, and production environments. This topic guides you through the process of creating and applying a deployable package.

Overview of the process

In order to deploy your code and customizations to a runtime environment (demo, sandbox, or production), you must create deployable packages of your solution or implementation. Deployable packages can be created by using **Visual Studio dev tools** or by using the **build automation process** that is available on build environments. These deployable packages are referred to as Application Deployable Packages or AOT Deployable Packages. The following image shows an overview of the process. After a deployable package is created, it must be uploaded to the Lifecycle Services (LCS) project's asset library. An administrator can then go to the LCS environment page and apply the package to a runtime environment using the **Maintain > Apply updates** tool.

> **NOTE**
>
> Custom payment connector for Commerce needs to be packaged using a combined AOT deployable package. For more information, see Create payment packaging for Application Explorer in Service Fabric deployments.



> **NOTE**
>
> Application Deployable Packages do not contain source code.

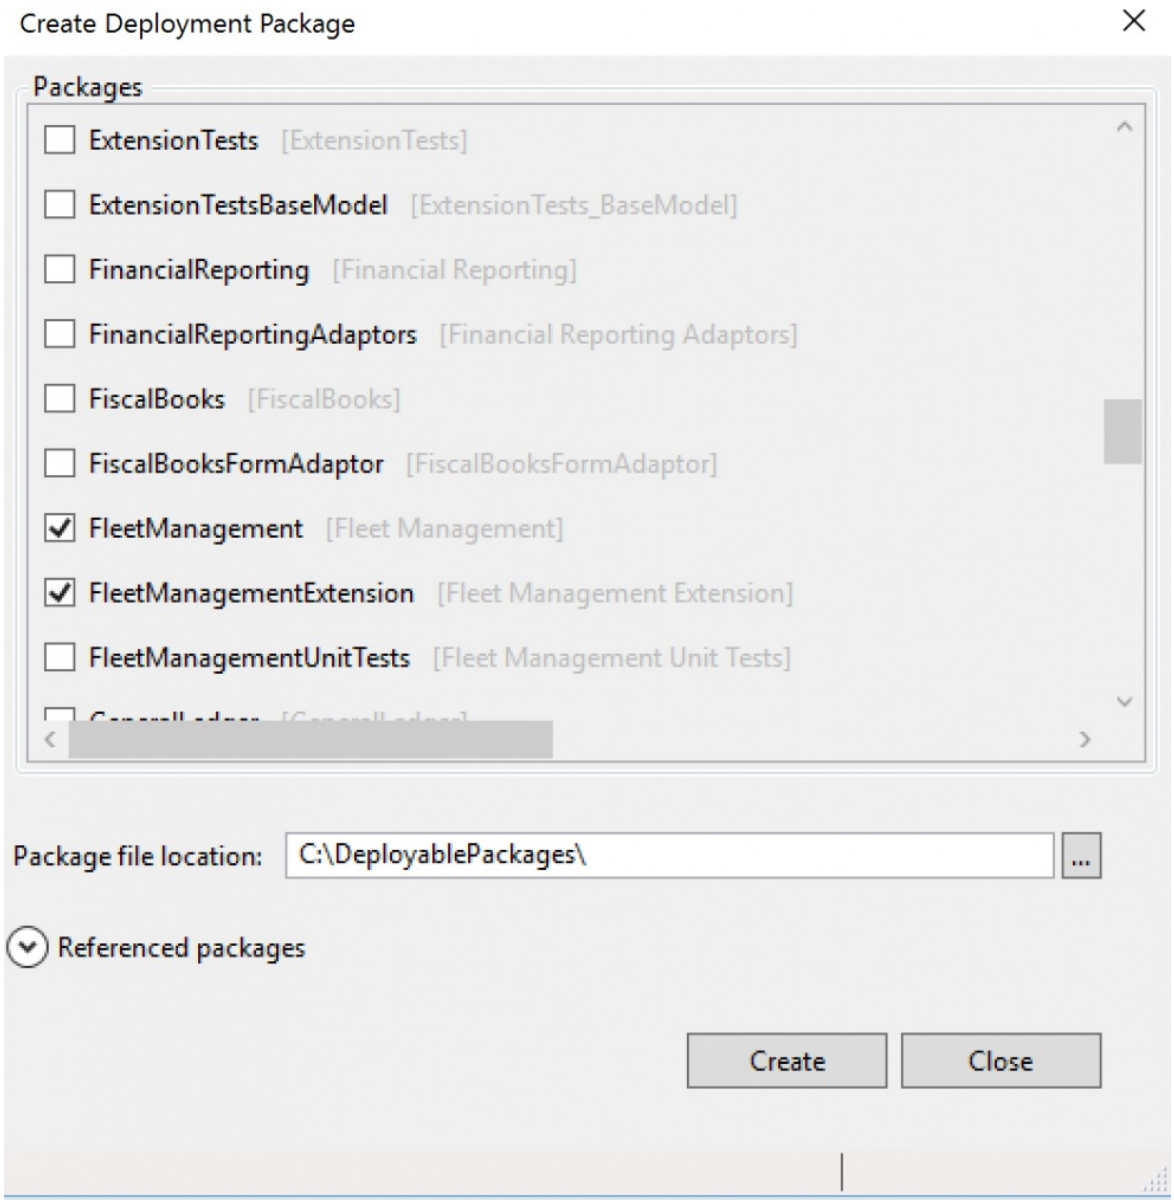
> It is always recommended to use a build environment to create deployable packages that are intended to go to production.

Create a deployable package

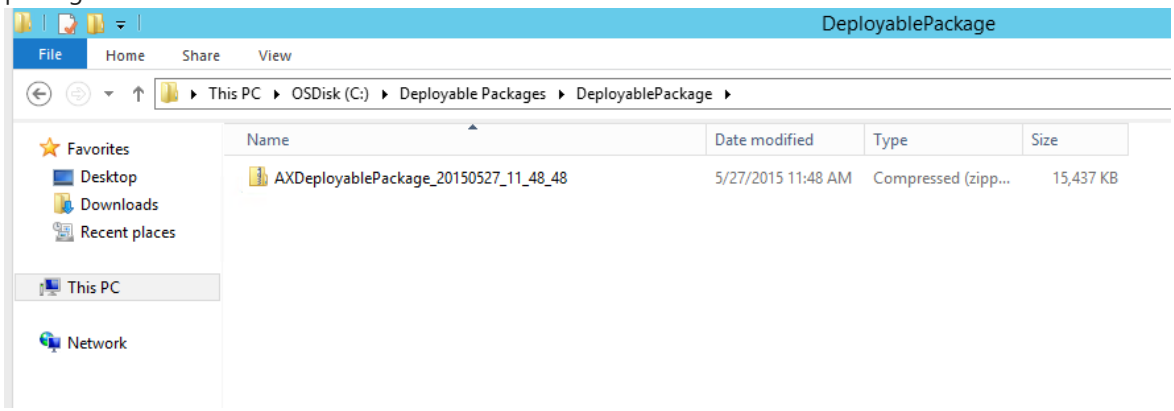
We recommend using a build environment to create deployable packages. You can also create a deployable package on a development environment.

On a development environment, after you have completed development and testing, follow these steps to create a deployable package in Visual Studio.

1. In Microsoft Visual Studio, select **Dynamics 365** > **Deploy** > **Create Deployment Package**.



2. Select the packages that contain your models, and then select a location in which to create the deployable package.



3. After a deployable package is created, sign in to Lifecycle Services, and then, in your LCS project, click the **Asset Library** tile.

4. Upload the deployable package that you created earlier.

Apply a deployable package

To apply a deployable package to an environment, see Apply updates to cloud environments.

Remove a deployable package

To uninstall or remove a deployable package from an environment, see Uninstall a package.

Install deployable packages from the command line

2/18/2021 • 6 minutes to read • Edit Online

This topic walks you through the steps for using the command line to apply either a binary update or an application (AOT) deployable package that was created in your development or build environment.

> **IMPORTANT**
>
> For most types of environments, you can apply a deployable package to an environment directly from Microsoft Dynamics Lifecycle Services (LCS). For more information, see Apply updates to cloud environments. Therefore, this topic applies primarily to environment types that don't support the application of updates via LCS. Examples include local development environments (downloadable virtual hard disks [VHDs]), multi-box development/test environments in Microsoft Azure (LCS Partner and trial projects), and build environments. However, you can also use this topic any time that you want to install deployable packages by using the command line instead of LCS.

Key concepts

- **Deployable package** – A deployable package is a unit of deployment that can be applied to any environment. It can consist of a binary hotfix to the runtime components of Application Object Server (AOS), an updated application package, or a new application package.
- **AXUpdateInstaller** – AXUpdateInstaller is an executable program that is bundled in the deployable package. When the package is downloaded to a computer, the installer is available.
- **Runbook** – The deployment runbook is a series of steps that is generated and used to apply the deployable package to the target environment. Some of the steps are automated, and some are manual. AXUpdateInstaller enables these steps to be run one at a time and in the correct order.

Install an application (AOT) deployable package on a development environment

> **NOTE**
>
> The steps listed below are for customization packages only. Do not use the **devinstall** parameter when running the Data Upgrade deployable package as part of an upgrade from Microsoft Dynamics AX 2012 to a Finance and Operations app.

An AOT deployable package is a package that contains customizations and extensions to your application. If you want to use the command line just to install an AOT deployable package on a development or demo environment, follow the instructions in this section. You can then skip the rest of this topic.

1. On the virtual machine (VM), download the zip file for the deployable package. Make sure that the zip file is stored in a non-user folder.

   > **NOTE**
   >
   > After you download the zip file, right-click it, and then select **Properties**. Then, in the **Properties** dialog box, on the **General** tab, select **Unblock** to unlock the files.

2. Extract the files.

3. Open a Command Prompt window, and go to the folder where you extracted the deployable package.
4. Run the following command.

```
AXUpdateInstaller.exe devinstall
```

The **devinstall** option installs the AOT deployable package on the VM.

> **NOTE**
> This command doesn't run database synchronization. You must run database synchronization from Microsoft Visual Studio after you install the deployable package.

Collect topology configuration data

1. In LCS, on the **Environment** page, select the name of a VM. Establish a Remote Desktop connection to the VM by using the user name and password that are provided on the **Environment** page.
2. On the VM, download the zip file for the deployable package from LCS. Make sure that the zip file is stored in a non-user folder.

> **NOTE**
> After you download the zip file, right-click it, and then select **Properties**. Then, in the **Properties** dialog box, on the **General** tab, select **Unblock** to unlock the files.

3. Extract the files.
4. In the folder where you extracted the deployable package, find and open the file that is named **DefaultTopologyData.xml**. You must specify the VM name and the installed components in this file.
   - To specify the VM name, follow these steps:
     a. In File Explorer, right-click **This PC**, and then select **Properties**.
     b. In the system properties, find and make a note of the computer name (for example, **AOS-950ed2c3e7b**).
     c. In the DefaultTopologyData.xml file, replace the machine name with the computer name that you found in the previous step.
   - To specify the installed components, follow these steps:
     a. Open a Command Prompt window as an administrator.
     b. Go to the extracted folder, and run the following command to see a list of all the components that are installed on the computer.

```
AXUpdateInstaller.exe list
```

     c. Update the DefaultTopologyData.xml file with the list of components.

   When you've finished specifying the VM name and the installed components, the DefaultTopologyData.xml file should resemble the following illustration.

```
<?xml version="1.0" encoding="utf-8"?>
<TopologyData xmlns:xsd="http://www.w3.org/2001/XMLSchema" xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance">
  <Name>VAL200AA2BMEDIU</Name>
  <MachineList>
    <Machine>
      <Name>AOS-950ed2c3e7b</Name>
      <ServiceModelList>
  <string>AOSService</string>
        <string>DIXFService</string>
        <string>RetailCloudPos</string>
        <string>RetailSelfService</string>
        <string>RetailServer</string>
  <string>SCMSelfService</string>
      </ServiceModelList>
    </Machine>
    <Machine>
      <Name>AOS-499ee94c842</Name>
      <ServiceModelList>
  <string>AOSService</string>
        <string>DIXFService</string>
        <string>RetailCloudPos</string>
        <string>RetailSelfService</string>
        <string>RetailServer</string>
  <string>SCMSelfService</string>
      </ServiceModelList>
    </Machine>
    <Machine>
      <Name>BI-1a62b3b31d78</Name>
      <ServiceModelList>
  <string>ReportingService</string>
      </ServiceModelList>
    </Machine>
    <Machine>
      <Name>BI-7ee6d8fbed7a</Name>
      <ServiceModelList>
  <string>ReportingService</string>
      </ServiceModelList>
    </Machine>
  </MachineList>
  <BackupScript>
    <FileName />
    <Automated>false</Automated>
    <Description>Please backup your enviorment now, set the step to complete once you finsihed backup</Description>
  </BackupScript>
</TopologyData>
```

5. Repeat steps 1 through 4 for every other VM that is listed on the **Environment** page.

Generate a runbook from the topology

Based on the topology information in the DefaultTopologyData.xml file, you must generate the runbook file that will provide step-by-step instructions for updating each VM.

- On any VM, run the following command to generate the runbook.

  ```
  AXUpdateInstaller.exe generate -runbookid=[runbookID] -topologyfile=[topologyFile] -servicemodelfile=
  [serviceModelFile] -runbookfile=[runbookFile]
  ```

  Here is an explanation of the parameters that are used in this command:

  - **[runbookID]**– A parameter that is specified by the developer who applies the deployable package.
  - **[topologyFile]**– The path of the DefaultTopologyData.xml file.
  - **[serviceModelFile]**– The path of the DefaultServiceModelData.xml file.
  - **[runbookFile]**– The name of the runbook file to generate (for example, **AOSRunbook.xml**).

    Example

    ```
    AXUpdateInstaller.exe generate -runbookid="VAL200AA2BMEDIU-runbook" -
    topologyfile="DefaultTopologyData.xml" -servicemodelfile="DefaultServiceModelData.xml" -
    runbookfile="VAL200AA2BMEDIU-runbook.xml"
    ```

The runbook provides the sequence of steps that must be run to update the environment. The following illustration shows an example of a runbook file. Each step in a runbook is associated with an ID, a machine name, and step execution details.

```
<?xml version="1.0" encoding="UTF-8"?>
- <RunbookData xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance" xmlns:xsd="http://www.w3.org/200
    <RunbookID>AXDeployablePackage_20160212_22_57_44</RunbookID>
  - <RunbookTopologyData>
      <Name>AX topology</Name>
    - <MachineList>
      - <Machine>
          <Name>AOS-77edc66f7a1</Name>
        - <ServiceModelList>
            <string>AOSService</string>
            <string>DIXFService</string>
            <string>RetailCloudPos</string>
            <string>RetailSelfService</string>
            <string>RetailServer</string>
            <string>SCMSelfService</string>
          </ServiceModelList>
        </Machine>
      + <Machine>
      + <Machine>
      + <Machine>
      </MachineList>
    + <BackupScript>
    </RunbookTopologyData>
  + <RunbookServiceModelData>
  - <RunbookStepList>
    - <Step>
        <ID>1</ID>
        <Description>Stop script for service model: AOSService on machine: AOS-77edc66f7a1</Description>
        <MachineName>AOS-77edc66f7a1</MachineName>
        <ServiceModelName>AOSService</ServiceModelName>
      - <ScriptToExecute>
          <FileName>AutoStopAOS.ps1</FileName>
```

Install a deployable package

1. On the first machine (VM) that is listed in the runbook file, follow these steps:

   a. Import the runbook by running the following command.

   ```
   AXUpdateInstaller.exe import -runbookfile=[runbookFile]
   ```

   Example

   ```
   AXUpdateInstaller.exe import -runbookfile="VAL200AA2BMEDIU-runbook.xml"
   ```

   b. Verify the runbook.

   ```
   AXUpdateInstaller.exe list
   ```

   c. Run the runbook.

   ```
   AXUpdateInstaller.exe execute -runbookid=[runbookID]
   ```

   Example

   ```
   AXUpdateInstaller.exe execute -runbookid="VAL200AA2BMEDIU-runbook"
   ```

   AXUpdateInstaller updates the runbook file after each step is run on a VM. The runbook also logs information about each step.

   For manual steps, follow the instructions, and then run the following command to mark the step as completed in the runbook.

```
AXUpdateInstaller.exe execute -runbookID=[runbookID] -setstepcomplete=[stepID]
```

Example

```
AXUpdateInstaller.exe execute -runbookid="VAL200AA2BMEDIU-runbook" -setstepcomplete=2
```

If errors occur during any step, debug the script or the instructions in the step, and update accordingly.

d. Export the runbook.

```
AXUpdateInstaller.exe export -runbookid=[runbookID] -runbookfile=[runbookFile]
```

Example

```
AXUpdateInstaller.exe export -runbookid="VAL200AA2BMEDIU-runbook" -
runbookfile="VAL200AA2BMEDIU-runbook.xml"
```

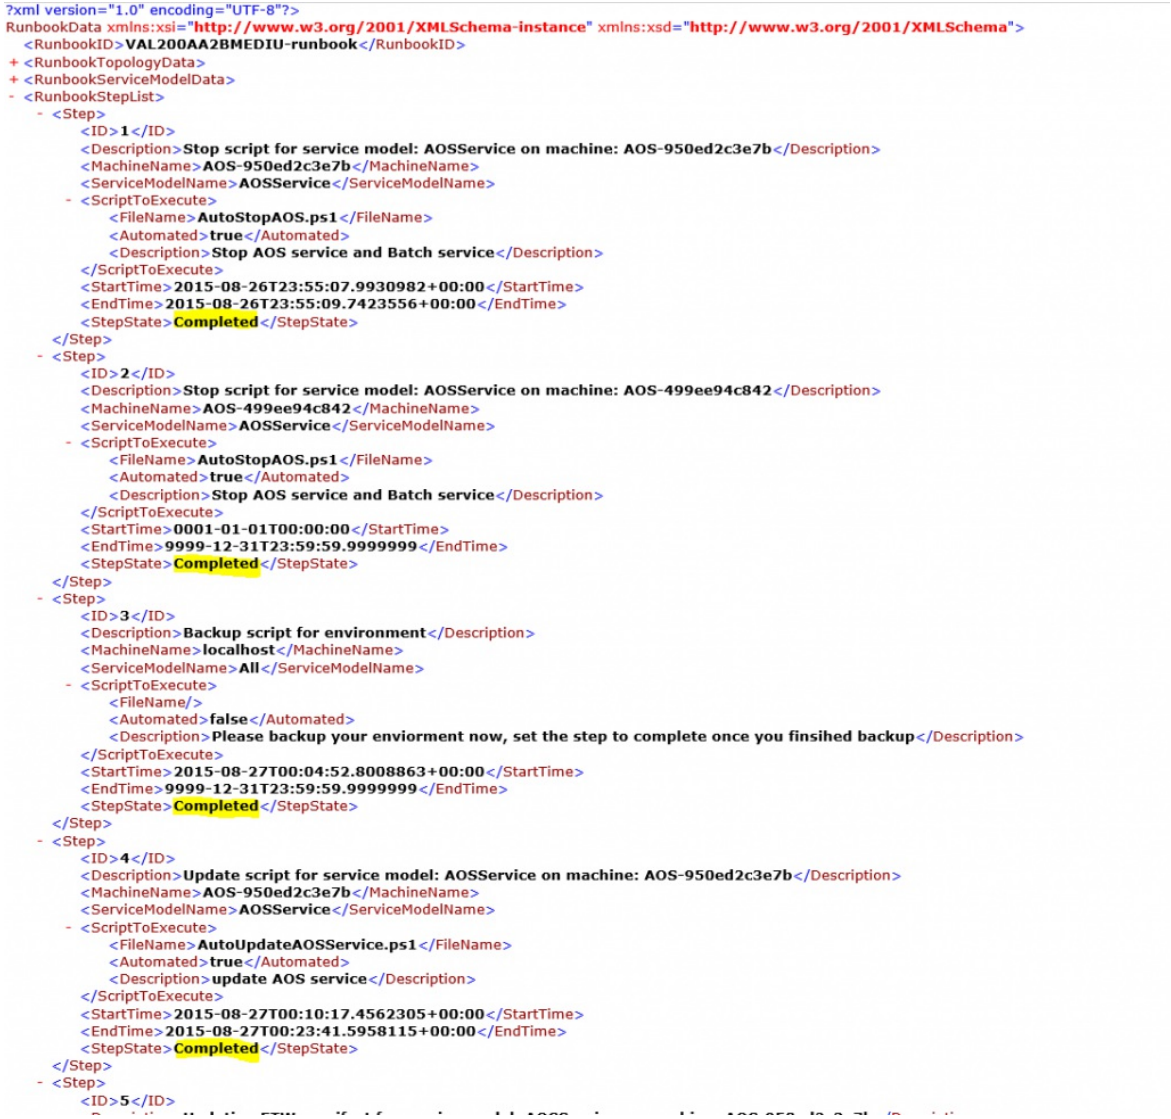
2. Repeat step 1 on every other VM that is listed in the runbook file. For one-box environments, such as development, build, and demo environments, there is only one VM.

Verify installation

1. Run the following command to verify that the new updates are installed.

```
AXUpdateInstaller.exe list
```

2. View the runbook to see the completed steps. Here is an example of a runbook file where the steps have been completed.



Backup the runbook file

- After all the steps in the runbook are completed and you've exported the runbook, save the file outside the computer for future reference. For example, you might have to use the runbook file in these situations:
  - You must analyze the downtime requirements for production, and so on.
  - You must send the file to Microsoft because a deployable package can't be installed.

Troubleshooting

- If any step in the runbook fails, you can rerun it by running the following command.

```
AXUpdateInstaller.exe execute -runbookid=[runbookID] -rerunstep=[stepID]
```

- To prevent version mismatch or downgrade, or installation of the same deployable package, run the following command.

```
AXUpdateInstaller.exe execute -runbookid=[runbook ID] -versioncheck=true
```

- To verify database synchronization, in the **aosservice\scripts** folder, find and open the **dbsync.error.txt** file, and look for any errors.

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Uninstall a package

2/18/2021 • 2 minutes to read • Edit Online

Occasionally, you might have to uninstall a deployable package. For example, you might be reorganizing your source code. Alternatively, you no longer require an independent software vendor (ISV) product and haven't renewed the license. Therefore, you must remove the package.

Remove a model

A model is a design-time concept that is part of a package. When a model isn't the only model in a module, you can just remove it from the source code. No other steps are required, because when you deploy the updated module, the old module is overwritten. All overlayer models fall into this category. For more information, see Deleting a model.

Prerequisites

- If any models reference the module that will be removed, the references must be removed from them. For information about how to find the references that must be removed, see Viewing model dependencies.
- Build and deploy any modules that references were removed from.
- All references to and from the modules must be removed before you begin to uninstall the module. To remove all a module's references, add a single class to the model. This class should contain no code. It should contain only a reference to the application platform.
- A Microsoft module cannot be removed. If this is attempted, a validation error will be shown on the package in Lifecycle Services.
- A module cannot be removed if it is part of the AOT deployable package being installed. If you want to remove a module, be sure that it is not part of the package before adding the name to the ModuleToRemove.txt file.

Uninstall a package

1. Create a file that is named **ModuleToRemove.txt**.
2. In the file, put the name of each module that you want to remove on a separate line. Make sure that you've completed the prerequisites for each module that you're removing.
3. Create a valid deployable package, and put the ModuleToRemove.txt file in the **package\AOSService\Scripts** folder.
4. Upload the package to the Lifecycle Services asset library. Wait for the asset to finish validation, and review any warnings that are shown on the Asset Details panel on the right side of the page.
5. Install the deployable package. For more information about how to install deployable packages, see Apply updates to cloud environments.
6. Verify that the package was uninstalled before you complete this procedure in a production environment.

Troubleshoot package application issues

2/18/2021 • 9 minutes to read • Edit Online

This topic provides detailed information that will help you troubleshoot issues that might occur when you apply packages on your Tier 1 or Tier 2 through Tier 5 environments. For information about how to apply a package, see Apply updates to cloud environments.

General troubleshooting and diagnostics

If a package isn't successfully applied, you have two options:

- Retry the operation that failed.
- Use the logs.

Retry the failed operation

If package application fails, and you want to retry the operation, select **Resume**.

Use the logs

If package application fails, and you want to use the logs, follow these steps.

1. Download and then unzip the log files.
2. Select the role that a step failed for, such as **AOS** or **BI**.
3. Select the virtual machine (VM) where the step failed. You can find this information in the **Machine name** column in the **Environment updates** section.
4. In the VM logs, select the folder that corresponds to the step where the issue occurred. The folder name identifies the step that each folder corresponds to.

   For example, if the issue occurred during the execution of a step, select the **ExecuteRunbook** folder. The step number is highlighted and is the number after the globally unique identifier (GUID).

Package application issues

Issue: The package that was applied isn't valid

Description

Because the package that was applied wasn't valid, the servicing status is **Failed**, and no updates are listed in the **Environment updates** section. To verify whether the package is valid, follow these steps.

1. Download and unzip the logs.
2. Navigate to the logs for the Application Object Server (AOS) machine.
3. Verify that the **DownloadFilesAndSlipstreamTools-xxx** and **GenerateRunbook-xxx** folders exist.
4. Open the **GenerateRunbook-xxx folder**, and then open the file for the output type.

   If you find an error message or an exception that states that a file is missing or failed to generate any steps for the runbook, there was an attempt to upload a package that wasn't valid.

Action

Select **Abort** to abort the current package, upload a new package, and then restart the servicing flow.

Issue: Package deployment fails even though no steps failed

Description

A time-out occurs when you download the package to the machine. During pre-servicing, a few steps must be completed before steps are completed in the runbook. As part of the pre-servicing, the package must be downloaded to all the machines. The time to download might vary slightly, depending on the datacenter where the environment resides. Any download doesn't occur within 30 minutes is considered a failure in the servicing status and will be stopped.

Action

1. Select **Resume** to see whether you can resolve the issue. If this step doesn't work, move on to step 2.
2. Download the logs from the **Environment** page.
3. Verify that the package download on all the machines has logs that include the DownloadFilesAndSlipstreamTools folder.
4. Review the log files. If you don't see the following text at the end of the log file, the issue occurred because the package download wasn't completed: "Completed file download and slipstream successfully"

Issue: Package deployment fails even though no steps failed

Description

There isn't enough disk space to download the package. Inspect all the machines. This issue occurs if the servicing drive of any machines is full.

Note that if you select **Resume** in this situation, you won't resolve the issue.

To verify that the deployment failed because space issues, follow these steps.

1. Navigate to the **DownloadFilesAndSlipstreamTools-xxx** folder.
2. Open the output file, and view the error message to see whether the step failed because space issues.

Action

As part of the automated cleanup on topologies, any deployable packages in %ServiceVolume%\DeployablePackages that are more than 30 days old are deleted. The same timeline is also used to delete servicing-related logs. These logs are usually located in C:\Dynamics.

However, on dev/one-box machines, there is more flexibility. The number of retention days and the minimum disk space of the ServiceVolume and Logs drives can be customized.

- Under the **HKLM:\SOFTWARE\Microsoft\Dynamics\Deployment** registry key, you can create the following keys to customize when cleanup should occur. The automated cleanup task will consider these values.
    - **CutoffDaysForCleanup** – The number of days that old packages and logs should be retained. The default value is **30**.
    - **CutoffDiskSpaceLimitForPackages** – The minimum free disk space (in gigabytes [GB]) on the service volume drive where the package folder is located. For example, if the disk space is 200 GB, the cleanup task will remove the packages, based on the number of days.
    - **CutoffDiskSpaceLimitForLogs** – The minimum free disk space (in GB) of the system drive where the log folder is located. For example, if the disk space is 100 GB, the cleanup task will remove the servicing-related logs, based on the number of days.

Issue: A step failed with errors

Description

A step might fail with errors for one of the following reasons:

- The package has customization issues or is missing dependencies.
- There is an issue with the servicing scripts.
- A random failure occurred when the step was executed.

To verify what the issue is, follow these steps.

1. Download and navigate to the step logs.
2. Open the output file for the step, and see whether there are any errors.
3. If any additional log files are available, inspect them for errors.

Action

1. Download the logs.
2. Select **Rerun step** to retry the failed step.

If the step fails again, and the same error occurs, go back to the logs to look for more information.

- If you notice that there is an issue with the customizations, abort this package, and retry by using the new package.
- See whether a fix for the issue is available in Issue search.
- If you see the following step failure, either database synchronization or report deployment might have failed: "GlobalUpdate script for service model: AOSService"
- Look for the DBSync.err file, and see what the errors are. Inspect the DBSync.log file. For specific failures during the DB Sync step, look in the **Common DB Sync Failures** section.

Issue: The deployment status is Servicing but the servicing status is Failed

Description

A built-in mechanism enables the system to retry multiple times before it gives up. The following preparation steps can also be retried several times:

- Download the package to the machines.
- Slipstream the servicing package.
- Generate the runbook.

Action

You can download the logs to view the error and take action before all retries are exhausted. If the retry mechanism fails to go beyond the preparation stage, and you see a status of **Failed**, open a ticket so that the Microsoft team can investigate the issue further.

Issue: The dashboard doesn't open after package deployment is completed

Description

If the dashboard doesn't open after package deployment is completed, a run-time error might be occurring when the AOS machine is started.

Action

1. Start Event Viewer.
2. Navigate to **Applications and Services Logs** > **Microsoft** > **Dynamics** > **Ax-SystemRuntime** > **Operational Filter by errors**, see whether there are any errors, and investigate the errors as required.

Issue: A package application failed with error code : DSU#####

Description

You may receive an error stating **A critical component has encountered an error processing your**

request. Error code: DSU#####, or similar. The error code of **DSU#####** indicates that there's a temporary outage happening in the underlying Microsoft API. This type of outage may also impact database movement functionality.

Action

Microsoft is proactively monitoring the service status and this type of outage is expected to be mitigated shortly.

There's no impact on the status and the health of your environment.

If you experience this error when scheduling a service request or performing a database movement task, please try again at a later time.

Typical database synchronization issues

If you see the following step failure, a database synchronization issue might be occurring: "GlobalUpdate script for service model: AOSService"

Follow these steps to look for the DBSync.err file, find the errors, and inspect the DBSync.log file.

1. Download and navigate to the step logs.
2. Open the output file for the step, and see whether there are any errors.
3. If additional log files are available, inspect the logs for any errors.
4. The following table shows the failures that are seen most often and the action that you should take. The **Issue** column shows the error message that you will see in the dbsync.err file. The percentage sign (%) can be replaced with the metadata name of the table, field, index, and so on.

ISSUE	ACTION
%Table Sync Failed for Table%Create Unique Index%	This issue typically occurs when a unique index is created, but the data isn't unique. Fix the data before you run the step again.
%Application configuration sync failed.%Custom action sync failed with error:%	View the information in the error message and the call stack to determine the application code that is causing the issue.
%cannot be found from underlying query''s table%	This issue was fixed. For more information, refer to KB 4018815.
%Table Sync Failed for Table%Converting Field%	Follow the error message, fix the issue, and run the step again.
%failed because one or more objects access this column%	See whether the index is in the metadata. If the index is in the metadata, this issue is a SyncEngine product issue. If the index isn't in the metadata, remove the index from the SQL database before you run the step again.
%cannot be found from underlying data source''s table%	This issue was fixed. For more information, refer to KB 4018815.
'%Table Sync Failed for Table%' and errorMessage like '%There is already an object named%'	The Internal SqlDictionary table and SQL schema are out of sync. There isn't enough information in the logs to understand how this state was reached.

ISSUE	ACTION
%Table Sync Failed for Table%Column names in each table must be unique%	SqlDictionary entries for the table are corrupted, and the field is missing. There isn't enough information in the logs to understand how this state was reached.
%Column name 'LOAD_' does not exist in the target table or view. CREATE INDEX%	This issue appears to be a SyncEngine issue. Create a ticket on Microsoft Support.
Cannot drop the index 'VENDREQUESTPROFILEQUESTIONNAIRE.I_1301PROFILEQUESTIONNAIRE', because it does not exist or you do not have permission	This issue appears to be a SyncEngine issue. Create a ticket on Microsoft Support.
%The index entry of length 2046 bytes for the index 'I_65750INDEX1' exceeds the maximum length of 1700 bytes for nonclustered indexes%	Modify the index before you run the step again.
%Incorrect syntax near%	This issue is a SyncEngine issue. Create a ticket on Microsoft Support.
Reference to database and/or server name in 'TEMPDB.DBO.T_TRVREQUISITIONLINE_C4C3569DD5A14CDABAE71A341743FB61' is not supported in this version of SQL Server	This issue is a SyncEngine issue. Create a ticket on Microsoft Support.
%Error: Timeout expired. The timeout period elapsed prior to obtaining a connection from the pool.%	Retry the step.
Database execution failed: Invalid column name 'DEFAULTDIMENSION'. CREATE VIEW	This issue appears to be a SyncEngine issue. Create a ticket on Microsoft Support.
Database execution failed: Invalid object name 'PMBI_DEPROJECTTIMESHEET'. CREATE VIEW	This issue appears to be a SyncEngine issue. Create a ticket on Microsoft Support.
%provider: Named Pipes Provider, error: 40 - Could not open a connection to SQL Server%	This issue should have been fixed in Platform Update 3. Retry the step.

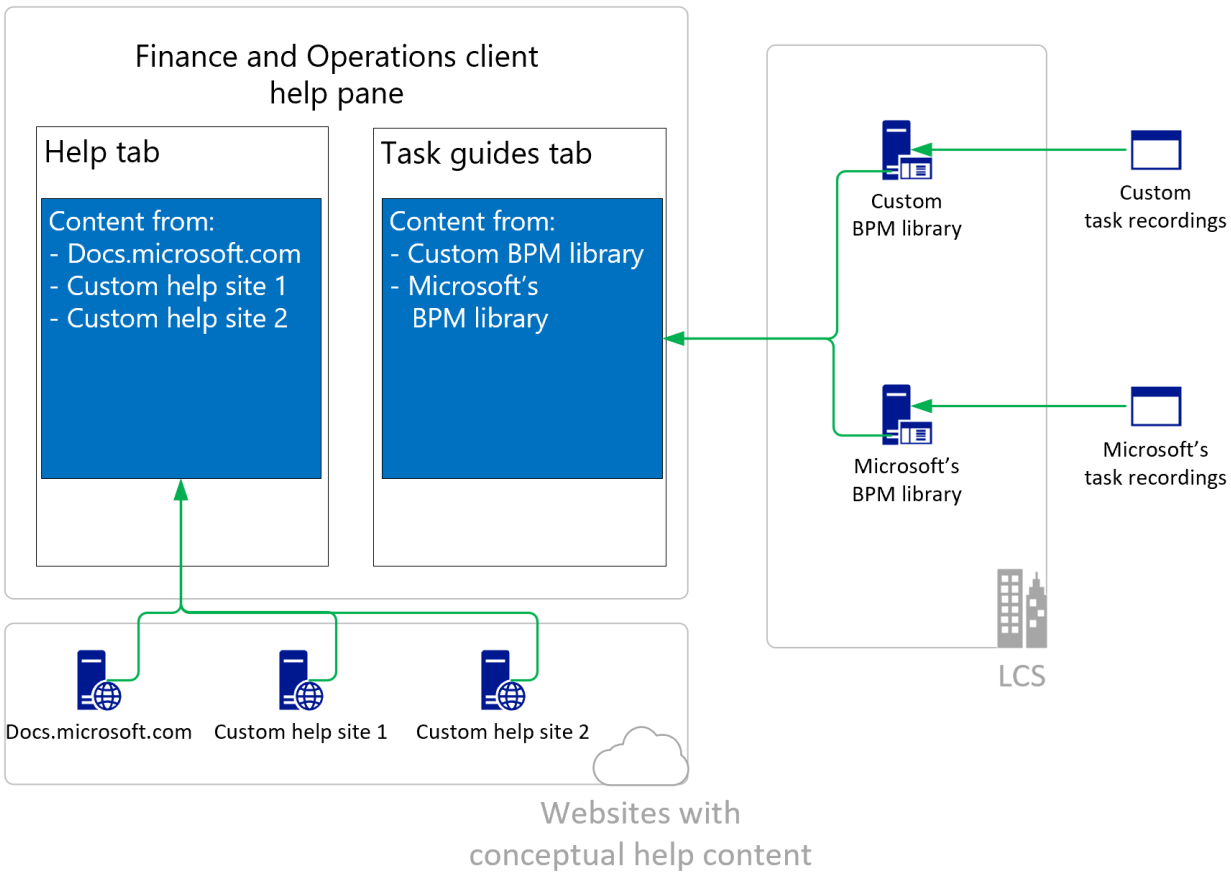
Custom Help overview

2/18/2021 • 4 minutes to read • Edit Online

Finance and Operations apps are often customized and extended to fit an organization's needs. If your solution is based on Microsoft Dynamics 365 Finance, Dynamics 365 Supply Chain Management, or Dynamics 365 Commerce, you can connect solution-specific and customer-specific Help content to the Help pane in the Finance and Operations client. This topic describes the main steps and decision points.

> **NOTE**
>
> Users of Finance and Operations apps can create custom task guides to supplement conceptual content that describes the functionality of their solution. These conceptual descriptions are also referred to as Help and can be provided by Microsoft, partners, and an organization itself. For more information, see Help system.

The following illustration, and this topic in general, use the term *Help* for conceptual descriptions that either include or exclude how-to guides. The term *task guides* refers to in-product task guides.



Custom Help content

Custom Help content typically originates from one of three sources:

- Microsoft documentation repositories (repos)

  You can use the HTMLFromRepoGenerator tool from the Custom Help Toolkit to clone content from any of the Finance and Operations repositories and generate corresponding HTML files. Those files can then be updated with content that is specific to your solution.

- Existing customized Dynamics AX content

  You can convert Dynamics AX custom Help content so that it can be used in Dynamics 365.

- HTML files that are created specifically for your solution

  Learn more about the metadata that must be added to your HTML files for context-sensitive Help and search to work correctly.

Process

The end-to-end process depends on the actual customer solution and the users' expectations. A typical process involves the following steps:

1. Create the custom Help content.
2. Publish the content on a website.
3. Index the content by using a search service.
4. Connect the custom **Help** pane to the website and the search service.

Microsoft provides a toolkit that can help you generate HTML files from the Microsoft Help repositories, generate JavaScript Object Notation (JSON) files for search services, and change the locale of HTML files so that it matches the locale of your solution.

You're welcome to share your knowledge by contributing to this documentation through the link at the bottom of the page or by joining the Dynamics 365 community.

The following table outlines the main objectives that admins typically have for configuring the Help experience.

OBJECTIVE	LEARN MORE
I want to give my users a customized in-product Help experience that reflects their actual solution.	See the Custom Help websites section of this topic and Create documentation or training with Task Recorder.
I want to use the Microsoft Help content as a baseline for Help content that is specific to my solution.	See Custom Help Toolkit: The HtmlFromRepoGenerator tool.
I want to contribute to the Microsoft Help content.	See Extend, customize, and collaborate on the Help.
I want to reuse my existing Dynamics AX content.	See Convert Dynamics AX custom Help for use in Dynamics 365.
I want to set up a website for my Help content.	See the Custom Help websites section of this topic.
I want to add my content to the **Help** pane.	See Connect a custom Help website to the Help pane.
Our technical writers want guidance that will help them convert our earlier content into Markdown so that it becomes easier for them to customize the Microsoft content.	See Moving to Markdown.

Custom Help websites

Before the product can connect to your Help content, you must customize the in-product **Help** pane so that it shows your content. The following conditions must be met:

- Your content must be available on a website.

  You can deploy your content to an existing website, or you can set up a dedicated website to host your

content. The website can be private or public, but we recommend that users **not** be required to sign in to access your content.

- Your content must be indexed by a search service.

  If you use the AzureSearchCustomHelp solution that is part of the Custom Help Toolkit for context-sensitive Help, the **Help** pane will generate a query that must be run against the search service's index. The query depends on specific metadata in the Help topics. For more information, see Metadata requirements for custom Help topics.

The Deploy custom Help to Azure topic describes an approach for hosting content on Azure. It includes information about how to set up a search service that indexes your content so that it can be found by the in-product **Help** pane. If you don't have an Azure subscription, create an account before you begin. You can start with a free account for 12 months. For more information, see Create your Azure free account today.

Prepare content for use with the Help pane

2/18/2021 • 4 minutes to read • Edit Online

Content that can be used with the **Help** pane in Microsoft Dynamics 365 Finance, Dynamics 365 Supply Chain Management, and Dynamics 365 Commerce can be derived from existing Microsoft content, migrated from existing Dynamics AX 2012 Help content, or created as new files.

Microsoft creates Help in multiple languages for the locales that are supported by Finance, Supply Chain Management, and Commerce. However, locale support isn't restricted to those locales.

Creating custom Help content that is derived from existing Microsoft content

You can use Microsoft Help content as a baseline for content that describes your solution. The HtmlFromRepoGenerator tool can retrieve the content from Markdown files in Microsoft repositories (repos) and convert it to HTML files.

For more information about how to use existing Microsoft content as a baseline for content that describes your solution, see Extend, customize, collaborate on the Help.

Migrating content from existing AX 2012 Help content

If you have existing content from AX 2012, you can reuse it for Finance, Supply Chain Management, and Commerce. However, you must transform the HTML files so that they can be used in the custom Help environment. The Custom Help Toolkit includes a Windows PowerShell script, **run_ax2012.ps1**, that transforms AX 2012 HTML files so that they can be used in the custom Help environment.

Creating new Help content

You use the AzureSearchCustomHelp solution that is provided as part of the Custom Help Toolkit to connect your content to the **Help** pane. The **Help** pane will generate a query that is run against the search service's index. Context-sensitive Help and full-text search in the **AzureSearchCustomHelp** solution require that each topic contain specific metadata.

Metadata requirements for custom Help topics

The following metadata must be present in your topics for context-sensitive Help and full-text search to return results in the AzureSearchCustomHelp solution.

PROPERTY	DESCRIPTION
title	The value is used for full-text search from the **Help** pane.
description	The value is used for full-text search from the **Help** pane.
ms.search.form	The value contains the Application Object Tree (AOT) name of a page and is used for context-sensitive search from the **Help** pane.

PROPERTY	DESCRIPTION
ms.locale	The value indicates the language of the topic. It's mapped against the current browser locale when the **Help** pane searches the content. Language fallback can be configured for the target custom Help website. For more information, see Language and locale descriptors in the product and in Help.
ms.search.scope	The value determines which client the Help topic is shown in. You can specify one or more values. Values include **Core**, **Operations**, **Retail**, and **Human Resources**.

The following table describes the values that can be specified for the **ms.search.scope** property. You can specify one or more values. The values determine which client a Help topic is shown in.

VALUE	DESCRIPTION
Core	If this value is present, the topic appears in the **Help** pane. Otherwise, the topic doesn't appear in the **Help** pane. This value is set for the part of the Microsoft content that must always be available in the **Help** pane, for all users across all supported Dynamics 365 solutions.
Operations	This value applies to solutions that are based on Finance or Supply Chain Management.
Retail	This value applies to solutions that are based on Commerce.
Human Resources	This value applies to solutions that are based on Dynamics 365 Human Resources.
Talent	This value applies to solutions based on Dynamics 365 Talent. (Note that the Dynamics 365 Talent: Attract and Dynamics 365 Talent: Onboard apps are being retired. For more information, see Retiring Dynamics 365 Talent: Attract and Onboard apps.)

Non-required metadata

The following properties are reserved for future use:

- **ms.search.region** – Eventually, this property might be used to limit the content that is shown to content that is tagged either as global or for the region of the implementation.
- **ms.search.validFrom** – Eventually, this property might be used to limit the content that is shown to content for a product that was released on a given date or earlier.
- **ms.dyn365.ops.version** – Eventually, this property might be used to limit the content that is shown to content for a specific version of a product or earlier.
- **ms.search.industry** – Eventually, this property might be used to limit the content that is shown to content for a specific industry.

> **TIP**
> Microsoft content in the public GitHub repos contains additional metadata that Microsoft uses in internal processes that aren't related to the mechanics of the Help system. You can ignore these metadata properties if you extend or customize the Microsoft content.

Changing the locale of topics to match the locale of solutions

If your solution is intended to support multiple markets, you will want to provide Help content for each market. For example, your solution might support German (Germany) and German (Austria), but you have HTML files only for German (Germany). To make the same content available in German (Austria), you can make a copy of the HTML files and then use the HtmlLocaleChanger tool to update the **ms.locale** metadata. You can also add content that is specific to Austria to these new HTML files, as required.

Converting HTML files to JSON files for use with an Azure search service

If you use the AzureSearchCustomHelp solution that is provided as part of the Custom Help Toolkit, the search service requires that all your content be in JavaScript Object Notation (JSON) format. The ConvertHtmlToJson tool transforms HTML files into JSON files.

Deploy custom Help to Azure

2/18/2021 • 12 minutes to read • Edit Online

This topic describes the steps for setting up a web app to host your content and for setting up a search service to make the content discoverable by the in-product **Help** pane. You will set up a Microsoft Azure web app and then use that web app to host content that is connected to the in-product **Help** pane.

If you don't have an Azure subscription, create an account before you follow the steps in this topic. You can start with a free account for 12 months. For more information, see Create your Azure free account today.

Get started

The Prepare content for use with the Help pane topic describes the steps for preparing Help content so that it can be used with the in-product **Help** pane. After you have a set of HTML files and their equivalent JavaScript Object Notation (JSON) files, you can set up the web app and the search service.

Process overview

The general process for creating your Azure resources consists of the following steps:

1. In the Azure portal, create a resource group.
2. In the Azure portal, create a web app, a storage account, and a search service.
   - The web app stores and serves HTML files. The HTML files contain your Help content.
   - The storage account uses a blob container to store JSON files. The JSON files are your Help files after they have been converted to JSON format so that they can be used to generate an index of your content for search purposes. For more information, see Custom Help Toolkit: The ConvertHtmlToJson tool.
   - The search service indexes the Help content. An index makes your content discoverable by the in-product **Help** pane. For more information, see Create a basic index in Azure Cognitive Search.
3. Upload HTML files to the web app by using File Transfer Protocol (FTP).

   When you complete this step, you put the HTML files in the relevant language subfolders, based on the locales that the content was written for. For information about the names to use for these subfolders, see Language and locale descriptors in the product and in Help.
4. Upload JSON files into Azure Blob storage in the storage container, in subfolders that correspond to the language subfolders for the HTML files.
5. Configure the search service so that it has a data source, index, and indexer on the search service, by using the REST application programming interface (API).

   In this example, an API tool that is named Postman is used to make the REST API calls. To use a language-specific index analyzer, you must create language-specific indexes.

In the remaining sections of this topic, the assumption is that you have an Azure account and a valid subscription. If you don't have an Azure subscription, create an account before you begin. You can start with a free account for 12 months. For more information, see Create your Azure free account today.

Create a resource group

To host your web app, search service, and storage account, you must first create one or more resource groups. We recommend that you create all resources in a single resource group to make management easier. For more

information, see Create resource groups.

1. In the Azure portal, select **Resource groups**, select **Add**, and then specify a name for the resource group, such as **MyCustomHelp**.
2. Select **Review + Create** to finish creating the resource group.

Create a web app

To host your content, you must create a web app in Azure. For more information, see Create a static HTML web app in Azure.

Create the web app

1. In the Azure portal, go to your resource group, select **Add**, select **Web App**, and then specify the runtime stack and a name for the web app, such as **MyCustomHelpWebApp**.

   You can use any .NET Core stack as the runtime stack. For more information, see Create an ASP.NET Core web app in Azure.

2. After the deployment is completed, select **Go to resource**.

3. On the left side of the page, select **Deployment Center**. Under **Manual Deployment (push/sync)**, select **FTP**, and then select **Dashboard**.

   You can use either *app credentials* or *user credentials* to upload your content to the web app. We recommend that you use app credentials. To upload your content, you must have the FTP/FTPS endpoint, the user name, and the password.

   You might want to copy the user name and password to a temporary location before you continue. Additionally, we recommend that you reset the credentials after you've completed the deployment. For more information, see Configure deployment credentials for Azure App Service.

Next, you will add your HTML files to the web app. You can use an FTP client such as FileZilla, Visual Studio, Cyberduck, or WinSCP. For more information, see Deploy your app to Azure App Service using FTP/S.

Upload HTML files

1. Open your preferred FTP client. For information about best practices that are related to uploading files to a web app, see Deploy your app to Azure App Service using FTP/S.

2. Enter the host (the FTPS endpoint value from the Deployment Center for the web app), user name, and password, and then connect.

3. Under **/site/wwwroot** on the host, create a language folder for each language that your custom Help website must support. Upload the HTML files and other associated files to each language folder.

   > **IMPORTANT**
   > Remember to use folder names that correspond to the languages that the client expects. For more information, see Language and locale descriptors in the product and in Help.

Your custom Help website has now been deployed to Azure and should be visible in a browser.

Create a storage account

Next, create a storage account that uses a blob container to store the JSON files that the search service will use. For more information about Azure Storage, see the Azure Storage documentation.

You can generate the JSON files from your HTML Help files by using the ConvertHtmlToJson tool that is part of

the Custom Help Toolkit.

1. In the Azure portal, go to your resource group, select **Add**, select **Storage account**, and specify a name for the storage account, such as **mycustomhelpstorage**. Then select **Review + Create**. For more information, see Create a storage account.

2. Validate and create the storage account.

   After the deployment is completed, the new storage account is listed under the resource group.

3. Select your storage account, and then, on the left side of the page, under **Blob Service**, select **Containers**. Add a container, and specify a name, such as **mycustomhelpcontainer**. For more information, see Quickstart: Upload, download, and list blobs with the Azure portal.

You can now upload your JSON files. The folder structure that you use must match the folder structure that you created for the HTML files to match the languages of your solution. For example, if your web app has HTML files in an **en-US** folder, create an **en-US** folder in the container, and upload the en-US JSON files to this folder.

There are several ways to upload JSON files to the blob container. If you prefer to use a user interface (UI), Azure Storage Explorer is a convenient tool that lets you use Azure Storage to manage file operations. If you prefer a command-line option, you can use AzCopy. For more information, see Transfer data with the AzCopy on Windows.

Create a search service

Next, create a search service, so that the content can be indexed and is discoverable by the in-product **Help** pane. For more information, see What is Azure Cognitive Search?

- In the Azure portal, go to your resource group, select **Add**, and select **Azure Cognitive Search**, and then, under **URL**, specify a name for the service, such as **mycustomhelpsearch**. Then select **Review + Create**.

  The service is added to the resource group.

Configure the search service

In the previous section, you created a search service. In this section, you will configure it by creating a data source, an index, and an indexer for each locale. The JSON files that you uploaded to the blob container will then be indexed and searchable. In the examples that follow, the Postman tool is used to make several API calls. However, you can use your own method to call those APIs.

Create a data source

1. Open Postman, and create a new POST request. If you're unfamiliar with this tool, see Explore Azure Cognitive Search REST APIs using Postman.

2. In the **Enter request URL** field, enter `https://[AzureSearchServicename].search.windows.net/datasources?api-version=2017-11-11`. Replace **[AzureSearchServicename]** with the name of the search service that you created in the Create a search service section of this topic (for example, **mycustomhelpsearch**).

3. On the **Headers** tab, set **"Content-type"** to **application/json**, and set **api-key** to the key from your Azure Cognitive Search service. You can find the key in **Access keys** under **Settings** on the left side of the search service.

4. In the **Authorization** tab, set **Type** to **No Auth**.

5. On the **Body** tab, paste the following text.

```
{
    "name" : "[datasourcename]",
    "type" : "azureblob",
    "credentials" :
    {
        "connectionString" : "DefaultEndpointsProtocol=https;AccountName=
[StorageAccountName];AccountKey=[key];EndpointSuffix=core.windows.net"
    },
    "container" :
    {
        "name" : "[JSONStorageContainerName]"
    }
}
```

Replace the following parameters with the relevant values:

- **[datasourcename]** – Specify a name for the data source, such as **mycustomhelpdatasource**.
- **[StorageAccountName]** – Specify the name of the storage account that you created in the Create a storage account section (for example, **mycustomhelpstorage**).
- **[key]** – Specify the access key for your storage account. You can find the key in **Keys** under **Settings** on the left side of the storage account.
- **[JSONStorageContainerName]** – Specify the name of the blob container that you created in the Create a storage account section (for example, **mycustomhelpcontainer**).

6. Select **Send**, and make sure that the value in the **Status** field is **201 Created**.

Next, you will configure the search service so that it has an index of the content for each locale that you want to support.

Create an index

1. In Postman, create a new POST request that has the following parameters:
   - **URL**: `https://[AzureSearchServicename].search.windows.net/indexes?api-version=2017-11-11` (Replace **[AzureSearchServicename]** with the name of your search service.)
   - **Type** (on the **Authorization** tab): **No Auth**
   - **Content-Type** (on the **Headers** tab): **application/json**
   - **api-key** (on the **Headers** tab): The key from your Azure Cognitive Search service
2. On the **Body** tab, paste the following text.

```
{
    "name" : "[IndexName]",
    "fields": [
        { "name": "id", "type": "Edm.String", "key": true,"searchable": true, "filterable": true,
"sortable": true, "facetable": true },
        { "name": "title", "type": "Edm.String", "searchable": true, "filterable": true, "sortable":
true, "facetable": true, "analyzer":"[AnalyzerName]" },
        { "name": "description", "type": "Edm.String", "searchable": true, "filterable": true,
"sortable": true, "facetable": true, "analyzer":"[AnalyzerName]" },
        { "name": "ms_search_form", "type": "Edm.String", "searchable": true, "filterable": true,
"sortable": true, "facetable": true },
        { "name": "ms_search_region", "type": "Edm.String", "searchable": true, "filterable": true,
"sortable": true, "facetable": true },
        { "name": "ms_locale", "type": "Edm.String", "searchable": true, "filterable": true,
"sortable": true, "facetable": true },
        { "name": "metadata_storage_path", "type": "Edm.String", "searchable": true, "filterable":
true, "sortable": true, "facetable": true },
        { "name": "metadata_storage_name", "type": "Edm.String", "searchable": true, "filterable":
true, "sortable": true, "facetable": true },
        { "name": "metadata_storage_content_type", "type": "Edm.String", "searchable": true,
"filterable": false, "sortable": false, "facetable": false }
    ]
}
```

Replace the following parameters with the relevant values:

- **[IndexName]** – Specify the name of the index that should be created, such as **indexenus**.
- **[AnalyzerName]** – Specify the name of the language analyzer that should be used, such as **en.microsoft**.

> **NOTE**
>
> The index is language-specific. The **title** and **description** fields contain translations, and it's important that you set the corresponding language analyzer value. Use an appropriate value, based on the language of the index that you're creating. For a list of language analyzers, see Analyzer List.

3. Select **Send**, and make sure that the **Status** field is set to **201 Created**.
4. If you prepared custom Help content for multiple languages, repeat these steps to create a unique index for each language.

The index isn't an index until it has been processed by an indexer. Think of the table of contents in a reference book. It would not really be useful unless it also lists the page numbers for where to find the various sections in the book. Similarly, the indexer for your search service fills in the index, based on a search. For more information, see Indexers in Azure Cognitive Search.

Create an indexer

1. In Postman, create a new POST request that has the following parameters:
   - **URL**: `https://[AzureSearchServicename].search.windows.net/indexers?api-version=2017-11-11` (Replace **[AzureSearchServicename]** with the name of your search service.)
   - **Type** (on the **Authorization** tab): **No Auth**
   - **Content-Type** (on the **Headers** tab): **application/json**
   - **api-key** (on the **Headers** tab): The key from your Azure Cognitive Search service
2. On the **Body** tab, paste the following text.

```
{
    "name" : "[IndexerName]",
    "dataSourceName" : "[DatasourceName]",
    "targetIndexName" : "[IndexName]",
    "schedule" : { "interval" : "PT10H" },
    "parameters" : { "configuration" : { "parsingMode" : "json" } },
    "fieldMappings" : [
        { "sourceFieldName" : "/title", "targetFieldName" : "title" },
        { "sourceFieldName" : "/ms.search.form", "targetFieldName" : "ms_search_form" },
        { "sourceFieldName" : "/ms.search.region", "targetFieldName" : "ms_search_region" },
        { "sourceFieldName" : "/ms.locale", "targetFieldName" : "ms_locale" },
        { "sourceFieldName" : "/description", "targetFieldName" : "description" }
    ]
}
```

Replace the following parameters with the relevant values:

- **[IndexerName]** – Specify the name of the indexer that should be created, such as **indexerenus**.
- **[DatasourceName]** – Specify the name of the data source that you created, such as **mycustomhelpdatasource**.
- **[IndexName]** – Specify the name of the index that you created, such as **indexenus**.

> **NOTE**
>
> This configuration will set up an indexer that is scheduled to run every 10 hours (**"schedule" : { "interval" : "PT10H" }**). However, you can adjust the interval as appropriate.

3. Select **Send**, and make sure that the **Status** field is set to **201 Created**.
4. If you prepared custom Help content for multiple languages, repeat these steps to create a unique indexer for each index.

> **NOTE**
>
> An index will contain data only after its indexer has run. You might want to manually run the indexer if you're planning to test the index immediately.

> **IMPORTANT**
>
> If you update your content, remember to regenerate the JSON files and upload them to the storage service. If you add content, you can either manually run the indexers or wait for the next scheduled run. Your updated content won't be available in search results until the next time that the indexers are run.

You can optionally use Postman to test the search. For an example that shows how to use Postman for testing, see Search your JSON files.

Next steps

If you completed all the steps in this topic, your Help content has now been uploaded to an Azure web app, and it has been indexed.

The next step is to extend the **Help** pane so that it can detect your content. In that way, when users open the **Help** pane in your Dynamics 365 solution, the in-product **Help** pane will be able to generate context-sensitive links to your Help. For more information, see Connect a custom Help website to the Help pane.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Connect a custom Help website to the Help pane

2/18/2021 • 4 minutes to read • Edit Online

If you deliver custom Help content for a Finance and Operations solution, you can extend the **Help** pane so that it consumes that content. You complete this one-time configuration by using the Finance and Operations development environment in Microsoft Visual Studio. After you've finished, users can select among tabs for task guides, Microsoft Help content, and your Help content.

The process for connecting your custom Help website to the in-product **Help** pane involves the following steps:

1. Extend the **Help** pane in Visual Studio.
2. Assign an index to a language.
3. Customize language fallback.

> **IMPORTANT**
> The procedures that follow require the development tools for Finance and Operations apps in Visual Studio. For more information, see Development tools in Visual Studio.

Extend the Help pane and assign the custom Help indexes to languages

The **Help Pane extension** folder of the Custom Help Toolkit contains the **AzureSearchCustomHelp** solution that you can open in the Finance and Operations development environment. That folder also contains the **HelppaneOption.axpp** project that you can then import into the solution in Visual Studio.

Extend the Help pane

1. In the Finance and Operations development environment, open the **AzureSearchCustomHelp.sln** solution.
2. On the **Dynamics 365** menu, select **Import project**.
3. In the **File name** field, specify the path of the **HelppaneOption.axpp** project, and then select **OK** to complete the import process. Update the references so that no references are missing.
4. In the **HelppaneMacro** file, update the values of the following parameters:
   - **[WebAppName]** – Specify the name of the web app that you created in Create a web app. For example, specify **MyCustomHelpWebApp**.
   - **Admin key value** – Specify the admin key for the Azure Cognitive Search service. You can find the key in **Access keys** under **Settings** on the left of the search service in the Azure portal.
   - **[SearchServiceName]** – Specify the name of the search service that you created in Create a search service. For example, specify **mycustomhelpsearch**.

   The following example shows the content of the HelppaneMacro file.

```
#define.webApp('http://[WebAppName].azurewebsites.net/')
#define.queryApiKey('Admin key value')
#define.defaultstring('dashboard')
#define.searchservicename('[SearchServiceName]')
#define.CustomResultError('error')
#define.CustomTabPage('CustomTabPage')
#define.CustomHelp('Custom Help')
#define.CustomTitle('CustomTitle')
#define.htm('html')
```

5. Optional: If you want to change any of the user interface (UI) strings that appear in the **Help** pane, edit the **Customhelppane.en-US.label.txt** file.

Next, you must specify the language that the search index for your custom Help is intended for.

Assign a custom index to a language

1. Open the **Language.config** file in the solution.
2. In the list, find the language of the index, and specify an index name by using the **index=""**, **parentindex=""**, or **ultimateindex=""** key.

   For example, you created search indexes for English (United States) and German (Austria), and you named them **myenusindex** and **mydeatindex**, respectively. In this case, here is what your entries will look like.

   ```
   <add language="en-US" ultimateindex="myenusindex" />
   <add language="de-AT" parentlanguage="de" index="mydeatindex" />
   ```

3. Optional: Customize language fallback for your index, as described in the next section.
4. Build the **AzureSearchCustomHelp** solution.

The result is a model that you upload to the Asset library of the customer project or the solution project in Microsoft Dynamics Lifecycle Services (LCS).

Customize language fallback

Language fallback means that the **Help** pane runs a search in additional languages if the intended language either doesn't return a result or doesn't exist.

> **NOTE**
> A custom index must be available for the additional languages.

The search and fallback order have the following order of priority:

1. The language that is set in the client (for example, **de-AT**)
2. The language that is defined in the **parentlanguage** attribute for that language (for example, **<add language="de-AT" parentlanguage="de" index="mydeindex" />**)
3. The language that the **ultimateindex** attribute is set for (for example, **<add language="en-US" ultimateindex="myenusindex" />**)

> **IMPORTANT**
> If the **parentlanguage** attribute is set, there must be a corresponding **parentindex** key.

The following scenario is valid, because **language="de"** has **parentindex="indexde"**, and both **de-DE** and **de-AT** are descendants of **de**.

```
<add language="de" parentindex="indexde"/>
<add language="de-DE" parentlanguage="de" index=""/>
<add language="de-AT" parentlanguage="de-DE" index="indexdeat"/>
```

For more information about languages, see Languages, translations, and adaptations.

The following sections provide sample configurations.

Help content for one locale

In this configuration, you have Help content only for English (United States). Regardless of the locale that clients are set to, they will show the Help content in English (United States).

```
<add language="en-US" ulitmateindex="indexenus"/>
```

Help content for multiple locales

In this configuration, you have Help content for French, German, and English (United States). Clients that are set to the **de** locale will show the Help content in German, clients that are set to the **fr** locale will show the content in French, and clients that are set to any other locale will show the content in English (United States).

```
<add language="en-US" ulitmateindex="indexenus"/>
<add language="fr" parentindex="indexfr"/>
<add language="de" parentindex="indexde"/>
```

If clients are set to the **de** or **fr** locale, but no results are found in the German or French content, respectively, results will be shown in English (United States), if content is available in that language.

Help content that uses parent locales

In this configuration, you have Help content for German, German (Austria), and English (United States). For example, you have several topics that are related specifically to features for Austria, but topics in German can be used otherwise.

```
<add language="en-US" ulitmateindex="indexenus"/>
<add language="de" parentindex="indexde"/>
<add language="de-AT" parentlanguage="de" index="indexdeat"/>
```

If the client is set to the **de-AT** locale, but no results are found in the German (Austria) content, results will be shown in German and English (United States), if content is available in those languages.

Custom Help Toolkit

2/18/2021 • 2 minutes to read • Edit Online

Microsoft has published a GitHub repository (repo) that includes scripts and tools that can help you prepare context-sensitive Help for customized Finance and Operations solutions. This context-sensitive Help can be accessed from the in-product **Help** pane.

Tools in the toolkit

The Custom Help Toolkit is available at https://github.com/microsoft/dynamics365f-o-custom-help. The repo contains the following tools and the source code for those tools:

- The **HtmlFromRepoGenerator** tool

  For more information, see Custom Help Toolkit: The HtmlFromRepoGenerator tool.

- The **ConvertHtmlToJson** tool

  For more information, see Custom Help Toolkit: The ConvertHtmlToJson tool.

- The **HtmlLocaleChanger** tool

  For more information, see Custom Help Toolkit: The HtmlLocaleChanger tool.

- The **Help Pane extension** Microsoft Visual Studio project

  For more information, see Connect a custom Help website to the Help pane.

- Dynamics AX 2012 metadata scripts

  For more information, see Convert Dynamics AX custom Help for use in Dynamics 365.

> **NOTE**
>
> The first version of the toolkit is available as a release in the GitHub repo.

Custom Help Toolkit: The HtmlFromRepoGenerator tool

2/18/2021 • 5 minutes to read • Edit Online

The Custom Help Toolkit includes the **HtmlFromRepoGenerator** tool, which gets Microsoft content in Markdown files and converts it to HTML files. You can then deploy the HTML files to a website.

Use the HtmlFromRepoGenerator tool to get Markdown files and generate HTML files

The **HtmlFromRepoGenerator** tool provides functionality that supports the creation of custom Help that is based on source files from Microsoft. You can use the tool to perform these tasks:

- Clone a Microsoft documentation repository (repo).
- Remove developer and admin content from your clone of the Microsoft repo.
- Update links to files that are no longer present in the clone.
- Update the value of the **ms.locale** property so that it matches the language options that are supported by the Finance and Operations client.

  The language descriptors that the client uses differ from the language descriptors that are used in the corresponding GitHub repos. Before localized custom Help can be called, the language descriptors in the source content must be changed so that they match the client's languages. For more information, see Language and locale descriptors in the product and in Help.
- Generate HTML files that can be used to publish content.

  The HTML files will be generated in the **d365F-O** subfolder. The files are generated based on style sheets and templates that are part of the tool. For more information, see the Modifying the styling of the generated HTML files section of this topic.
- Compare a localized Microsoft repo to the en-US repo to identify differences and update links accordingly.

In the first version of the Custom Help Toolkit, this tool was named ConsoleApp.

Syntax

Here is the syntax for running HtmlFromRepoGenerator.exe.

```
HtmlFromRepoGenerator.exe --Json <Articles/> --Out <path> --ExternalText <text> [--DoNotClone <true|false>]
[--Repo <URL>] [--RemoveGitFolder <true|false>] [--ReplaceUrl <URL>] [--LogsDir <.\logs>] [--EnRepo <URL>]
[--EnOut <path>] [--Lng <language code>] [--Rtl] [--?[--]]
```

Here is an explanation of the parameters.

PARAMETER	DESCRIPTION
Json	Specify a relative path for the location of the **docfx.json** file. In Microsoft documentation repos, this location is typically **articles/**.

PARAMETER	DESCRIPTION
Out	Specify the folder where your existing cloned repo exists, or the folder to clone the repo to. If you run the **HtmlFromRepoGenerator** tool to clone a repo, this folder must not already exist. Use the language name as the folder name, as described in Language and locale descriptors in the product and in Help.
ExternalText	Specify text that should be added to the updated links if the **HtmlFromRepoGenerator** tool must replace the original links.
DoNotClone	Set this parameter when you run the tool against a previously cloned repo.
Repo	Specify the repo URL. This parameter is optional if you run the tool against a previously cloned repo. Examples of URLs for Microsoft documentation repos include `https://github.com/MicrosoftDocs/Dynamics-365-Unified-Operations-public` for English (United States) and `https://github.com/MicrosoftDocs/Dynamics-365-Operations.de-de` for German (Germany).
RemoveGitFolder	Specify whether the **.git** folder should be removed.
ReplaceUrl	Specify the URL that should replace links between files when the target files aren't present. This parameter is intended to be used to turn relative links into absolute links.
LogsDir	Specify the folder to save logs files to.

The following additional parameters are used when the tool is run against the localized Microsoft documentation repos.

PARAMETER	DESCRIPTION
EnRepo	Specify the URL of the en-US repo. This parameter is optional if you run the tool against a previously cloned repo. The URL of the Microsoft documentation repo for English (United States) is `https://github.com/MicrosoftDocs/Dynamics-365-Unified-Operations-public` .
EnOut	Specify the folder where the en-US repo exists, or the folder to clone it to. If you run the tool against a previously cloned repo, this folder must not already exist.
Lng	Specify the language value that should be used for **ms.locale** metadata in the generated HTML files. The value must correspond to the value that is specified in the language settings of the Finance and Operations client. If this parameter isn't set, the tool uses **en-US**. For more information, see Language and locale descriptors in the product and in Help.

PARAMETER	DESCRIPTION
Rtl	Include this parameter if the language uses right-to-left (RTL) formatting. Examples of RTL languages include Arabic and Hebrew.

Examples

> **NOTE**
> Because the Microsoft repos contain many files, the process takes several minutes. If you run the tool against multiple localized repos, the process takes longer.

The following example clones the en-US repo and generates HTML files for en-US.

```
HtmlFromRepoGenerator.exe --json articles/ --out "D:\D365-Operations\en-US" --repo
"https://github.com/MicrosoftDocs/Dynamics-365-unified-Operations-public" --externalText "(This is an
external link)" --replaceUrl "https://docs.microsoft.com/en-us/dynamics365/supply-chain" --LogsDir D:\D365-
Operations\logs\en-US
```

The following example uses a previously cloned en-US repo and generates HTML files for en-US.

```
HtmlFromRepoGenerator.exe --json articles/ --out "D:\D365-Operations\en-US" --externalText "(This is an
external link)" --replaceUrl "https://docs.microsoft.com/en-us/dynamics365/supply-chain" --LogsDir D:\D365-
Operations\logs\en-US
```

The following example clones the de-DE and en-US repos, and generates HTML files for de.

```
HtmlFromRepoGenerator.exe --json articles/ --out "D:\D365-Operations\de" --repo
"https://github.com/MicrosoftDocs/Dynamics-365-Operations.de-de" --externalText "(This is an external link)"
--EnRepo "https://github.com/MicrosoftDocs/Dynamics-365-unified-Operations-public" --EnOut "D:\D365-
Operations\en-us" --replaceUrl "https://docs.microsoft.com/de-de/dynamics365/supply-chain" --lng "de" --
LogsDir D:\D365-Operations\logs\de
```

The following example uses the existing de-DE and en-US repos, and generates HTML files for de. If you use the existing de-DE repo, make sure that it's up to date.

```
HtmlFromRepoGenerator.exe --json articles/ --out "D:\D365-Operations\de" --DoNotClone --externalText "(This
is an external link)" --enOut "D:\D365-Operations\en-us" --replaceUrl "https://docs.microsoft.com/de-
de/dynamics365/supply-chain" --lng "de" --LogsDir D:\D365-Operations\logs\de
```

> **IMPORTANT**
> Because the **HtmlFromRepoGenerator** tool changes links during processing, don't run HtmlFromRepoGenerator.exe more than one time against a previously cloned repo. If it's run more than one time against the same content, links will be incorrect. If you want to rerun HtmlFromRepoGenerator.exe, either use the **HtmlFromRepoGenerator** tool to create a new clone of the repo, or revert all local changes that have been made to your existing clone.

Modifying the styling of the generated HTML files

The HTML files that the **HtmlFromRepoGenerator** tool generates are based on a set of predefined templates. In most cases, you can edit the style sheets in the **d365F-O\styles** folder to change the appearance of your

content.

For advanced scenarios, you can change the templates that the **HtmlFromRepoGenerator** tool uses. The source files are included in the **SourceCode** folder in the GitHub repo. The templates are in the **SourceCode\HtmlFromRepoGenerator\HtmlFromRepoGenerator\HtmlFromRepoGenerator\Resources** subfolder.

> **NOTE**
> If you change the templates, you must rebuild HtmlFromRepoGenerator.exe.

For more information, see Introduction to DocFX Template System.

Convert Dynamics AX custom Help for use in Dynamics 365

Custom Help Toolkit: The ConvertHtmlToJson tool

2/18/2021 • 2 minutes to read • Edit Online

The Custom Help Toolkit includes the **ConvertHtmlToJson** tool, which converts HTML files to JavaScript Object Notation (JSON) files. The search service uses the JSON files to index Help content.

Use the ConvertHtmlToJson tool to generate JSON files

The **ConvertHtmlToJson** tool transforms HTML files into JSON files. You can then add the JSON files to the Microsoft Azure Search service, which will generate context-sensitive links to your Help content.

The JSON files include metadata that the indexer uses to identify the form and language that the target Help page is intended for.

Here is the syntax for running ConvertHtmlToJson.exe.

```
ConvertHtmlToJson.exe --h <path> -j <path> --v <true|false>
```

Here is an explanation of the parameters.

PARAMETER	DESCRIPTION
h	Specify the path of the HTML files to process.
j	Specify the folder to save the JSON files to. The specified folder must already exist.
v	Set this parameter to **true** to turn on verbose logging. Otherwise, set it to **false**.

Example

The following example generates JSON files without verbose logging.

```
ConvertHtmlToJson.exe --h D:\D365-Operations\d365F-O\supply-chain\de -j D:\D365-Operations\json\supply-chain\de
```

Language and locale descriptors in the product and in Help
Convert Dynamics AX custom Help for use in Dynamics 365

Custom Help Toolkit: The HtmlLocaleChanger tool

2/18/2021 • 2 minutes to read • Edit Online

The Custom Help Toolkit includes the **HtmlLocaleChanger** tool, which can process HTML files that are generated by the HtmlFromRepoGenerator tool tool.

Use the HtmlLocaleChanger tool to align locales

The **HtmlLocaleChanger** tool can update your HTML files by setting a new value for the **ms.locale** property. For example, you have HTML files for German (Germany), and you want to make the same content available in German (Austria). In this case, you can run the tool to change the setting from **ms.locale: de-de** to **ms.locale:de-at**.

Here is the syntax for running HtmlLocaleChanger.exe.

```
HtmlLocaleChanger.exe --h <path> --l <locale> --v <true|false>
```

Here is an explanation of the parameters.

PARAMETER	DESCRIPTION
h	Specify the path of the HTML files to process.
l	Specify the new locale for the HTML files.
v	Set this parameter to **true** to turn on verbose logging. Otherwise, set it to **false**.

Example

The following example changes the locale to **de-at** and turns on verbose logging.

```
HtmlLocaleChanger.exe --h D:\D365-Operations\d365F-O\supply-chain\de --l de-at --v
```

Convert Dynamics AX custom Help for use in Dynamics 365

Convert Dynamics AX custom Help for use in Dynamics 365

2/18/2021 • 2 minutes to read • Edit Online

If you have existing content from Microsoft Dynamics AX 2012, you can reuse it for Dynamics 365 Finance, Dynamics 365 Supply Chain Management, and Dynamics 365 Commerce. However, you must first transform the HTML files so that they can be used in the custom Help environment.

Converting AX 2012 content

The Microsoft Custom Help Toolkit includes a Windows PowerShell script, **run_ax2012.ps1**, that can transform AX 2012 HTML files so that they can be used in the custom Help environment. The script makes the following changes to the AX 2012 HTML files:

- Replace the **Microsoft.Help.F1** metadata name with **ms.search.form**.
- Replace the **Title** metadata name with **title**.
- Change the file name extension from **.htm** to **.html**.
- Add the following metadata.

```
<meta name="ms.search.region" content="Global" />
<meta name="ms.search.scope" content="Operations, Core" />
<meta name="ms.dyn365.ops.version" content="AX 7.0.0" />
<meta name="ms.search.validFrom" content="2016-05-31" />
<meta name="ms.search.industry" content="cross" />
```

Running the script

You can run the following command from a Command Prompt window, or you can run the script directly in Windows PowerShell.

```
PowerShell.exe -File run_ax2012.ps1 "Original file location" "New file location"
```

The following metadata is currently used, or it's reserved so that it can be used during indexing.

```
<meta name="title" content="Title of file" />
<meta name="ms.locale" content="locale" />
<meta name="ms.search.form" content="FormAOTName" />
<meta name="description" content="Description of file" />
<meta name="ms.search.region" content="Global" />
<meta name="ms.search.scope" content="Operations, Core" />
<meta name="ms.dyn365.ops.version" content="AX 7.0.0" />
<meta name="ms.search.validFrom" content="2016-05-31" />
<meta name="ms.search.industry" content="cross" />
```

For a description of the required metadata, see Metadata requirements for custom Help topics.

Moving to Markdown

To convert your existing content to Markdown, you can use various third-party tools, such as PanDoc and the

Writage plug-in for Word.

After you've converted your content to Markdown, you can use open-source tools such as DocFx to generate content for your website. In general, by working in Markdown, you gain access to a wide range of open-source tools. For more information, see Extend, customize, and collaborate on the Help.

Language and locale descriptors in the product and in Help

2/18/2021 • 2 minutes to read • Edit Online

The client that Finance and Operations apps use supports multiple languages and locales. To add custom Help content for one or more locales to the in-product **Help** pane, you must make sure that both the following conditions are met:

- The value of the **ms.locale** property in each HTML file matches the locale of the content.

  For example, the German (Germany) content must have a setting of **ms.locale: de-de**.

- On the custom Help website, the content is in a folder has the same name as the locale.

  For example, the German (Germany) content must be in a folder that is named **de-de**.

For more information, see Custom Help overview and Deploy custom Help to Azure.

Languages and descriptors

The following table maps the language names between the Finance and Operations client and the GitHub repositories (repos) that contain translated Microsoft Help content.

LANGUAGE/LOCALE IN THE CLIENT	LANGUAGE/REGION NAME	NAME OF THE GITHUB REPO
ar	Arabic (Saudi Arabia)	Dynamics-365-Operations.ar-sa
ar-ae	Arabic (United Arab Emirates)	Dynamics-365-Operations.ar-ae
cs	Czech	Dynamics-365-Operations.cs-cz
da	Danish	Dynamics-365-Operations.da-dk
de	German (Germany)	Dynamics-365-Operations.de-de
de-at	German (Austria)	Dynamics-365-Operations.de-de
de-ch	German (Switzerland)	Dynamics-365-Operations.de-de
en-au	English (Australia)	Dynamics-365-Unified-Operations-Public
en-ca	English (Canada)	Dynamics-365-Unified-Operations-Public
en-gb	English (United Kingdom)	Dynamics-365-Unified-Operations-Public
en-ie	English (Ireland)	Dynamics-365-Unified-Operations-Public

LANGUAGE/LOCALE IN THE CLIENT	LANGUAGE/REGION NAME	NAME OF THE GITHUB REPO
en-in	English (India)	Dynamics-365-Unified-Operations-Public
en-my	English (Malaysia)	Dynamics-365-Unified-Operations-Public
en-nz	English (New Zealand)	Dynamics-365-Unified-Operations-Public
en-sg	English (Singapore)	Dynamics-365-Unified-Operations-Public
en-us	English (US)	Dynamics-365-Unified-Operations-Public
en-za	English (South Africa)	Dynamics-365-Unified-Operations-Public
es	Spanish (Spain)	Dynamics-365-Operations.es-es
es-mx	Spanish (Mexico)	Dynamics-365-Operations.es-es
et	Estonian	Dynamics-365-Operations.et-ee
fi	Finnish	Dynamics-365-Operations.fi-fi
fr	French (France)	Dynamics-365-Operations.fr-fr
fr-be	French (Belgium)	Dynamics-365-Operations.fr-fr
fr-ca	French (Canada)	Dynamics-365-Operations.fr-fr
fr-ch	French (Switzerland)	Dynamics-365-Operations.fr-fr
hu	Hungarian	Dynamics-365-Operations.hu-hu
is	Icelandic	Dynamics-365-Operations.is-is
it	Italian	Dynamics-365-Operations.it-it
it-ch	Italian (Switzerland)	Dynamics-365-Operations.it-it
ja	Japanese	Dynamics-365-Operations.ja-jp
lt	Lithuanian	Dynamics-365-Operations.lt-lt
lv	Latvian	Dynamics-365-Operations.lv-lv
nb-no	Norwegian Bokmål	Dynamics-365-Operations.nb-no
nl	Dutch (Netherlands)	Dynamics-365-Operations.nl-nl

LANGUAGE/LOCALE IN THE CLIENT	LANGUAGE/REGION NAME	NAME OF THE GITHUB REPO
nl-be	Dutch (Belgium)	Dynamics-365-Operations.nl-nl
pl	Polish	Dynamics-365-Operations.pl-pl
pt-br	Portuguese (Brazil)	Dynamics-365-Operations.pt-br
ru	Russian	Dynamics-365-Operations.ru-ru
sv	Swedish	Dynamics-365-Operations.sv-se
th	Thai	Dynamics-365-Operations.th-th
tr	Turkish	Dynamics-365-Operations.tr-tr
zh-hans	Chinese	Dynamics-365-Operations.zh-cn

Languages, translations, and adaptations

Microsoft teams create content in English (United States). That content is then translated into several languages, and the translated content is made available in a public GitHub repo for each language.

To maximize reuse of translations, translation services treat some languages as variants of another language. For example, German for Austria and German for Germany are considered so closely related that they are treated as variants of each other. Therefore, you can use the files in the Dynamics-365-Operations.de-de GitHub repo as a starting point for both German (Germany) content and German (Austria) content.

When you extend the in-product **Help** pane, you must assign indexes for the relevant locales. For more information, see Customize language fallback.

Custom Help overview
Custom Help Toolkit

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Extend, customize, and collaborate on the Help

2/18/2021 • 5 minutes to read • Edit Online

The source files for the Microsoft Help for Finance and Operations apps are available in public GitHub repositories (repos). Any solution provider can easily extend and customize the content for specific solutions. This topic explains how to work with the GitHub repos and Markdown files.

For information about how to create Markdown files in GitHub repos, see the Docs contributor guide. For information about how to deploy custom Help, see Custom Help overview.

Contribute to the content

One benefit of GitHub is that you can contribute to the core content that the Microsoft team provides in the MicrosoftDocs/Dynamics-365-Unified-Operations-public repo. For example, you have a new topic that you think will be helpful to other users, or you have a correction to an existing topic. If you want to contribute to the Dynamics-365-Unified-Operations-public repo, you can create a *pull request* from your repo to the Dynamics-365-Unified-Operations-public repo. The Microsoft team will then review the request and include your changes as appropriate.

You can also contribute and make edits to the existing documentation. To get started, select the **Edit** button (pencil symbol) in a topic. The following video shows how you can contribute to the Microsoft documentation.

> **NOTE**
> Microsoft currently accepts pull requests only to the Dynamics-365-Unified-Operations-public repo, not to the language-specific repos. If you have feedback about translations, you can report a GitHub issue in the relevant repo.

Extend and customize Microsoft source content from GitHub repos

Microsoft uses separate repos in GitHub for the source content and for each language that Microsoft translates content into. The Dynamics-365-Unified-Operations-public repo contains the source content in English (United States). If you want to access the content in other languages, the names follow the pattern **Dynamics-365-Operations.<language>-<country>**. For example, the version for German (Germany) is named Dynamics-365-Operations.de-de.

When Microsoft publishes an update to the content, the *live* branch in the corresponding GitHub repo is updated. The source repo is updated weekly. However, the related language-specific repos are updated less often. The frequency depends on when new translations are made available. If you fork one of the Microsoft repos, you can choose to update your fork with updates from the Microsoft repo on a monthly basis or less often, depending on your preferred work processes. The GitHub platform and tooling will help you manage any potential merge conflicts if you change files that Microsoft has also changed. For more information, see Set up Git repository locally for documentation in the Docs authoring guide and Fork a repo in the Help for GitHub.

> **TIP**
> If you just want to get the Microsoft content as it is, you don't have to be familiar with GitHub. For more information, see the Get the content without a GitHub account section of this topic. However, if you want to extend or customize the Microsoft content, we recommend that you join Microsoft on GitHub.

Get started with GitHub

To join Microsoft in the world of GitHub and Markdown, you must be familiar with some new terminology and tools. The following list outlines the main steps, but you can find additional content, tools, and ideas in the GitHub documentation and other forums.

1. Sign up for GitHub.

   For more information, see GitHub account setup and Install content authoring tools in the Docs contributor guide.

2. Fork the appropriate repo.

   To extend and customize Microsoft content for a custom Help solution, you must create a fork of the repo. If you want to customize Microsoft content in Markdown format, we recommend that you manually fork the relevant repo and use your favorite Markdown editor. For more information, see Set up Git repository locally for documentation and Git and GitHub essentials for Docs in the Docs contributor guide.

   > **TIP**
   > You aren't required to make your GitHub repos public. When you fork a public repo, in the settings for the new repo, you can specify whether the repo is public, private, or available only to specific GitHub accounts.

Markdown format

The syntax that is used to format text for topics is named Markdig Flavored Markdown. This syntax complies with CommonMark. To learn more about how to work with Markdown, see Getting started with writing and formatting on GitHub.

You can convert content from Microsoft Word to Markdown by using open-source tools or other tools. In this way, you can easily recycle content.

Get updates from Microsoft

Microsoft makes frequent changes to the content, and those changes show up in the public GitHub repos. The base repo, MicrosoftDocs/Dynamics-365-Unified-Operations-public, is updated weekly. However, you can choose to get updates monthly, twice a year, or once a year, for example. The translation repos are updated less frequently, so you might want a monthly schedule or less frequent updates, as appropriate.

When you decide that it's time to get the latest version of the content from Microsoft, you can use the Git command line or GitHub Desktop. The Help for GitHub provides an example that shows how this process works in GitBash. In GitHub Desktop, you use the **Merge into current branch** command to pull changes from the origin into your fork.

If your solution is available in more than one country or region, you will probably want to make the content available in multiple languages. Although Microsoft has a GitHub repo for each supported language, the configuration files are available only in the English (United States) version of the base repo, MicrosoftDocs/Dynamics-365-Unified-Operations-public. You can use the HtmlFromRepoGenerator tool from the Custom Help Toolkit to get the files.

Because the Microsoft repos are public, you don't have to have a valid GitHub account to get the content. However, we recommend that, at a minimum, your organization have a system account that has access to GitHub.

For more information, see Custom Help Toolkit.

Get the content without a GitHub account

If you don't want to collaborate with Microsoft on the content, you can get the latest version of the content from

GitHub even if you don't have a GitHub account. For example, you can just clone the relevant GitHub repo. A GitHub account isn't required to clone a repo. Because the Microsoft repos are public, anyone can always access them.

Translate the content

You can use the Dynamics 365 Translation Service (DTS) to translate your own or the Microsoft-provided content into other languages. The service is hosted in Microsoft Dynamics Lifecycle Services (LCS), and currently supports translation of content in Word documents and HTML files. For more information, see Translate documentation files.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Develop and customize home page

2/18/2021 • 3 minutes to read • Edit Online

This topic provides links to topics about development.

Overview

The Finance and Operations applications represent the next-generation enterprise resource planning (ERP) offering from Microsoft. The apps enable the entire ERP application suite as a cloud-based solution, for both public and private clouds, as well as on-premises. The apps leverage the speed, simplicity, and cost-effectiveness of working in the cloud, while building on the latest technology from Microsoft. The development experience includes:

- Development tools that are decoupled from any running environment. You develop against local, XML-based files, not the online database.
- Microsoft Visual Studio is the development environment. The Visual Studio environment is customized to provide you with a smooth and familiar experience.
- The X++ compiler generates Common Intermediate Language (CIL) for all features. CIL is the same intermediate language used by other .NET-based (managed) languages, such as the C# programming language.
- You can leverage the browser-based client and the design patterns for forms to provide an improved end-user experience.
- The Application Lifecycle Model (ALM) supports build automation, test automation, and deployment of models to the cloud.

Architecture

- Application stack and server architecture

Getting started

- Get evaluation copies
- Sign up for preview subscriptions

Insider tips on development

Application stack and server architecture

2/18/2021 • 4 minutes to read • Edit Online

The application stack is divided into platform models and application-specific models. The platform models are Application Platform, Application Foundation, and Test Essentials. There are many application-specific models. Some examples are Application Suite, Ledger, Retail, and Case Management.

Overview

The application stack and server architecture align with three key pillars:

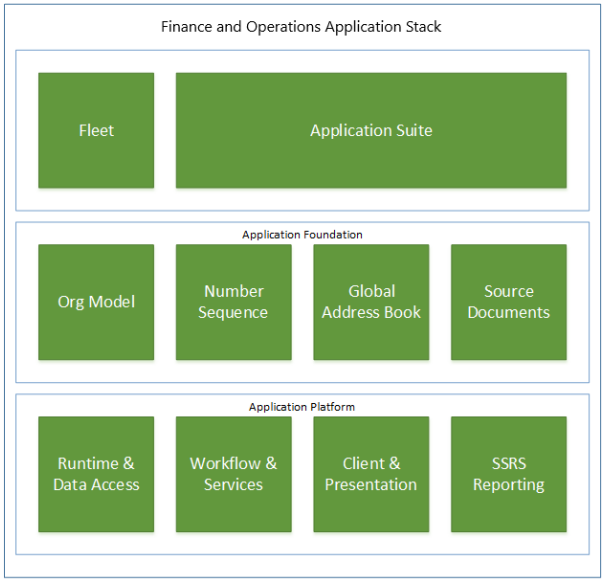
- New client
- Cloud readiness
- New development stack

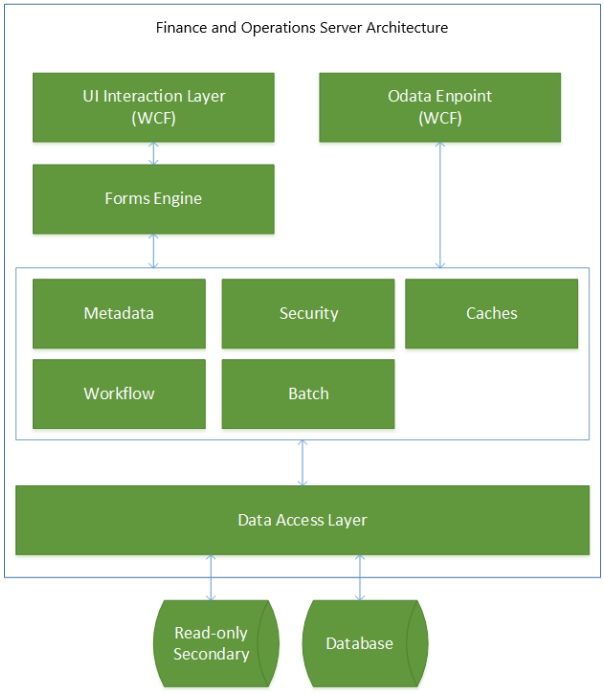
The application stack is divided into several models: Application Platform, Application Foundation, Test Essentials, and the application suites. The separation enables new application development on the base foundation models, just as the Fleet Management sample application has been developed. Note the following important points about the changes in the server architecture:

- The services endpoint on the server is now responsible for returning all form and control metadata and data to the browser-based client. There is no longer any remote procedure call (RPC)-based communication with the server. The form objects still run on the server, and rendering has been optimized for browsers and other clients through server and client-side (browser) investments.
- The server, including the application code base, is deployed to an Internet Information Services (IIS) web application. In the cloud, it's deployed to Microsoft Azure infrastructure as a service (IaaS) virtual machines (VMs).
- It is hosted on Azure and is available for access through the Internet. A user can use a combination of clients and credentials to access it. The recommended primary identity provider is OrgID, and the store for the identity is Azure Active Directory (Azure AD). The security subsystem uses the same AuthZ semantics for users and roles.
- Two types of clients must be considered for access in the cloud: active clients and passive clients.
    - Active clients can programmatically initiate actions based on responses from the server. An active client doesn't rely on HTTP redirects for authentication. A smart/rich client is an example of an active client.
    - Passive clients can't programmatically initiate actions based on responses from the server. A passive client relies on HTTP redirects for authentication. A web browser is an example of a passive client.

  Currently, Access Control Service (ACS) doesn't support a mechanism for non-interactive authentication. Therefore, even when active clients try to authenticate by using ACS, they must use passive client authentication, in which a browser dialog box prompts the user to enter their credentials.
- A completely revamped metadata subsystem incorporates the new compiler and Microsoft Visual Studio–based development model. The model store is represented as a set of folders and XML artifacts that are organized by model. The model elements, such as tables, forms, and classes, are represented by an XML file that contains both metadata and source code.

The left side of the following diagram shows how the application stack has been split into distinct models. The right side shows how the key components are stacked in the server.





The Finance and Operations applications use an entry point security model. A form allows read-only access if the menu item used for navigation to that form has only Read Permissions. However, navigation to that same form through another menu item that provides Create Permissions, Delete Permissions, or Update Permissions allows write operations on the form. This behavior simplifies the development experience, because developers can specify the behavior for a form through a given entry point.

Cloud architecture

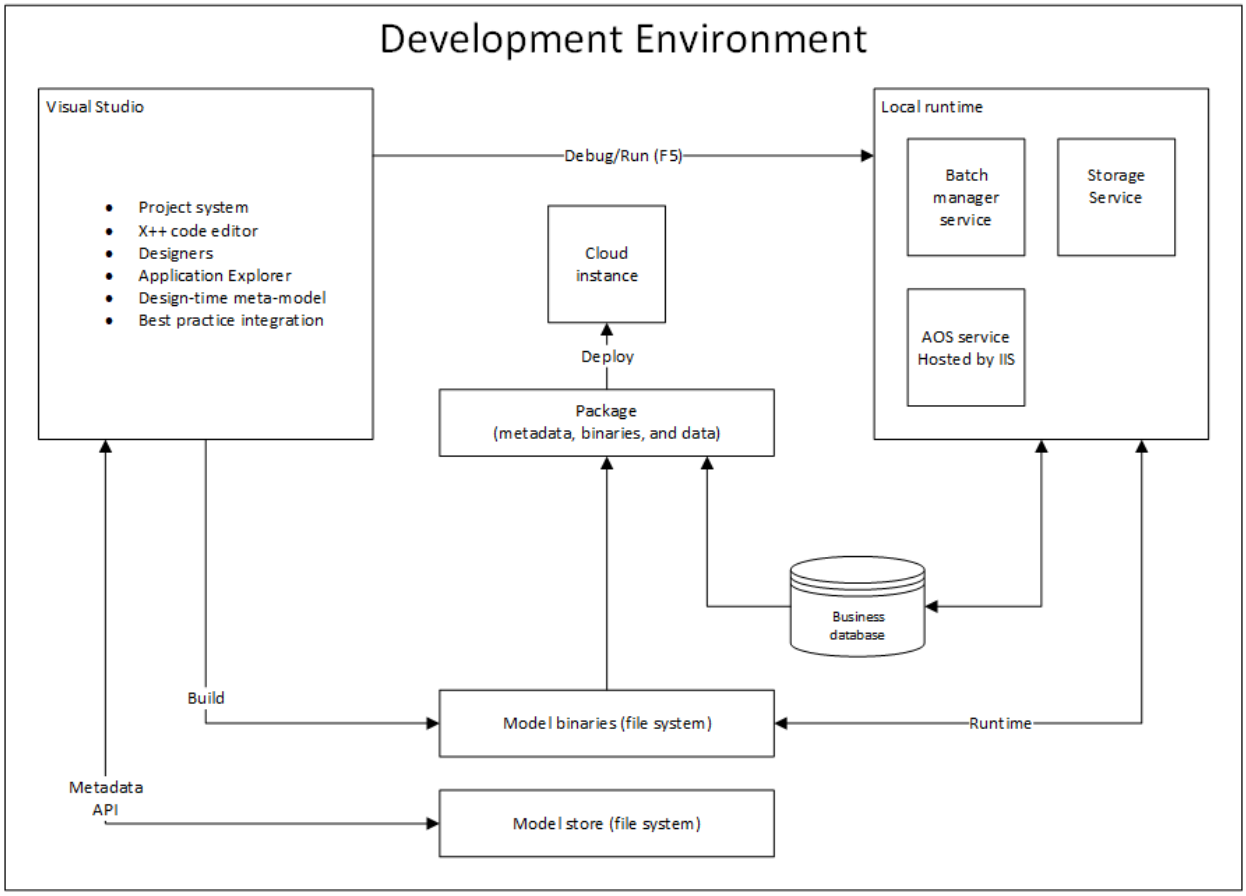
The cloud architecture includes services that automate software deployment and provisioning, operational monitoring and reporting, and seamless application lifecycle management. The cloud architecture consists of three main conceptual areas:

- **Lifecycle Services (LCS)** – LCS is a multi-tenant shared service that enables a wide range of lifecycle-related capabilities. Capabilities that are specific to this release include software development, customer provisioning, service level agreement (SLA) monitoring, and reporting capabilities.
- **Finance and Operations** – The VM instances are deployed through LCS to your Azure subscription. Various topologies are available: demo, development/test, and high-availability production topologies.
- **Shared Microsoft services** – A Finance and Operations application uses several Microsoft services to enable a "One Microsoft" solution where customers can manage a single sign-in, subscription management, and billing relationship with Microsoft across Finance and Operations applications, Microsoft 365, and other online services.

Many features of the Azure platform are used, such as Microsoft Azure Storage, networking, monitoring, and SQL Azure, to name a few. Shared services put into operation and orchestrate the application lifecycle of the environments for participants. Together, Azure functionality and LCS will offer a robust cloud service.

Development environment

The architecture of the development environment resembles the architecture of the cloud instance. It also includes the software development kit (SDK), which consists of the Visual Studio development tools and other components. Source control through Team Foundation Server or Visual Studio Online enables multiple-developer scenarios, where each developer uses a separate development environment. Deployment packages can be compiled and generated on a development environment and deployed to cloud instances by using LCS. The following diagram shows how the key components interact in a development environment.



NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Get evaluation copies

2/18/2021 • 2 minutes to read • Edit Online

A public preview is available. You can sign up and deploy a cloud instance of the latest build. This public preview available through Microsoft Dynamics Lifecycle Services (LCS). These links provide more information about how to download and use the public preview:

- Sign up for preview subscriptions
- Service update availability
- Partner Trial
- How can I setup a solution trial instance in Azure with my customization and demo data?
- How do I login to the new AX as a demo user persona?

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Sign up for preview subscriptions

2/18/2021 • 7 minutes to read • Edit Online

This topic explains how to subscribe to the preview/partner offer and deploy an environment. The subscription that you create gives you a Microsoft Online Services test tenant and a Microsoft Dynamics Lifecycle Services (LCS) project where you can deploy an environment. This topic will also help you set up additional users in your Microsoft Online Services tenant and gain experience with service administration capabilities. Here are the skills that you will learn:

- Subscribe, and create a new Microsoft Online test tenant.
- Navigate to LCS projects.
- Use various features of LCS.
- Add users to Microsoft Azure Active Directory (Azure AD) and the client.
- View resources in your subscription email.

Key terms

- **Microsoft Online Services tenant** – A tenant is the group of all subscriptions and users for your organization. The tenant is created at the same time as your first subscription in Microsoft Online Services.
- **Subscription** – A subscription gives you an online cloud environment and experience. It also lets you see how customizations that you develop can be deployed to the cloud.
- **Microsoft Azure Active Directory** – The cloud environment includes Azure AD. Azure AD helps you manage users, groups, security roles, and licenses for online applications, much as you manage them for on-premise environments.
- **Users** – Users of the services that your organization has subscribed to are managed in Azure AD. Any users in your tenant can be added and assigned to security roles.
- **Developers and administrators** – Developers and administrators are users who also have access to LCS that lets them manage projects and environments. These users are also end users.
- **Organizational account** – Users receive Azure AD credentials. These credentials are separate from other desktop or corporate credentials. The Azure AD credentials are used to sign in to Microsoft 365 and other Microsoft cloud services. Users sign in by using their organizational account.

  > **IMPORTANT**
  > For this release, we ask that you not use any existing credentials that are associated with other online services, such as Microsoft 365 or Microsoft Dynamics CRM Online.

- **Microsoft account** – Microsoft accounts were formerly known as Passport accounts or Windows Live ID accounts. Currently, Microsoft accounts can't be used with Finance and Operations applications, Microsoft Dynamics 365 Commerce, or other Microsoft Online Services. However, Microsoft accounts are still required for Microsoft Connect and other Microsoft Business Solutions sites, such as CustomerSource, PartnerSource, Information Source, and Microsoft Dynamics Community. You will continue to use your Microsoft account to access these services.
- **Microsoft 365 admin center** – Microsoft 365 admin center is the subscription management portal

that Microsoft 365 provides for administrators. Microsoft 365 admin center is used to provide management functions for users and subscriptions.

- **Environments** – You can deploy as many single instances of a virtual machine (VM) as you require. We call these instances *environments*.

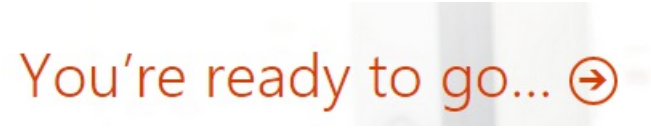
Prerequisites

1. You've received an email that invites you to participate in the preview.
2. If your company has an organizational account with Microsoft Online Services, and you're signed in, you must sign out before you continue. Alternatively, you can use **InPrivate Browsing** mode.
3. If you aren't sure whether you're signed in, delete your browser cookies, and then close your browser before you continue.

Subscribe

> **IMPORTANT**
> Only one person (tenant administrator) in an organization must perform this task. If you aren't the person who is subscribing to this release, wait until your organization has been signed up and you've received your user credentials. Then continue with the procedure.

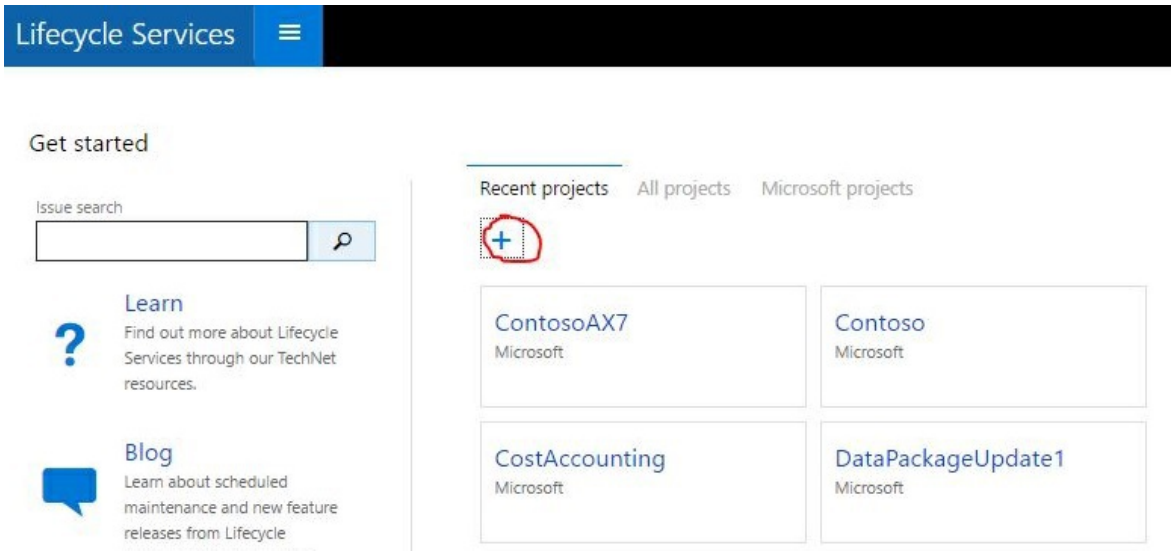
1. Finance and Operations applications and Retail are available only to existing Microsoft Dynamics 365 channel partners and customers who are currently enrolled in the Business Ready Enhancement Plan (BREP) service plan. To subscribe, visit PartnerSource Business Center.
2. On the **Account setup** page, in the **Country or region** field, select the country or region.
3. Follow the wizard and prompts to complete the sign-up, until you reach the last step.



Start a new project in LCS

To use LCS to manage your environments, you must create a new project.

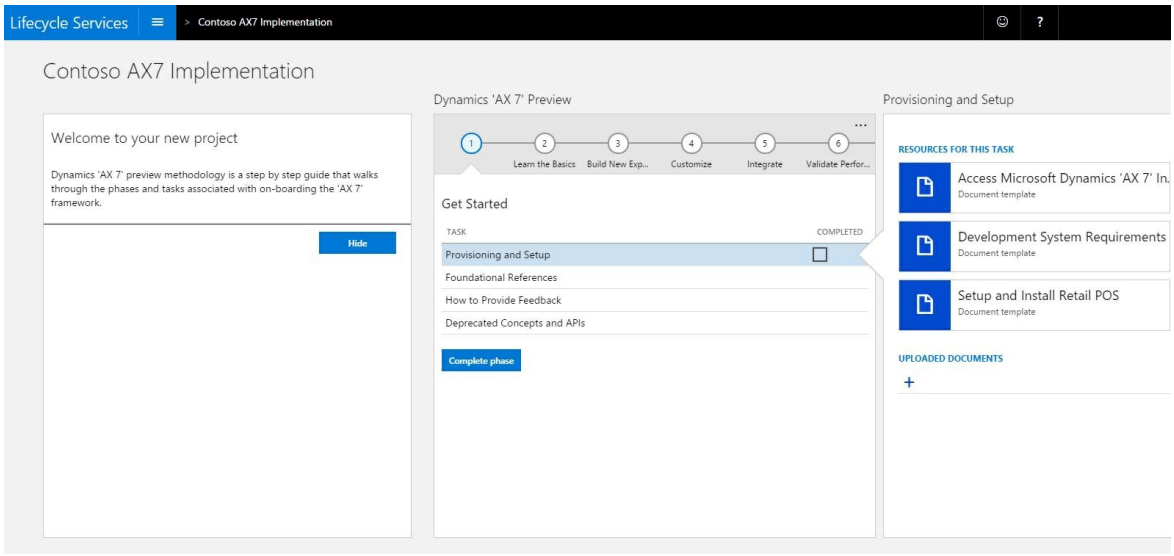
1. Go to https://lcs.dynamics.com/Logon/Index.
2. Select **Sign in**.
3. Sign in by using the account that you used to subscribe.
4. Select the plus sign (**+**) to create a new project.



5. Select the project type.
6. Enter the project information, and then select **Create**.

   If you plan to evaluate Commerce, be sure to select **Microsoft Dynamics 365 Commerce** in the **Product name** field.

   The new project for managing your instance is created.



Add users to LCS

You're already set up as a user of your LCS project. If you've also added other Microsoft 365 users, you must add them to this project. Other administrators and developers will then be able to deploy their own environments. These LCS users are team members who will actively work on the implementation. Don't confuse them with end users. Start on the project page in LCS.

1. Scroll to the right, and then, in the **More tools** section, select the **Project users** tile.
2. In the upper left, select the plus sign (**+**) to add a new user.
3. In the **Email** field, enter the email address of the user that you're adding. This email address should be the Microsoft 365 organization email address that you created earlier.
4. In the **Project role** field, select **Project Owner**.
5. Select **Invite**.
6. Repeat steps 2 through 5 for all users in your organization.

Deploy environments

Environments should be deployed to an existing Azure subscription.

> **NOTE**
> Each developer of an environment must deploy their own system to Azure. However, only the first project user must set up the Azure subscription for deployment.

You can create environments in two ways:

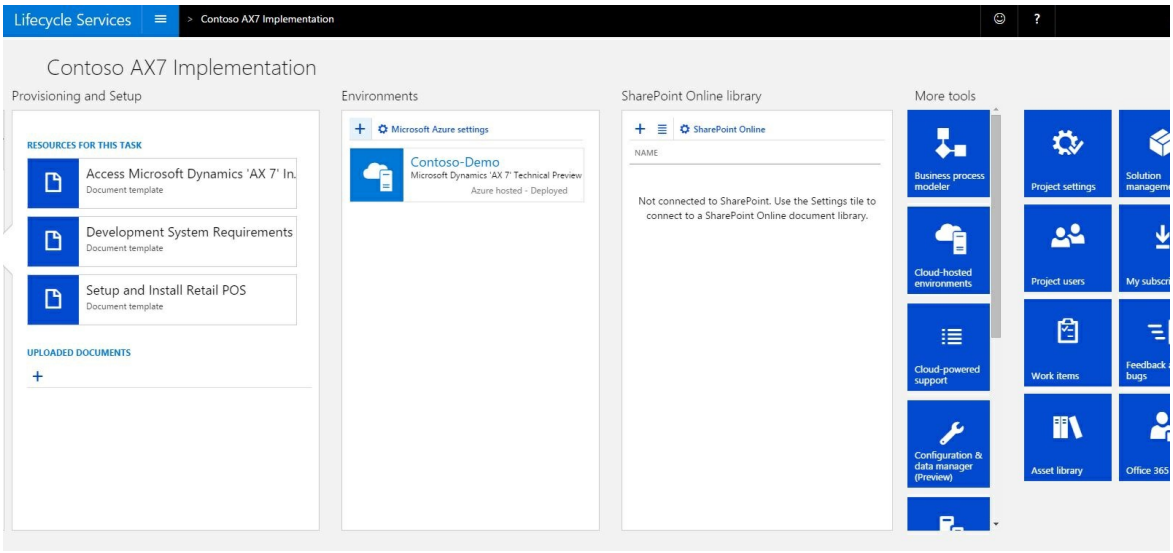
- Deploy to Microsoft cloud services (Azure).
- Download a local virtual hard disk (VHD).

Start on the project page in LCS.

1. In the **Environments** section, select the plus sign (**+**). The **Microsoft Azure setup** dialog box appears.
2. Enter your Azure subscription ID. You can find your Azure subscription ID in Azure Portal (https://ms.portal.azure.com/), under **Settings** in the lower left.
3. Select **Next**.
4. Download the Azure Management Certificate to a local folder on your computer, and then upload it to Azure Management Portal by going to **Settings** > **Management Certificates**. This certificate will enable LCS to communicate with Azure on your behalf.
5. Return to LCS, and select **Next**.
6. Select the Azure region to deploy in. The **West US** region will have the fastest deployments, but it's important that you select a data center that is close to where you plan to use this system.
7. Select **Connect**.
8. In the list of available topologies, select the topology to deploy. You can select either the **Download** link to download the VHD or **Next** to deploy on Azure. Azure is the preferred path.
9. Enter the name of the environment.
10. Read the pricing and licensing terms, and then select the check box to indicate that you understand them.
11. Select **Next**.
12. Confirm the details, and then select **Deploy**.

    > **NOTE**
    > Developers and administrators who will use their own environments must sign in and repeat these steps.

    After you deploy your environment, it's available in the **Environments** section.



13. Select the environment to view details about the deployment status. The first deployment will require a few hours, but each subsequent deployment will be much faster.

14. When the deployment status changes to **Deployed**, select **Login** to connect to the client, or select the name of the VM to connect to the development machine by using Remote Desktop. After the deployment is completed, you can find the base URL and the information that you require to connect to the environment via Remote Desktop.

Use the features of LCS

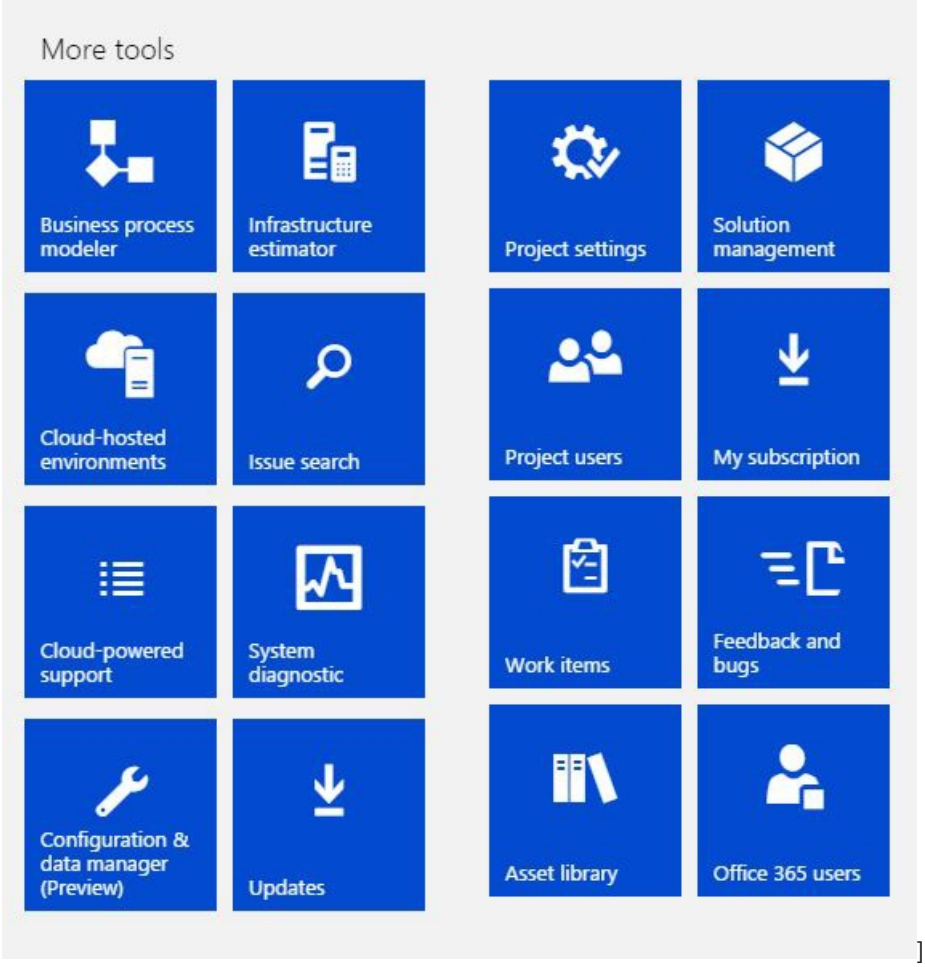
LCS is the starting point for performing online administrative activities. Here are some of these activities:

- Deploy VMs on Azure.
- Access materials.
- Access downloads of tools and resources.

Explore the LCS project

1. Review the methodology, and complete the tasks and phases as you progress through the life cycle. The phases and task information lets you view tools and resources that are available throughout your enterprise resource planning (ERP) experience.

2. Scroll to the right, and review the tiles.



]

The available tiles include various tools and services in LCS. They also include the following additional tiles:

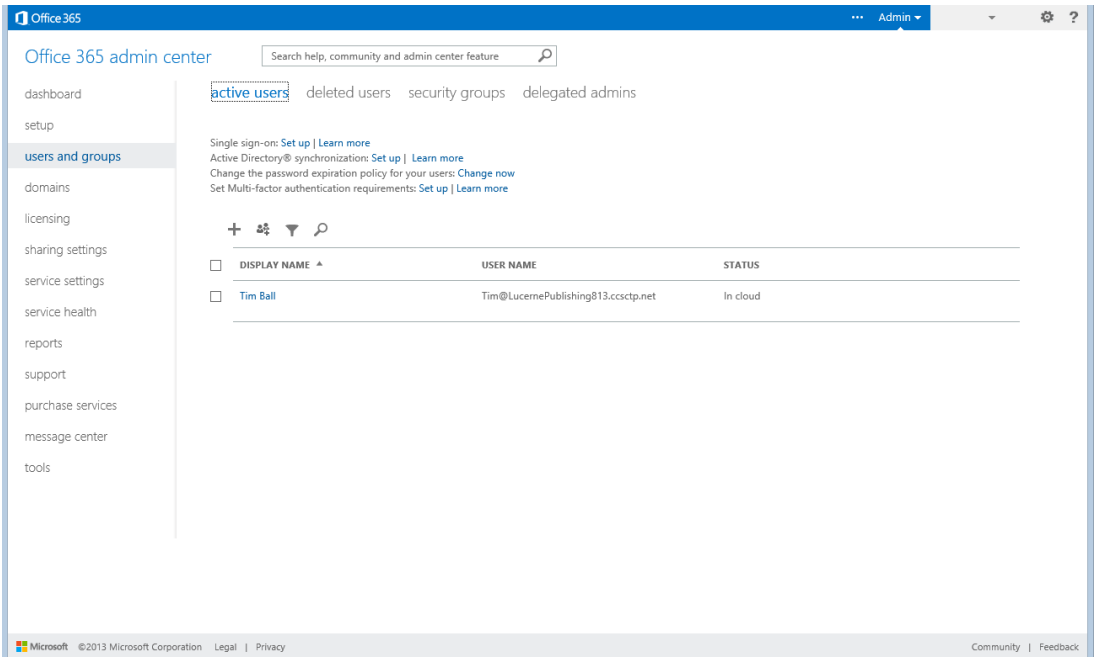
- **My subscription** – The Microsoft 365 subscription management portal is where you can view and work with your online subscriptions. By selecting **User and Groups** in the left navigation section of the page, you can also manage your online users.

  > **NOTE**
  > To access the page, you must be a member of the **Global Administrator** role for your organization's Microsoft Online Services tenant.

- **Feedback and bugs** – This tile opens the **General Feedback** page in Microsoft Connect. Use this page to record bugs, and to design change requests, feature requests, and suggestions.

- **Microsoft 365 users** – This tile opens the **Users and groups** page in Microsoft 365 admin center. You can add, update, and remove users, reset passwords, and assign licenses for other services.

  > **NOTE**
  > To access the page, you must be a member of the **Global Administrator** role for your organization's Microsoft Online Services tenant. The installing user is always a global administrator, but other users must be added to this role.



NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Deploy and access development environments

2/18/2021 • 10 minutes to read • Edit Online

This topic describes how to access development instances, configure local development virtual machines (VMs), and find important configurations settings for developers and administrators.

Definitions

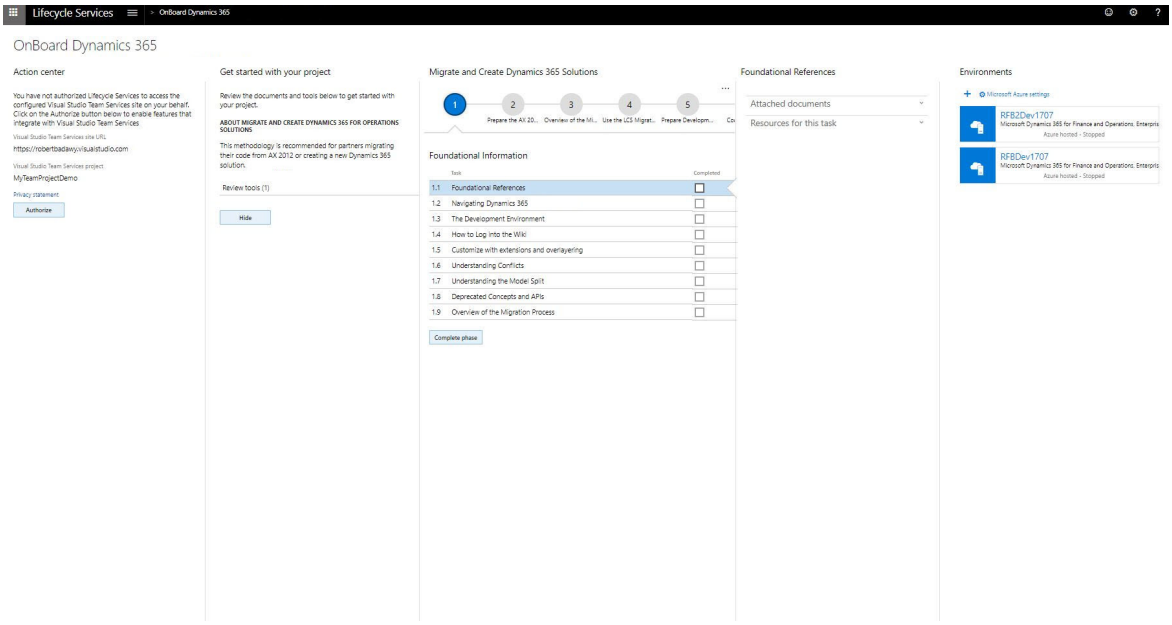
TERM	DEFINITION
End user	A user who accesses an instance through the web client. The end user must have Microsoft Azure Active Directory (Azure AD) credentials to access an instance and must be provisioned/added as a user of that instance.
Developer	A user who will develop code through the Microsoft Visual Studio environment. A developer requires Remote Desktop access to development environment (VM). The developer account must be an administrator on the VM.

Deploying cloud development environments

The process of deploying cloud hosted environments differs for Lifecycle Services (LCS) trial or partner projects and LCS customer implementation projects.

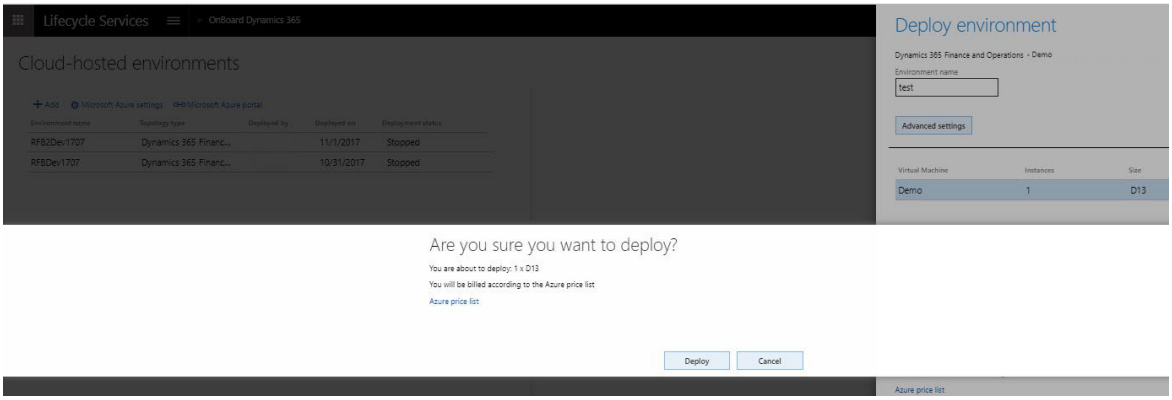
For a **Trial** or **Partner** project:

1. Create a connection between an LCS project and your Azure subscription. You will need your Azure subscription ID and authorize the use of the subscription.
2. Select **+** under **Environments** to deploy.



3. Select an application and platform version.
4. Select an environment topology. For more information, see Sign up for preview subscriptions.

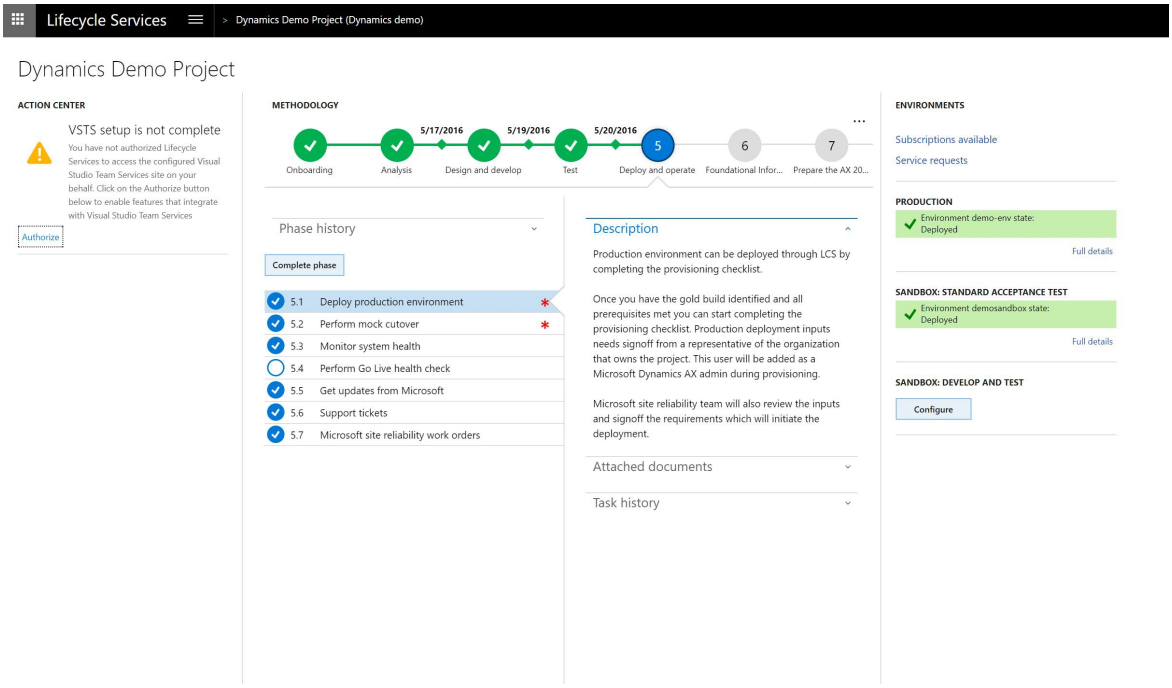
5. If you chose a cloud-hosted environment, select which Azure connector you want to use. Then select **Deploy**.



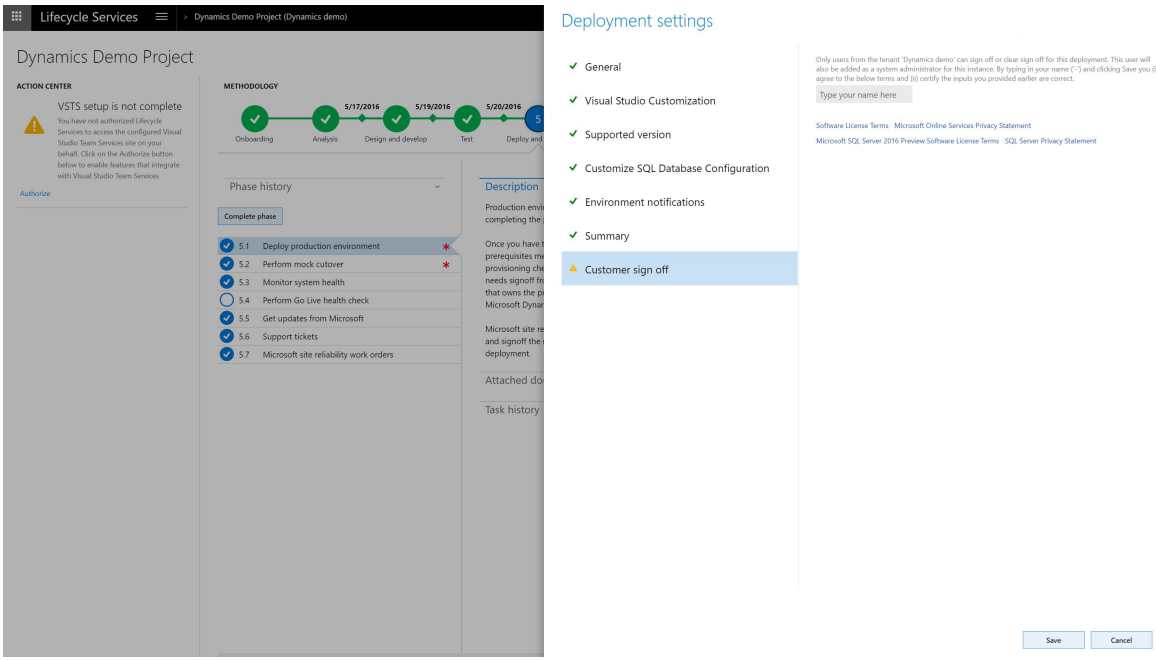
6. If you did not choose a cloud-hosted environment, select a VHD to download.

For a **Customer Implementation** project:

1. Sign in to your LCS Implementation project.
2. Select **Configure** to deploy.

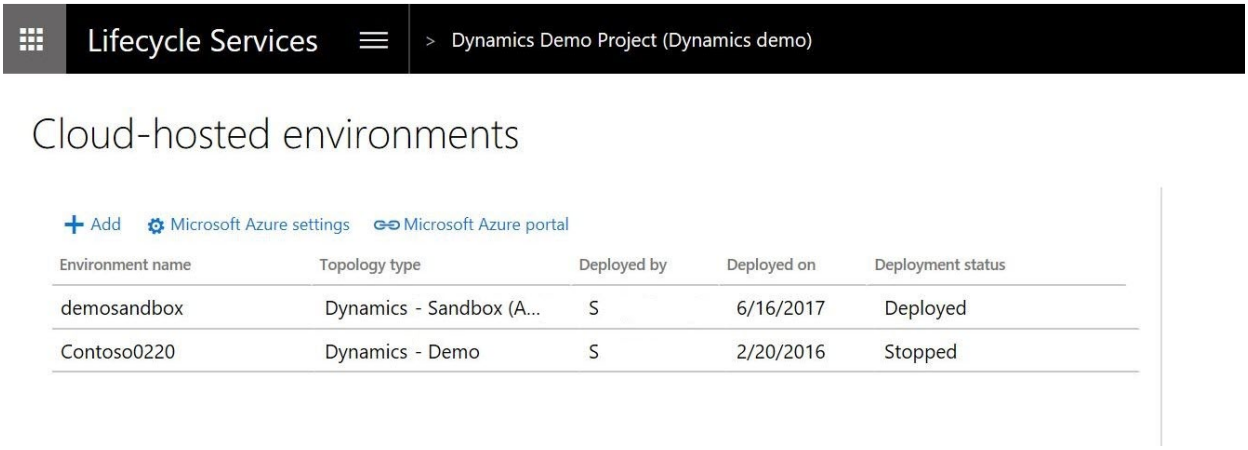


3. Select an application and platform version.
4. Specify the settings and select **Save**.



Customers are provided with one free "develop and test" environment hosted in Microsoft's Azure subscription. Under "Develop and test", there are two types of environments, **Develop** and **Build and Test**. For development and customization activities, configure a **Develop** environment. **Build and Test** environments are not supported for standard development activities. Instead, they are used for daily build and test automation. For more information, see Deploy and use an environment that supports continuous build and test automation.

Additional develop and build environments can either be purchased or hosted in your own Azure subscription. To deploy an environment in your own subscription, go to the **Cloud-hosted environment** page.



Cloud environment that is provisioned through LCS

When a cloud environment is provisioned through LCS:

- The user who requests the cloud environment is provisioned as the administrator in that environment.
- User accounts are provisioned on the development VM to allow access to the environment using Remote Desktop, these credentials are accessible on the environment page in LCS.

Accessing an instance through a URL

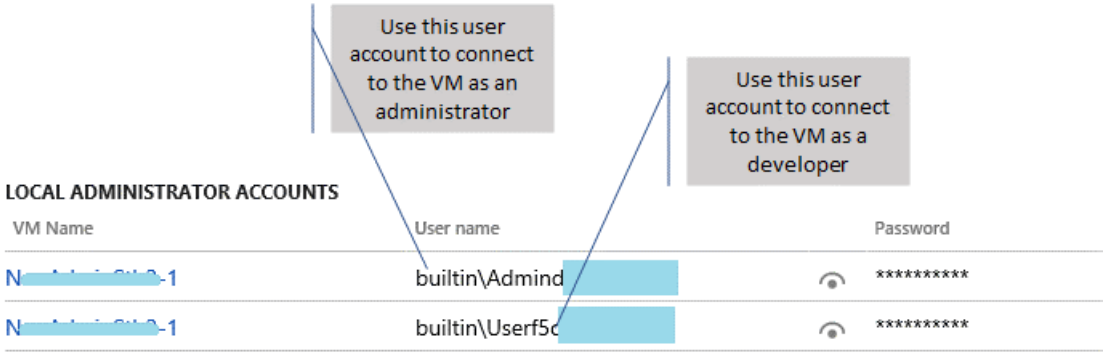
The system can be accessed by end users. The administrator can add users to this system by using the **Users** page in the instance. Note that these additional users don't have to be users in LCS. You obtain the base URL for the cloud environment from your LCS project site.

1. Go to your LCS project page.
2. In the **Environments** section, click the deployed environment.

3. When the environment page opens, you can access the application by clicking **Login** > **Log on to Finance and Operations** in the upper-right corner.
4. Use valid end user credentials to sign in to the application. If the current LCS user is the user who originally deployed the environment, that user is probably a valid end user and the administrator of the application.
5. In your browser, make a note of the base URL after you sign in. For example, the base URL might be `https://dynamicsAx7aosContoso.cloud.dynamics.com`.

Accessing the cloud instance through Remote Desktop

Cloud environments can be accessed both as an end user and as a developer. The developer gets access to the system through Remote Desktop credentials. The Remote Desktop credentials are obtained from the environment page on the LCS project site (see the illustration earlier in this topic).



For environments deployed **before Platform update 12**:

1. Click the VM name.
2. Use the local administrator user name and password that are shown to connect to the cloud VM through Remote Desktop. You can reveal the password by selecting the show password icon.

For any environments deployed **on or after Platform update 12** , there are distinct accounts, a developer account and an admin account. Customers will not have access to virtual machine admin accounts on development or build environments that are running in Microsoft subscriptions. Thus, the admin account will be hidden unless the environment is running in their Azure subscription. For more information, see Development and build VMs that don't allow admin access FAQ.

After you sign in to the environment through Remote Desktop, if you want to access the local application from the browser, use the same base URL that you use to access the application from a remote computer. The previous section explains how to obtain this base URL from LCS.

VM that is running locally

A virtual hard disk (VHD) is made available for download from LCS, so that you can set it up on a local machine. This system is intended to be accessed by a developer and is a pre-configured one-box development environment of Finance and Operations apps. The VHD is available in the Shared Asset library of LCS under the asset type **Downloadable VHD**.

1. Go to the LCS main page and select **Shared asset library** or go to Shared Asset Library.
2. Select the asset type **Downloadable VHD**.
3. Find the VHD you are looking for based on the desired Finance and Operation version. The VHD is divided into multiple file parts that you need to download. For example, the asset files that start with "VHD - 10.0.5" are the different files you need in order to install version 10.0.5.
4. Download all files (parts) associated with the desired VHD to a local folder.
5. After the download is complete, run the executable file that you downloaded, accept the software license agreement, and choose a file path to extract the VHD to.

6. This creates a local VHD file that you can use to run a local virtual machine.

Commerce configuration

Follow the steps in this section if you are also configuring for Commerce.

To use the downloadable VHD for POS customizations, you must also follow this step.

- On the host computer, enable Nested VM support. For more information, see Run Hyper-V in a Virtual Machine with Nested Virtualization.

Running the virtual machine locally

Follow these steps to run the VM from Hyper-V Manager.

1. To start the VM, select **Start**.
2. To open the VM in a window, select **Connect**.
3. Select the **Ctrl+Alt+Delete** button on the toolbar. The VM receives most keyboard commands, but Ctrl+Alt+Delete isn't one of them. Therefore, you must use the button or a menu command.
4. Sign in to the VM by using the following credentials:
   - User name: **Administrator**
   - Password: **pass@word1**

   > **TIP**
   > You can resize the VM window by changing the screen resolution. Right-click the desktop on the VM, and then click **Screen resolution**. Select a resolution that works well for your display.

5. Provision the administrator user. For more information, see the next section.
6. Start the Batch Manager Service. This step is required if you're running batch jobs or workflows.
   a. Open a **Command Prompt** window as an administrator.
   b. Type **net start DynamicsAxBatch**, and then press Enter.

   You can also start the service from the **Services** window.
7. Apply updates as needed.

Commerce configuration

For POS customizations, you must also follow these steps on the guest VM.

1. Download and install Microsoft Emulator for Windows 10 Mobile Anniversary Update.
2. Start the Hyper-V host service. For more information, see Hyper-V: The Hyper-V Virtual Machine Management service must be running. If errors occur during startup, you can also try to uninstall and reinstall the Hyper-V role on the guest VM.

Provisioning the administrator user

For developer access, you must be an administrator on the instance. To provision your own credentials as an administrator, run the admin user provisioning tool that is provided on the desktop, and provide your email address (Azure AD credentials) in the tool.

1. From the desktop, run the admin user provisioning tool as an administrator (right-click the icon, and then click **Run as administrator**).
2. Enter your email address, and then select **Submit**.

Commerce configuration

Follow the steps in this section if you are also configuring for Commerce.

For Dynamics 365 for Operations, Version 1611

1. Run the RetailTenantUpdateTool.

   - The icon for this tool is available on the desktop.
   - This tool is also available at the following location: C:\windows\System32\WindowsPowerShell\v1.0\PowerShell.exe -File C:\RetailSDK\Tools\RetailTenantUpdateTool.ps1

2. Double-click the icon to start this tool. You will be prompted for your Azure AD credentials. You must use the same credentials that you used in the admin user provisioning tool earlier.

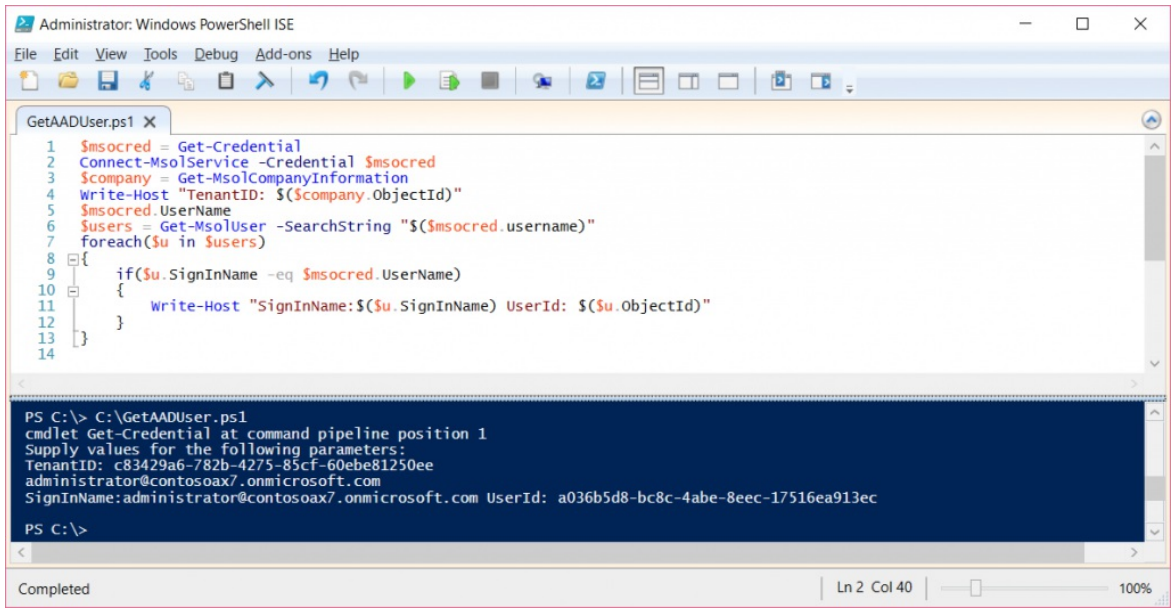
For Dynamics 365 for Operations 7.0

1. Install Microsoft Online Services Sign-In Assistant for IT Professionals RTW.

2. Install Azure Active Directory Module for Windows PowerShell (64-bit version).

3. Query Azure AD for your tenant and user ID. Open a Windows PowerShell Integrated Scripting Environment (ISE) window with administrative privileges, and run the following command. You will be prompted for Azure AD credentials. Use the same user account that you used in the admin user provisioning tool earlier.

```
$msocred = Get-Credential
Connect-MsolService -Credential $msocred
$company = Get-MsolCompanyInformation
Write-Host "TenantID: $($company.ObjectId)"
$msocred.UserName
$users = Get-MsolUser -SearchString "$($msocred.username)"
foreach($u in $users)
{
    if($u.SignInName -eq $msocred.UserName)
    {
        Write-Host "SignInName:$($u.SignInName) UserId: $($u.ObjectId)"
    }
}
```



4. Update the following SQL script, and run it in on AXDB for that environment. Supply values for the following parameters from the preceding Windows PowerShell script output:

   - **TenantID** – For example, c83429a6-782b-4275-85cf-60ebe81250ee
   - **UserId** – For example, a036b5d8-bc8c-4abe-8eec-17516ea913ec

```
DECLARE @TenantId NVARCHAR(1024)         DECLARE @UserId NVARCHAR(1024)
SET @TenantId = ‘‘
SET @UserId = ‘‘
IF(LEN(@TenantId) > 0 AND LEN(@UserId) > 0)
    BEGIN
    UPDATE AxDBRAIN.dbo.SYSSERVICECONFIGURATIONSETTING SET [VALUE] = @TenantId WHERE [NAME] =
‘TENANTID’
    UPDATE RetailHoustonStore.ax.SYSSERVICECONFIGURATIONSETTING SET [VALUE] = @TenantId WHERE [NAME]
= ‘TENANTID’
    UPDATE AxDBRAIN.dbo.RETAILSTAFFTABLE SET EXTERNALIDENTITYID = @TenantId, EXTERNALIDENTITYSUBID =
@UserId WHERE STAFFID = ‘000160’
    END
ELSE
    BEGIN
    RAISERROR (15600, -1, -1, ‘TenantId and UserId must be set before running this script’)
    END
```

5. Reset Internet Information Services (IIS) by running **IISRESET** in an elevated **Command Prompt** window.

6. Update the Real-time service profile to use the new admin user.

    a. Go to **Retail and Commerce** > **Headquarters setup** > **Commerce scheduler** > **Real-time service profiles**.
    b. Edit the JBB record so that it uses the user that you used earlier (for example, `administrator@contosoax7.onmicrosoft.com`).
    c. Run CDX Job 1070 (Staff) for the default channel database.
    d. Verify that the job succeeded by viewing the **Download Sessions** page on the client.

Base URL of the local application

After the user is provisioned as an administrator, that user can access the instance on the computer by navigating to the following base URL: `https://usnconeboxax1aos.cloud.onebox.dynamics.com`. If you're using version control and plan to connect multiple development VMs to the same Azure DevOps project, rename your local VM. For instructions, see Rename a local development (VHD) environment.

Commerce configuration

The URL of the POS app is `https://usnconeboxax1pos.cloud.onebox.dynamics.com/`.

The URL of the Cloud POS app is `https://usnconeboxax1pos.cloud.onebox.dynamics.com`. After you complete the configuration steps, this VM is provisioned with your Azure AD tenant. Your Azure AD admin account is mapped to a cashier worker account in demo data. You can use this cashier account to easily activate a POS device in this environment.

- Cashier user ID: **000160**
- Cashier password: **123**
- Cashier LE: **USRT**
- Cashier store: **Houston**

Location of packages, source code, and other AOS configurations

On a VM, you can find most of the application configuration by opening the web.config file of AOSWebApplication.

1. Start IIS.
2. Go to **Sites** > **AOSWebApplication**.
3. Right-click, and then click **Explore** to open File Explorer.
4. Open the web.config file in Notepad or another text editor. The following keys are of interest to many

developers and administrators:

- **Aos.MetadataDirectory** – This key points to the location of the packages folder that contains platform and application binaries, and also source code. (Source code is available only in development environments.) Typical values are: c:\packages, c:\AosServicePackagesLocalDirectory, and J:AosServicePackagesLocalDirectory.
- **DataAccess.Database** – This key holds the name of the database.
- **Aos.AppRoot** – This key points to the root folder of the Application Object Server (AOS) web application.

Commerce configuration

The software development kit (SDK) is available at C:\RetailSDK. For more information about how to use and customize applications, see the following topics:

- Retail software development kit (SDK) architecture
- Point of sale (POS) device activation

Redeploying or restarting the runtime on the VM

To restart the local runtime and redeploy all the packages, follow these steps.

1. Open File Explorer, and go to C:\CustomerServiceUnit.
2. Right-click **AOSDeploy.cmd**, and then click **Run as administrator**.

This process might take a while. The process is completed when the cmd.exe window closes. If you just want to restart AOS (without redeploying the runtime), run **iisreset** from an administrator **Command Prompt** window, or restart AOSWebApplication from IIS.

Configure one-box development environments

2/18/2021 • 2 minutes to read • Edit Online

This article describes recommended configurations of your one-box developer environment.

Setup

1. Start Visual Studio, and on the toolbar, click **Dynamics 365 **> **Options**.
2. Expand the **Microsoft Dynamics** node, and then click **Projects**.
3. Verify that the **Organize projects by element type** check box is selected, and click ***OK.***
4. To view the line numbers in your code editor, select **Tools** > **Options** > **Text Editor** > **All Languages**.
5. Select the **Line numbers** check box.

Debugging

For better performance of the X++ debugger, you might want to turn off IntelliTrace. IntelliTrace collects the complete execution history of an application. It is not supported for X++ debugging and causes performance issues in the IDE when debugging large packages like Application Suite. To turn off Intellitrace, click **Options** > **IntelliTrace** > **Enable IntelliTrace**, clear the check box, and then click **OK**. Note that Intellitrace is only available in the Enterprise version of Visual Studio.

Create new users on development machines

2/18/2021 • 2 minutes to read • Edit Online

This article explains how to enable another user account as a developer on a development VM.

> **NOTE**
> This topic only applies to downloaded local virtual machines (VMs) or VMs that are hosted in a customer's subscription. You can't create new users on Microsoft-managed developer and build machines where developers have no administrator acces to the VM (Platform update 12 or newer).

When an environment is first deployed, only one user account is enabled as a developer on the virtual machine (VM). This user is preconfigured by Microsoft Dynamics Lifecycle Services (LCS) or is the local administrator account on downloaded virtual hard disks (VHDs). However, you can enable a new user account to develop on the VM. Even after you enable a new account, only one developer can develop at a time on the same VM/application.

Prerequisites

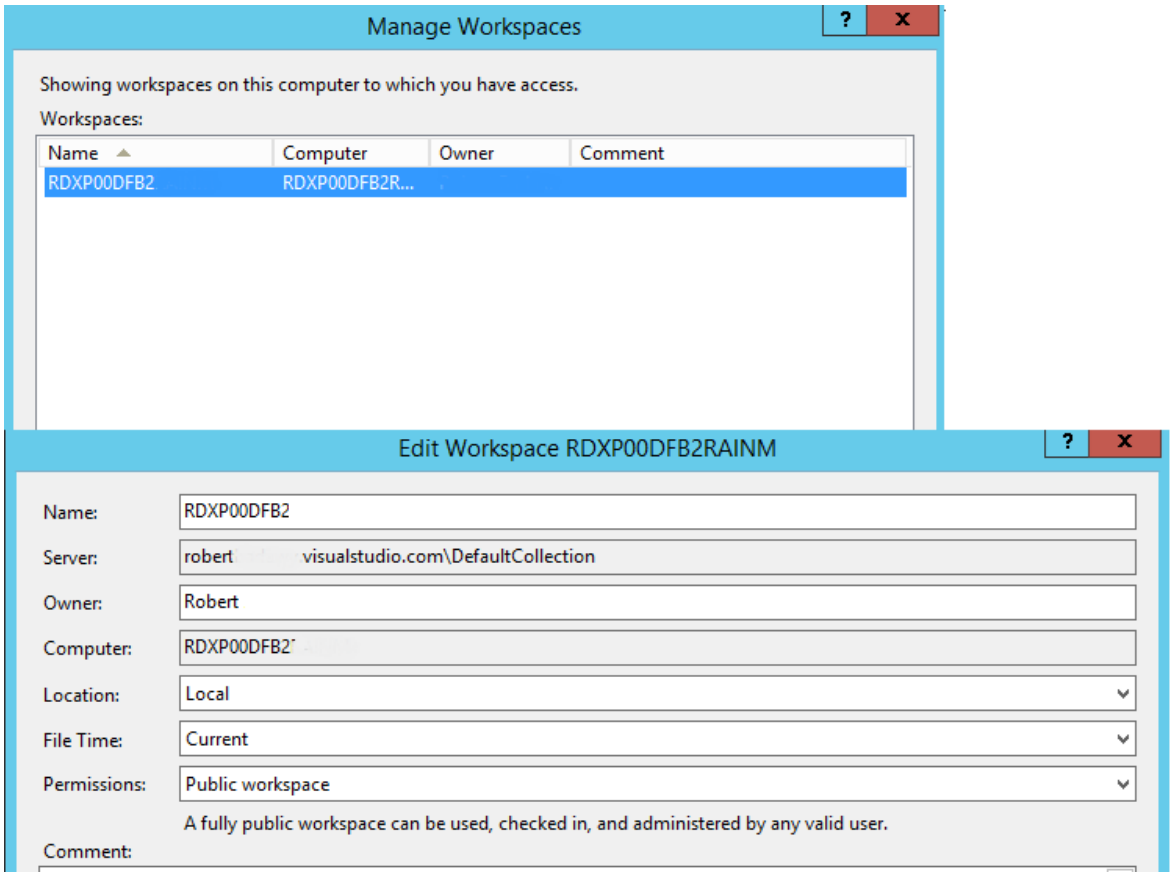
To enable a new user account to develop on the VM, the user account must be an administrator on the VM. Additionally, you must log on to the VM by using the credentials of the default developer account. If the VM is a Microsoft Azure VM, the account information is available on the environment page in LCS. If the VM is a local VM that runs on the downloaded VHD, use the local administrator account. For more information, see Deploy and access development environments.

Steps

1. Download the following script: ProvisionAxDeveloper.ps1, the script is available at https://github.com/Microsoft/Dynamics-AX-Scripts.
2. Open a Microsoft Windows **PowerShell Command Prompt** window as an administrator.
3. Run the ProvisionAxDeveloper.ps1 script. Specify the following parameters:
   - **DatabaseServerName** – Typically, this is the machine name.
   - **Users** – Use the following format: <domain or machine name>\user1, … <domain or machine name>\user n

   Examples

   - `ProvisionAxDeveloper.ps1 RDXP00DB20RAINM RDXP00DB20RAINM\username1`
   - ```
     ProvisionAxDeveloper.ps1 -databaseservername RDXP00DB20RAINM -users
     RDXP00DB20RAINM\username1,RDXP00DB20RAINM\username2
     ```
4. If more than one user account will be developing on the same version control workspace, you need to make the workspace public.
   a. In Visual Studio, open **Source Control Explorer**, select the workspace drop-down and select **Manage workspaces**.
   b. Select the application workspace, click **Edit,** then click **Advanced** and set the workspace to **Public workspace**.
     ```



NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Development and build VMs that don't allow admin access FAQ

2/18/2021 • 6 minutes to read • Edit Online

This topic provides answers to frequently asked questions (FAQ) about virtual machines (VMs) that don't allow administrator access.

How can I install a deployable package?

Whenever possible, use Microsoft Dynamics Lifecyle Services (LCS) to install a deployable package. You can install a deployable package by using the **-devinstall** option. Remember that this option requires manual database synchronization.

For more information about how to install a deployable package, see Install deployable packages from the command line.

Is the Finance and Operations website accessible when Visual Studio isn't running?

Yes, you can access the Finance and Operations website when Microsoft Visual Studio isn't running. Microsoft Internet Information Services (IIS) Express is an .exe file that runs as the user. However, when you close Visual Studio, the XPPC agent starts regular IIS (not IIS Express) before it closes. This behavior helps to ensure that you can remotely access the Application Object Server (AOS) instance and the website, even when you sign out or the machine is restarted. We recognize that many people use these developer machines as test machines, and that they expect the AOS instance always to be running. However, IIS Express doesn't support this behavior.

What about the other services?

You can restart Microsoft Windows services such as Microsoft SQL Server, SQL Server Reporting Services (SSRS), SQL Server Integration Services (SSIS), SQL Server Analysis Services (SSAS), Batch, Financial reporting (formerly Management Reporter), and IIS. (For IIS, you must restart the World Wide Web Publishing Service because you can't use iisreset.exe.)

Can I clean up the service volume drive?

Yes, you have full access to the service volume drive. Therefore, you can clean up the monitoring data, and so on.

What are the alternatives to VMs that don't allow administrator access?

Both a Microsoft Azure environment on a private Azure subscription and a local virtual hard disk (VHD) allow administrator access. However, you must run Visual Studio as an administrator. This requirement applies because the administrator has access to these alternatives only through the **administrator** group, not explicitly.

Can I run Visual Studio as an administrator?

You are not required to run Visual Studio as an administrator. You cannot use the Remote Desktop Protocol (RDP) to connect as an administrator to VMs that are under a Microsoft-owned Azure subscription. These VMs include the Tier 1 VM that is included in the subscription and Tier 1 add-on VMs. However, if you're connecting

as an administrator to a VM that isn't under a Microsoft-owned subscription, you must still run Visual Studio as an administrator.

A "get latest" operation in Visual Studio failed because files are blocked by the AOS instance. How do I start and stop IIS?

You must use IIS Express. See the next question for more information.

What are the instructions for using IIS Express?

When IIS Express is started, an icon appears in the notification area (near the clock). When you right-click on the IIS Express icon, all the running sites are listed. You can stop IIS Express from that menu. Some actions in Visual Studio cause IIS Express to be started, but you can also explicitly start IIS Express from Visual Studio by selecting **Restart IIS Express** on the **Dynamics 365** menu.

To ensure that debugging functions properly with IIS Express and Finance and Operations Visual Studio projects, we recommend the following Internet Options settings:

- Go to **Control Panel** > **Internet Options** > **Security** tab > **Internet**, and clear the **Enable Protected Mode** check box.
- Go to **Control Panel** > **Internet Options** > **Security** tab > **Restricted sites**, and clear the **Enable Protected Mode** check box.

Can I install additional development tools (such as Fiddler and Pepper)?

No, you can't install additional development tools.

Is there a way to run Windows PowerShell and command prompt commands as an administrator?

No, you can't run Windows PowerShell commands and commands at a prompt command as an administrator.

Is the Trace Parser supported?

Trace Parser currently requires the user to be an administrator. It is not supported on dev/test environments that are managed by Microsoft that do not allow administrator access.

Is the Admin user provisioning tool supported?

The **Admin user provisioning** tool currently requires the user to be an administrator. The **Admin user provisioning** tool is typically used to change the tenant of the environment, but that should not be necessary. You can update the sign in information in the database for the Admin user or any other user. You only need the SID and network alias (email address) from a user that can access the environment or another environment on the same tenant. In many cases, the SID and network alias can be found in the database that came with the environment originally. Run the following commands to get the good SID and network alias from the source environment and update them in the target environment, respectively.

```
-- get value from source env.
select ID, SID, NETWORKALIAS from USERINFO where ID = 'Admin'

-- update value in target env.
update USERINFO set SID = 'new_SID', NETWORKALIAS = 'new_NetworkAlias' where ID = 'Admin'
```

Can the system be put into maintenance mode?

You can put the system into maintenance mode to change the license configuration. However, the procedure that is described in Maintenance mode isn't supported. Self-service support for maintenance mode in all environments will be added to LCS in the future. Until this support is available in LCS, you can follow these steps to put a system into maintenance mode.

1. Establish an RDP connection to the developer machine.
2. On the developer machine, sign in to SQL Server by using the credentials for the axdbadmin user from LCS. Then switch to the AXDB database, and run the following command.

   ```
   update SQLSYSTEMVARIABLES SET VALUE = 1 where PARM = 'CONFIGURATIONMODE'
   ```

3. Restart the **World Wide Web Publishing Service** to reset IIS.

   After the service is restarted, the system will be in maintenance mode.

4. When you've completed your maintenance mode activities, repeat steps 2 and 3, but set the value to **0** in step 2.

Can I install a license deployable package?

Development environments

Use LCS to install a license deployable package on any cloud development environment.

Build environments

LCS does not allow AOT or license deployable packages to be installed on build environments. To work around this, remote into the VM and use the **-devinstall** option to install a license deployable package from the command line as described in the topic, Install deployable packages from the command line. This command line install works as of platform update 17. If you are running on a platform version that is older than Platform update 17, and you do not have admin access to your build environment, create a support request and ask Microsoft to install your license deployable package.

Is licensing Visual Studio by entering a product key supported?

Entering a product key directly in Visual Studio is not supported. Instead, use Visual Studio subscription licensing and sign in to Visual Studio with the email address (user account) associated with the license. You can link a Visual Studio license to a user account by assigning an MSDN license to the user account or by assigning a license to the user account by using https://www.visualstudio.com/subscriptions-administration.

Can I upgrade my database to a new application release?

As of the February 2018 release of Lifecyle Services (LCS), you can execute the data upgrade package from the LCS environment page of a development environment. Executing the data upgrade package from LCS does not require you to be an administrator on the VM.

The process described in Upgrade data in development or demo environments runs the data upgrade package from the command line. This requires you to be an administrator on the VM.

What do I need to know if I am developing for Commerce?

If you are developing for Dynamics 365 Commerce, configuration steps and other important information is described in Development in cloud-hosted development environments without admin access.

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Rename a local development (VHD) environment

2/18/2021 • 2 minutes to read • Edit Online

A local development (VHD) environment must be renamed for the following scenarios:

- **Accessing a single Microsoft Azure DevOps project across multiple machines:** Azure DevOps is required for version control. In development topologies, multiple virtual machines (VMs) can't access the same Azure DevOps project if they have the same machine name. Azure DevOps uses the machine name for identification. If you're developing on local VMs that were downloaded from Microsoft Dynamics Lifecycle Services (LCS), you might encounter issues.
- **Installing One Version service updates:** One Version service updates, such as 8.1.x, must be installed in VHD environments by using a runbook. To help guarantee that the runbook is completed successfully, the VHD environments must be renamed. Additional steps that are described in this topic must also be completed.

Rename the machine

Rename and restart the machine before you start development or connect to Azure DevOps. Make sure that the new name is unique among all the machines that are used with the Azure DevOps project.

Update the server name in SQL Server

Update the server name in Microsoft SQL Server 2016 by running the following commands.

```
sp_dropserver [old_name];
GO
sp_addserver [new_name], local;
GO
```

In these commands, be sure to replace **old_name** with the old name of the server and **new_name** with the new name. By default, the old name is **MININT-F36S5EH**, but you can run **select @@servername** to get the old name. Additionally, be sure to restart the SQL Server service after the commands have finished running.

Update SQL Server Reporting Services

Update the SQL Server Reporting Service (SSRS) database by using the Reporting Services Configuration Manager. Select **Database**, select **Change Database**, and use the new server name. Make sure that you use Reporting Services Configuration Manager for SQL Server 2016.

Additional steps to install One Version service updates

The following additional steps are required in order to install One Version service updates in a VHD environment.

Update the Azure Storage Emulator

Update the Azure Storage Emulator, and make sure that it's running. From the **Start** menu, open **Microsoft Azure Storage Emulator - v4.0**, and run the following commands.

This command starts the emulator.

```
AzureStorageEmulator.exe start
```

This command verifies that the emulator is running.

```
AzureStorageEmulator.exe status
```

Try the **init** option with the **-server** switch or the **-forcecreate** switch. Be sure to replace **new_name** with the new name.

```
AzureStorageEmulator.exe init -server new_name
AzureStorageEmulator.exe init -forcecreate
```

If the **init** command fails, delete the storage emulator database by using SQL Server Management Studio. Then try the following command.

```
AzureStorageEmulator.exe init
```

When you run this command, you might receive the following error message: "Error: Cannot create database." However, the emulator will usually still start. You just need the emulator to start.

Update financial reporting

Update the server name for financial reporting by using a script that is included in the One Version service update. To get the command, you must download and expand the One Version service update.

Open a Microsoft Windows PowerShell command window as an admin, and run the following command. This command contains the default passwords that might have to be updated. Be sure to replace **new_name** with the new name.

```
cd <update folder>\MROneBox\Scripts\Update
.\ConfigureMRDatabase.ps1 -NewAosDatabaseName AxDB -NewAosDatabaseServerName new_name -NewMRDatabaseName
ManagementReporter -NewAxAdminUserPassword AOSWebSite@123 -NewMRAdminUserName MRUser -NewMRAdminUserPassword
MRWebSite@123 -NewMRRuntimeUserName MRUSer -NewMRRuntimeUserPassword MRWebSite@123 -NewAxMRRuntimeUserName
MRUser -NewAxMRRuntimeUserPassword MRWebSite@123
```

Development system requirements

2/18/2021 • 2 minutes to read • Edit Online

This topic lists the system requirements for development.

Development environments can be hosted locally or in Microsoft Azure. The build process, X++ compilation, and generation of cross reference information, typically run satisfactorily on machines with 16 GB of memory and two CPU cores. The compiler uses available resources, so more RAM and more cores can speed up compilation, especially if there is contention for the resources from other concurrent processes. If you are running concurrent processes, then we recommend 24 GB of memory with four cores. At a minimum, two CPU cores are recommended because the developer environment contains many components that may be running concurrently. The components include the AOS web application, Visual Studio, Management Reporter, and SQL Server.

Version control, metadata search, and navigation

2/18/2021 • 11 minutes to read • Edit Online

This tutorial will walk you through configuring Microsoft Azure DevOps to enable source control on your models. It will also help you learn about other productivity features in the development tools, including the ability to create and organize TODO task, search metadata and source code, navigate between related model elements, and create a project from a model.

Configure your Azure DevOps organization and project

In this section, you'll create a new project in Azure DevOps. This project will host the source code of your model. You'll use the Fleet Management model as an example. If you don't have a Azure DevOps organization, you'll create one.

Sign up to Azure DevOps, create an account, and create a new project

Navigate to https://www.visualstudio.com/ to sign up for Azure DevOps. Click **Sign up**. If you already have an account in Azure DevOps, go to the Create a Azure DevOps project section later in this topic.

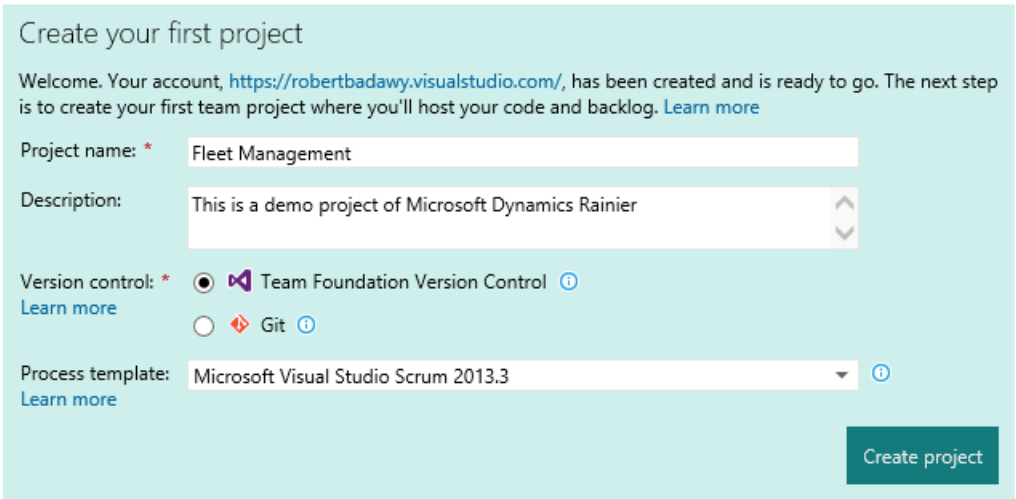
1. Sign in with your Microsoft account.

   > **NOTE**
   > You can also use an organizational account (Microsoft 365 domain).

2. Create a Azure DevOps organization, and select a URL for your account. You'll use this URL to connect from your development computer when you're configuring source control in Visual Studio. The following image is an example of the account URL.

   
   When the account is created, you're directed to your account main page where you're prompted to create your first project.

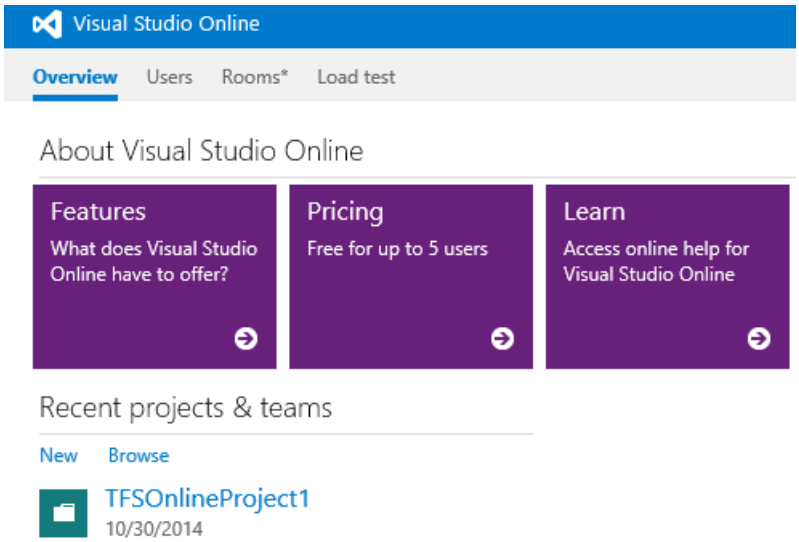
3. Create a demo **Fleet Management** project.

Create a Azure DevOps team project

If you already have a Azure DevOps organization, go to your account using Internet Explorer. This topic uses **.visualstudio.com** as the example URL for illustration purposes.

1. Go to https://www.visualstudio.com/.
2. Under **Recent projects & teams**, click **New** to create a new project.



3. In the **Project name** field, enter **Fleet Management**, enter a **Description**, and then click **Create project**.

Create the recommended folder structure in your team project

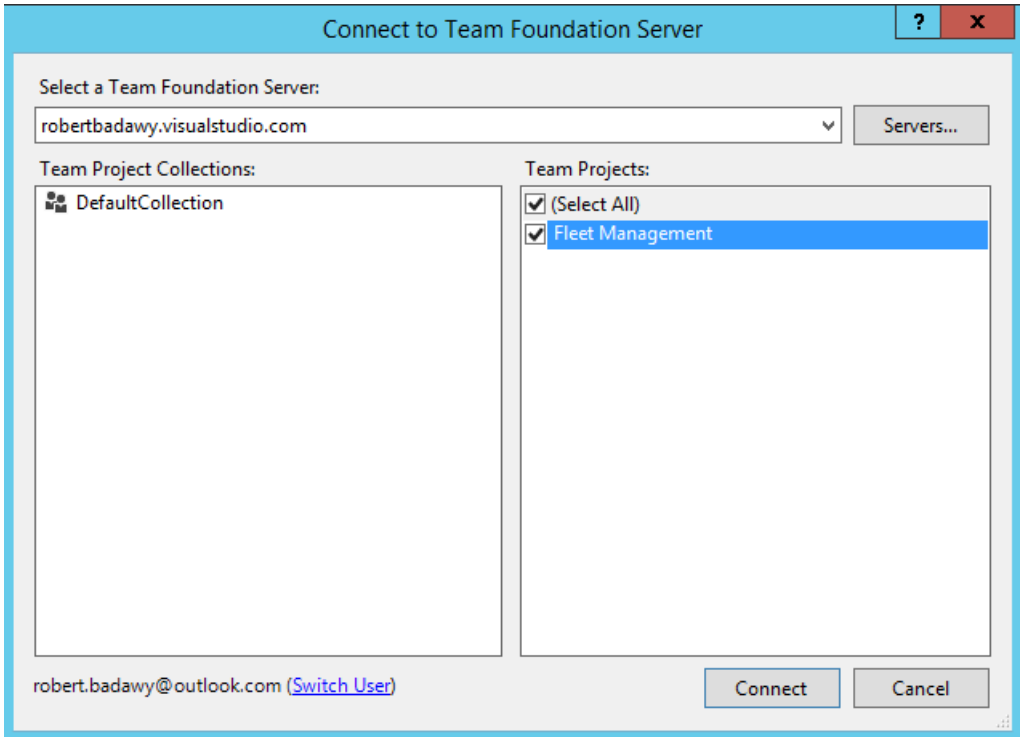
If you have migrated your code from a previous version using the Lifecycle Services (LCS) automated code upgrade tool, the following folder structure is automatically created in your Azure DevOps team project.

The **Metadata** folder contains your source XML files organized by packages and models and the **Projects** folder contains Visual Studio projects. If you are not migrating code and are starting from scratch, create a similar folder structure on the server in your team project before you start development.

Configure Visual Studio to connect to your team project

1. Start Visual Studio. If you are logged into the machine as an administrator, then you must start Visual Studio as an administrator.
2. Click **Tools > Options > Source Control > Plug-in Selection**.
3. In the Current source control plug-in field, select **Visual Studio Team Foundation Server**.
4. Select **Team > Connect to Team Foundation Server**.
5. In **Team Explorer**, click **Select Team Projects**.
6. In the **Select a Team Foundation Server** drop-down list, select the **Azure DevOps organization** that hosts the Fleet Management project, or click **Servers** if it isn't in the menu.
    a. When the **Add/Remove Team Foundation Server** dialog opens, click **Add**.
    b. Enter the URL of your Azure DevOps organization.
    c. Click **OK**.
    d. If prompted, enter your Microsoft Account username and password.

7. Select the **Fleet Management** check box under **Team projects**, and then click **Connect**.

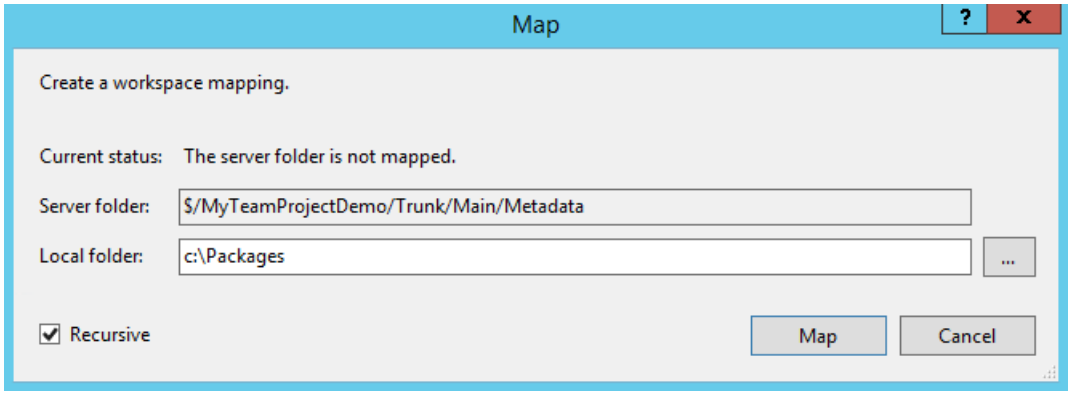


Map your Azure DevOps project to your local model store and projects folder

Your model store root folder contains source files of all packages and models that are part of your application. During deployment, you'll probably use source files from more than one model across more than one package. We recommend that you map your model store root folder to the Azure DevOps team project metadata folder.

1. In Visual studio **Team Explorer**, connect to the team project as described earlier in this document.
2. Open **Source Control Explorer** from **Team Explorer**.
3. Map the **Metadata** folder of your team project to the root folder of the model store on your local drive (Typically K:\AOSService\PackagesLocalDirectory), an example is shown in the image below.

> **NOTE**
> Your model store may be located under I:\AosService\PackagesLocalDirectory or another drive, depending on your machine configuration.



4. Click **Map**, and on the next dialog, click **No**.
5. Similarly, map the **/Trunk/Main/Projects** server folder to the **local projects folder** that will hold your Visual Studio solution and project files.

Scenario 1: Open the fleet management solution and add it to Azure DevOps source control

This section describes the steps needed to add a solution to Azure DevOps source control. This scenario is relevant when you have started development on a new model and you are adding it to source control for the first time. For code migration scenarios or in the case you are synchronizing new models that have been created by another developer, refer to scenario 2 below.

Open the FleetManagement solution

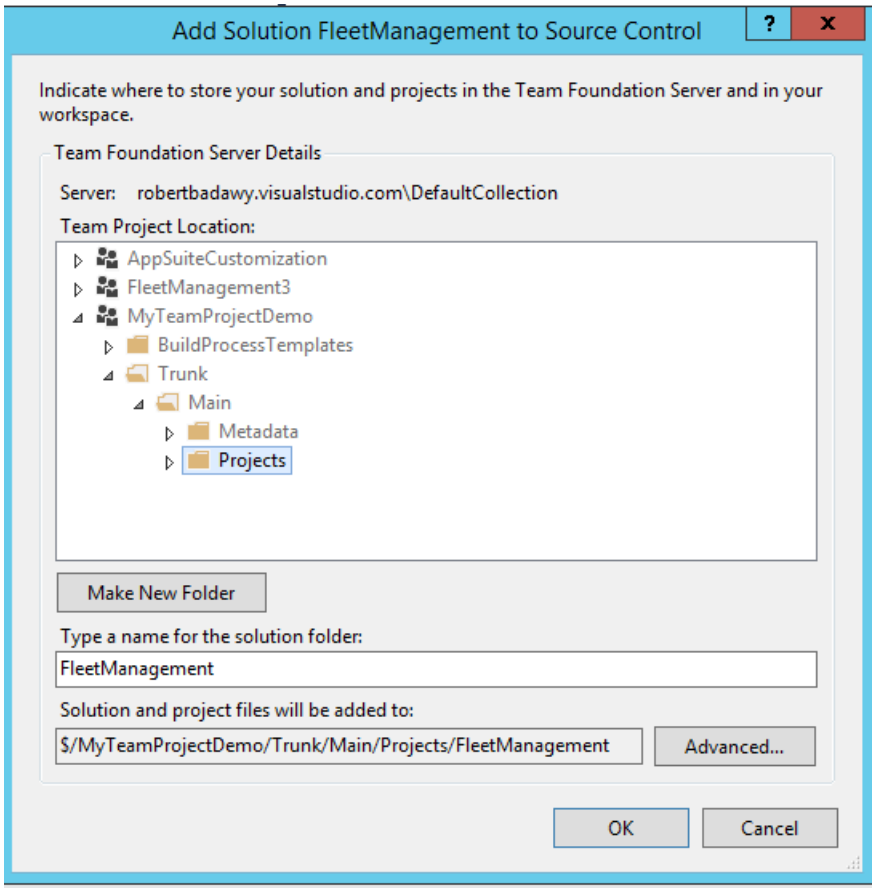
> **NOTE**
> This project is only an example. You can open any project/solution to learn about the process of adding a solution to source control.

1. On the **File** menu, point to **Open**, and then click **Project/Solution**.
2. Browse to the desktop and open the **FleetManagement** folder.
3. Select the solution file named **FleetManagement**. The file type listed is Microsoft Visual Studio Solution. If the solution file is not on your computer, the steps to create it are listed in Tutorial: Create a Fleet Management solution file out of the Fleet Management models in the AOT.
4. Click **Open**. Loading the solution may take some time.

Add the FleetManagement solution to source control

1. In **Solution Explorer**, right-click the Fleet Management solution, and select **Add Solution to Source Control.**
2. On the next dialog, select **Team Foundation Version Control**, and then click **Next**.
3. In the **Team Project Location**, select **Projects**, as shown in this image.

> **NOTE**
> If you have already mapped the server Projects folder to a local folder that contains the FleetManagement solution, steps 2 and 3 are omitted.



4. Click OK.

5. Go to **Team Explorer** > **Pending changes**, and then click **Check-in** to check-in your solution and its model element to the Azure DevOps source control.

Add the model descriptor file to source control

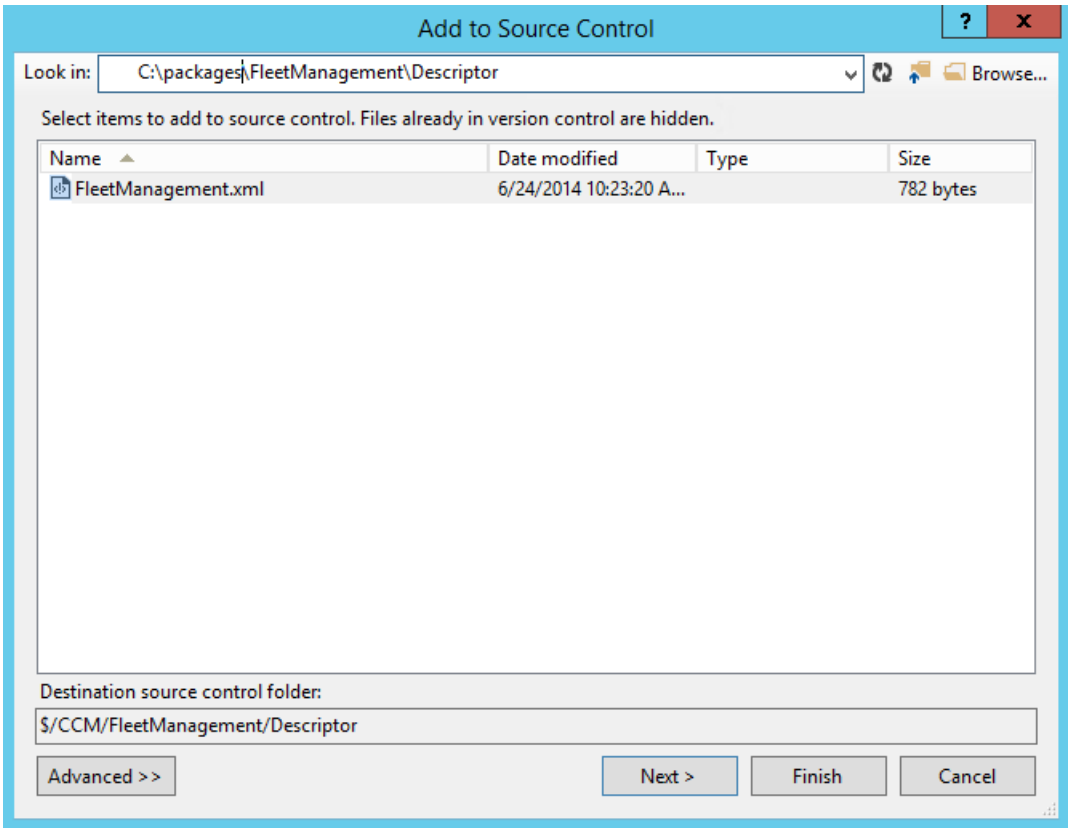
All Visual Studio projects belong to models. Models are source code distribution and deployment units that are typically larger in scope than a Visual Studio project. In the previous section, you added element files of the fleet management solution to source control. Because this was the first time that you added elements of the Fleet Management models to source control, you'll also need to check-in the model descriptor file.

1. In Visual Studio, in **Team Explorer**, open **Source Control Explorer**, and then right-click on the metadata folder (for example, **\Trunk\Main\Metadata**).

2. In the **Source Control Explorer** toolbar, click **Add Item to Folder**.

3. Select your model descriptor file. The model descriptor file is the XML file manifest of your model. It's located in the **Descriptor** folder of the package that the model belongs to. The following image shows an example of where the model descriptor file of the Fleet Management model exists (c:\packages\FleetManagement\Descriptor\FleetManagement.xml).

> **NOTE**
>
> Your model store may be located under I:\AosService\PackagesLocalDirectory or c:\AosService\PackagesLocalDirectory or another drive, depending on your machine configuration.



4. Click **Finish**.

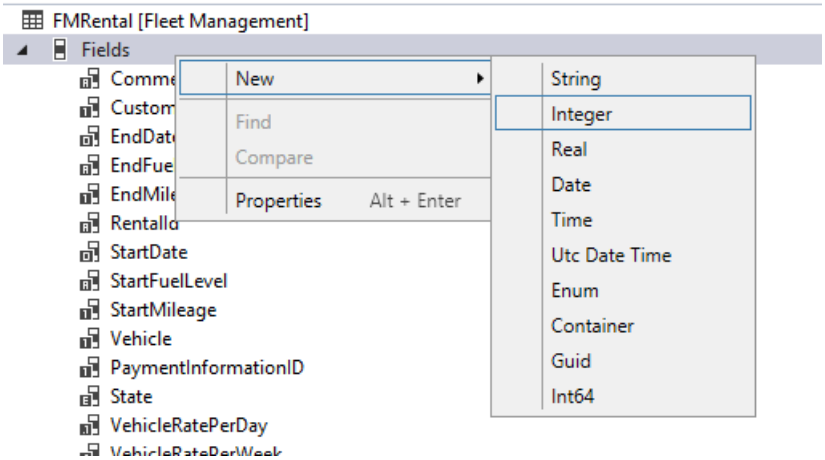
> **NOTE**
>
> Because your solution contained elements from two models, you'll need to add an additional model descriptor file to source control:
> K:\AOSService\PackagesLocalDirectory\FleetManagementExtension\Descriptor\FleetManagementExtension.xml

5. Check-in your pending items. Your item is now ready for development of the fleet management application using a state-of-the-art, cloud-based source control system, and many other application lifecycle features of Azure DevOps.

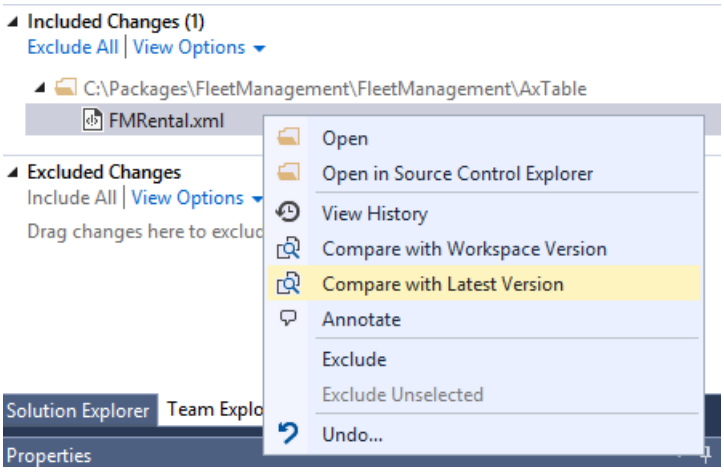
Experiment with source control

In this section, you'll make minor changes to the **FMRental** table and compare your changes with the latest version in your source code repository.

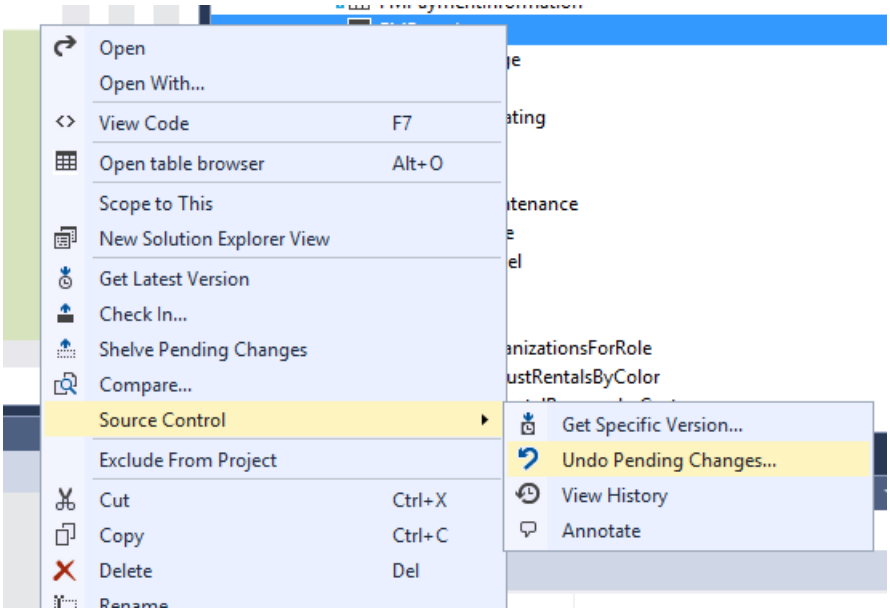
1. In **Solution Explorer**, select **Fleet Management Migrated** > **Data model** > **Tables** > **FMRental**.
2. Double-click **FMRental** to open the designer.
3. Right-click the **Fields** node, and then click **New** > **Integer**.



4. Right-click **Methods**, and add a new method.
5. In the X++ code editor, enter a comment in the new method.
6. Enter a comment in any existing method.
7. Save the **FMRental**.
8. In **Team Explorer**, right-click **FMRental.xml**, and select **Compare with Latest Version**.



9. Browse through the differences in the **comparison (Diff)** window.
10. In **Solution Explorer**, right-click on the **FMRental** table, and select **Source control > Undo > Pending Changes** to revert your changes.



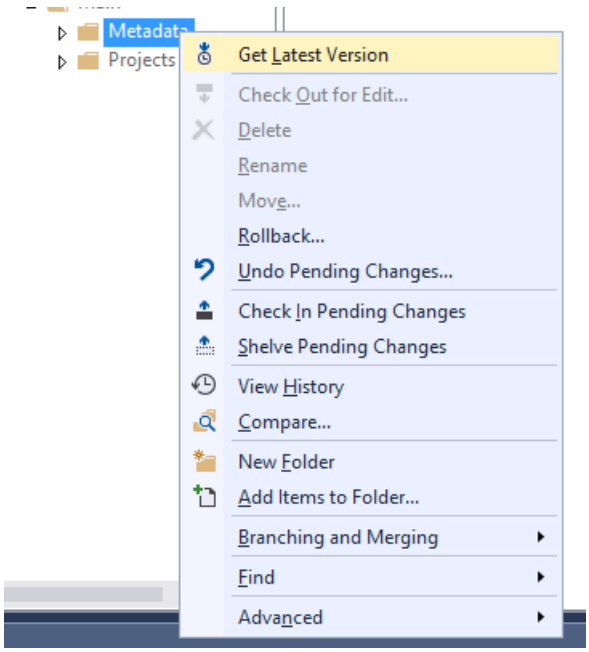
11. Confirm the undo on the next dialog and close the **diff** window.

Scenario 2: Synchronize models from source control

In this section, you will synchronize existing models and model elements from your Azure DevOps project. Synchronization is relevant in the following cases: 1) You have migrated your code from a previous version via LCS, or 2) another developer has checked-in a new model or new model elements and you would like to synchronize them to your development environment.

1. In Source Control Explorer, right-click on Metadata and select **Get Latest Version**. Getting the latest version will synchronize you local packages folder with the latest code.

2. Alternatively you can use the **Advanced** menu to synchronize specific build version or change sets.



3. Once synchronization is complete, and if the synchronization leads to synchronizing new models to your environment, you need to refresh your metadata from Visual Studio.

4. Go to **Dynamics 365 > Model Management > Refresh models**.

Organize TODO tasks in a project

This section describes how you can create a Visual Studio project out of tasks (TODO comments) embedded in your X++ code.

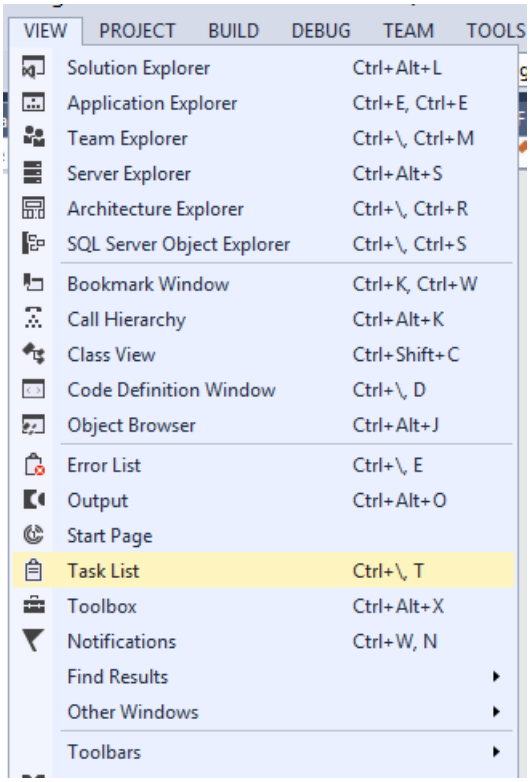
1. In **Solution Explorer**, select **Fleet Management Migrated > Code > Classes > FMDataHelper**, and then double-click **FMDataHelper**. The X++ code editor opens.

2. Enter a TODO comment (//TODO: my comment) inside any method.

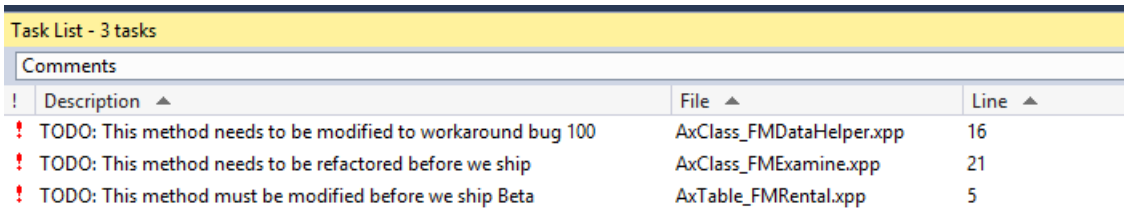
```
/// <summary>
/// Create a number sequence reference for the default scope.
/// </summary>
/// <param name = "_edt">The extended data type of the number seqeunce.</param>
private static void initializeNumberSequence(ExtendedTypeId _edt, boolean resetWizardDefaults)
{
    // TODO: This method needs to be modified to workaround bug 100
    NumberSequenceReference sequenceReference;
    NumberSequenceTable sequence;
    NumberSeqDatatype dataTypeObject;
    NumberSequenceDatatype dataTypeRecord;
    NumberSeqScope scope;
```

3. Open other Fleet Management classes or tables and add more TODO comments.

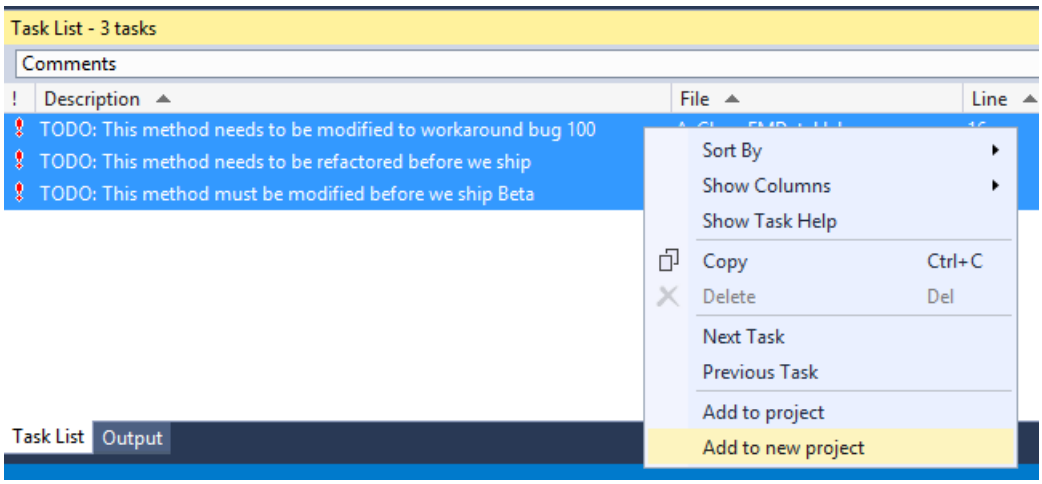
4. Rebuild the **FleetManagement Migrated** project.
5. Select **View** > **Task List**, to open the Visual Studio **Task List** window.



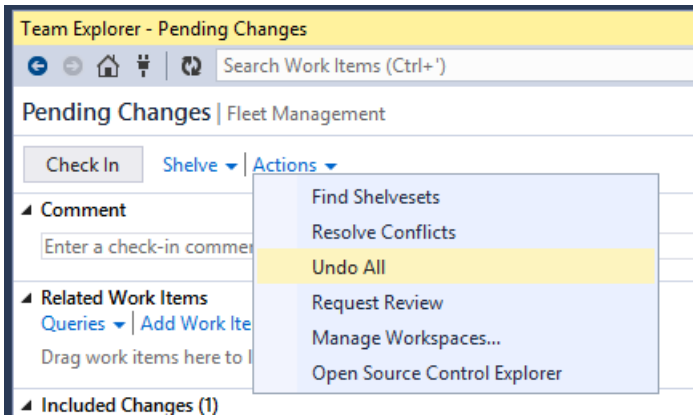
6. Select **Comments** from the drop-down list.



7. Select all TODO items, right-click, and select **Add to new project**.



8. Adding the items will open the **New project** dialog and enable you to create a new project that contains all of your TODOs.
9. You can save this project as a working project to manage your TODO list.
10. When you're finished, undo all of your pending changes in **Team Explorer**.



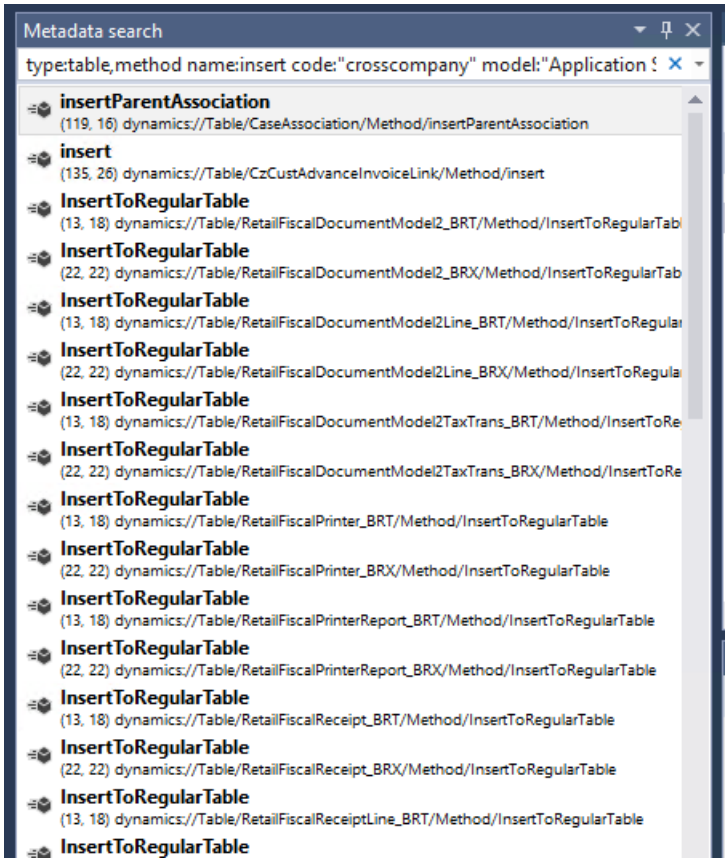
11. Click **File > Close Solution**, to close the FleetManagement solution.

Use metadata search and navigation tools to find elements and create projects

This section demonstrates how you can perform meta-data based searches throughout your application.

Use the Metadata search window

1. Click **Dynamics 365 > Metadata search**.
2. In the **Metadata search** window, in the **Search** field, enter the following text to find all of the table insert methods in the Application Suite model that contain a cross-company query.
   `type:table,method name:insert code:"crosscompany" model:"Application Suite"`.
3. Wait for the search to complete. It may take a while.



4. Double-click a result in the list. The code editor will open and place the cursor at the line that matches your search criteria.
5. Select several elements in the results list by holding down the Ctrl key for multiple selections, right-click, and then select **Add to new project**. Adding the elements will let you to create a new solution and

project containing the selected elements.

Try other search examples

You don't need to wait for the search to complete before you interact with search results. You can double-click results at any time to view the metadata or source code that matches your search criteria. The following are some suggested search examples:

- Find vertical tab controls defined in view mode and autowidth mode in the model Application Suite.

```
type:form,formtabcontrol property:arrangeMethod=Vertical,ViewEditMode=view,WidthMode=Auto
model:"Application Suite"
```

- Find all grid controls in forms that aren't editable and with the property heightmode = column.

```
type:form,formgridcontrol:allowedit=no,heightmode=column
```

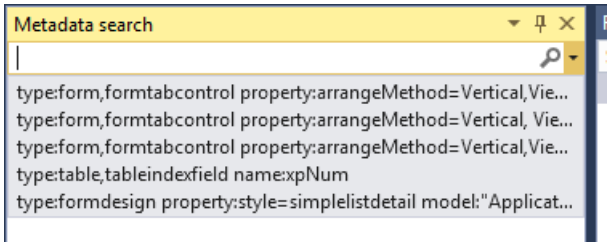
- Find all SimpleListDetail forms in the Application Suite model.

```
type:formdesign property:style=simplelistdetail model:"Application Suite"
```

- Find all tables that have an index field name that contains the keyword xpNum.

```
type:table,tableindexfield anem: xpNum*
```

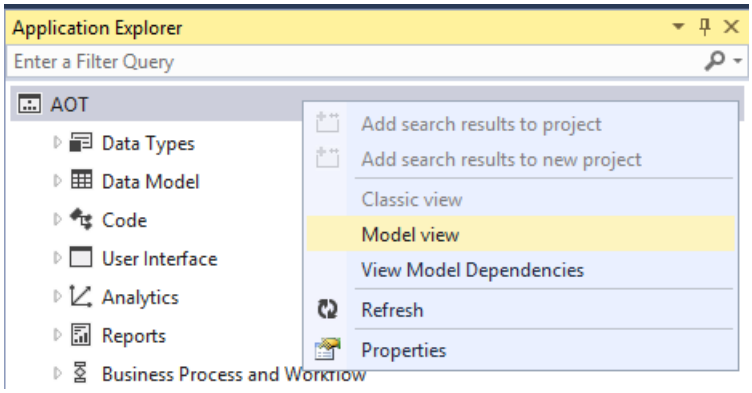
- Use the search bar drop-down menu to access previous searches.



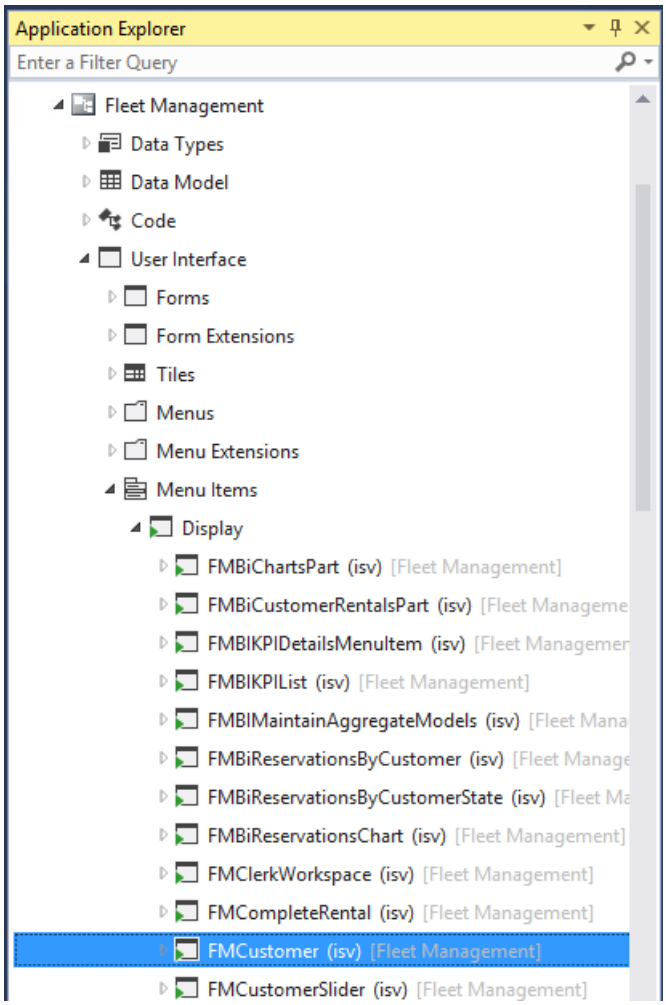
Navigate to related elements

This section highlights a feature that enables you to move from one element to a related element without having to find the related elements in **Application Explorer** or **Solution Explorer**.

1. Open **Application Explorer**, and switch the view to **Model View**.

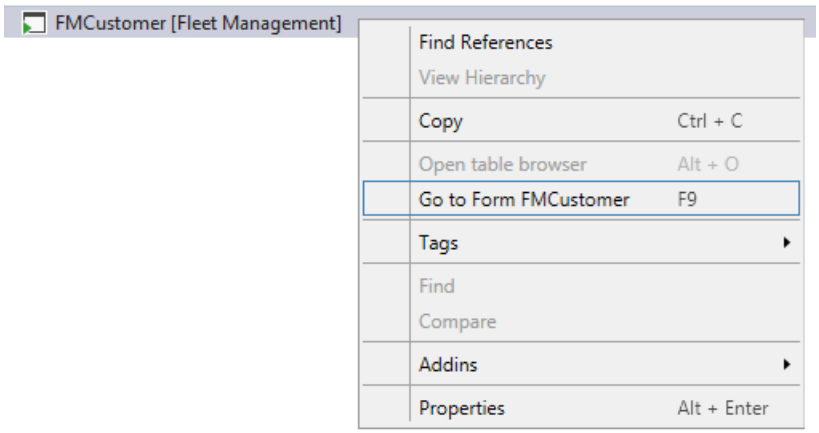


2. Under the **Fleet Management** model, click **User Interface** > **Menu items** > **Display Menu Items** > **FMCustomer**.



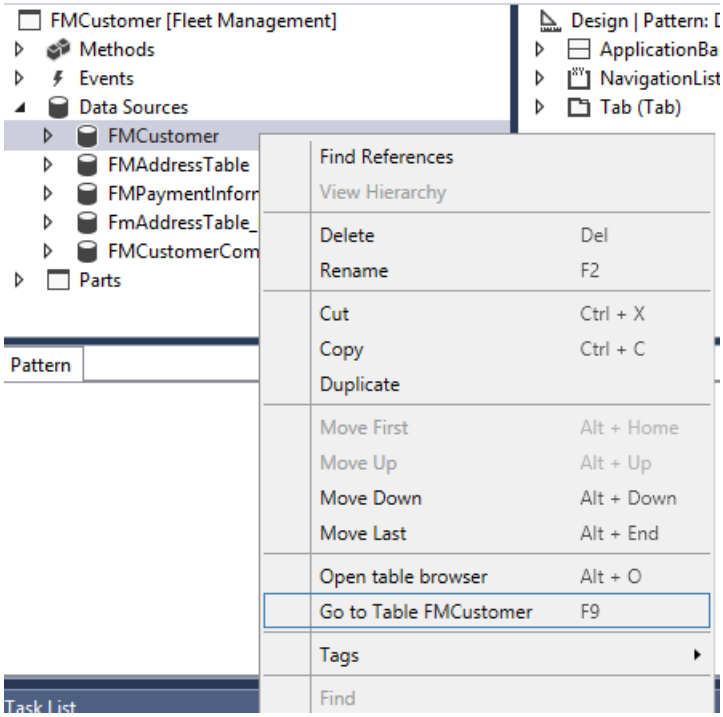
3. Right-click **FMCustomer**, and then select **Open designer**.

4. In the **FMCustomer** menu item designer, right-click the root node, and then select **Go to Form FMCustomer**.



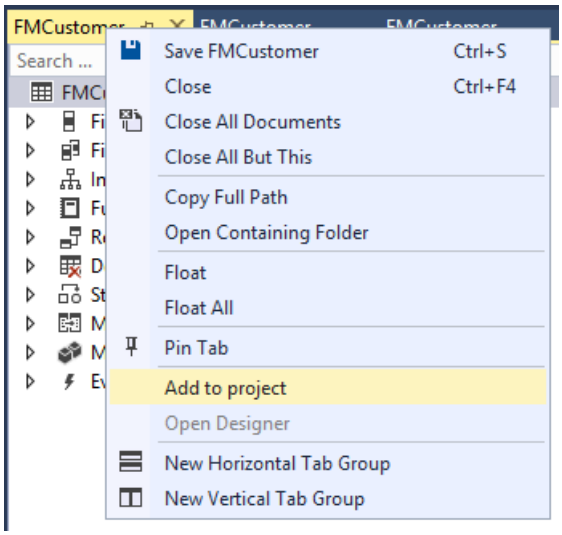
The **FMCustomer** form designer will open.

5. In the designer of the **FMCustomer** form, expand **Data sources**, right-click **FMCustomer**, and then select **Go to Table FMCustomer**



The **FMCustomer** table designer will open.

6. Using the same methodology, you can navigate to the EDT element that a table field references. **Tip**: Press F9 instead of opening the context menu. F9 will open the designer of the referenced element. **Tip**: You can add an element to the current project by right-clicking on the document tab and selecting **Add to project**.

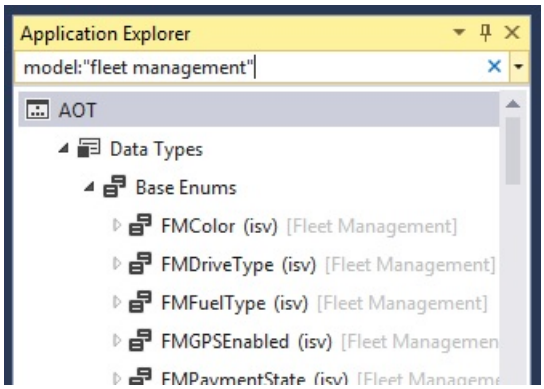


Use Application Explorer to create a project from a model

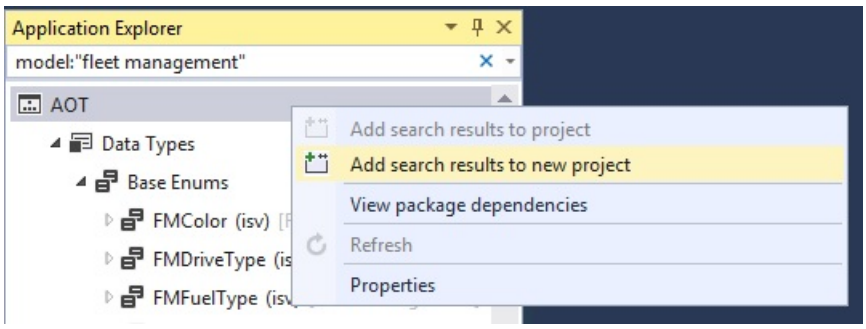
You can use Application Explorer to search for all or some elements of a model and create a project out of the search results.

1. Make sure the option to organize a project by element type is on. Go to **Dynamics 365** > **Options** > **Projects**.

2. Go to Application Explorer and search for elements in the desired model. For example, enter *model:"fleet management"* and click **Enter**.



3. When the search is complete, right-click the AOT root node and select **Add search results to new project.**



4. Specify your project properties in the new project dialog and click **OK** to create the project.

> **TIP**
>
> To create a project from search results, you can add any type, name, or other filters to your search as long as all results are in the same model. For example: *model:"Fleet Management" type:Table name:^FM* will return all tables in the Fleet Management model with a name starting with the letters FM.

> **NOTE**

>
> The survey will take about seven minutes. No personal data is collected (privacy statement).

Build automation that uses Microsoft-hosted agents and Azure Pipelines

2/18/2021 • 6 minutes to read • Edit Online

You can automate the process of building X++ code and creating deployable packages on any build agent that run on Microsoft Windows. These agents include Microsoft-hosted agents. This approach helps you avoid the setup, maintenance, and cost of deploying build virtual machines (VMs). It also lets you reuse the existing setup of build agents to run other .NET build automation.

> **NOTE**
>
> This feature is limited to compilation and packaging. There is no support for X++ unit testing (SysTest), database synchronization, or other features that require the runtime (Application Object Server [AOS]) or its components.

Prerequisites for building X++ code

Build projects

To use .NET tools for building X++ in Azure DevOps, the Microsoft Build Engine (MSBuild) and custom X++ targets are used. Your X++ source code repository must contain an X++ project for each package that you have to build. You can optionally use a solution file to group the projects, including C# project dependencies, and provide an explicit build order. If the repository doesn't already contain a project, you can create a project in Visual Studio.

> **NOTE**
>
> When you use an existing X++ project (rnrproj), make sure that you created it, or opened and saved it, by using Visual Studio tools on Platform update 27 or later.
>
> Although a package can contain multiple models, it must always be built in its entirety. Therefore, only one project for just one of the models is required to build the whole package. Additionally, although the project doesn't have to contain any objects, it can contain them.

NuGet packages

To build X++ code, the basic developer tools such as the X++ compiler (xppc.exe) are required. Additionally, any referenced packages, such as the Application Platform or Application Suite, must be available in a compiled format. To enable this process, the Shared asset library in Microsoft Dynamics Lifecycle Services (LCS) provides NuGet packages that are required to do an X++ build.

The following packages can be downloaded from the Shared asset library:

- **Microsoft.Dynamics.AX.Platform.CompilerPackage** – This package contains the X++ compiler and related tools that are required to do a build.
- **Microsoft.Dynamics.AX.Platform.DevALM.BuildXpp** – This package contains the compiled X++ code for the Application Platform and related modules. This code is optimized for building.
- **Microsoft.Dynamics.AX.Application.DevALM.BuildXpp** – This package contains the compiled X++ code for the Application Suite and related modules. This code optimized for building.

Download these packages from LCS, and add them to an Azure Artifacts feed in the Azure DevOps organization where the builds will run. For more information about how to create an Azure Artifacts feed and add NuGet

packages, see these topics:

- Get started with NuGet packages in Azure DevOps Services and TFS
- Create a feed
- Create and publish your own NuGet package

> **NOTE**
> Free Azure DevOps organizations have limited storage for Azure Artifacts. Consider deleting old and unused versions to free up storage capacity. For more information, see Sign up for Azure Artifacts.

To identify which packages should be used during the build, and where they can be found, you must provide a nuget.config file and a packages.config file during the build. We recommend that you create these files and add them to the source control repository. The files can be stored anywhere in source control, because the paths of these files are explicit inputs for the NuGet command.

The nuget.config file provides NuGet with the source feed where the packages can be found. The packages.config file specifies the packages and their versions. To build against a newer version, you just have to update the versions in the packages.config file. For more information, including a sample nuget.config file, see Restore Package Management NuGet packages in Azure Pipelines.

The following example shows a packages.config file for the three main packages that are required for a typical X++ build.

```
<?xml version="1.0" encoding="utf-8"?>
<packages>
    <package id="Microsoft.Dynamics.AX.Platform.DevALM.BuildXpp" version="7.0.5644.16778"
targetFramework="net40" />
    <package id="Microsoft.Dynamics.AX.Application.DevALM.BuildXpp" version="10.0.464.13"
targetFramework="net40" />
    <package id="Microsoft.Dynamics.AX.Platform.CompilerPackage" version="7.0.5644.16778"
targetFramework="net40" />
</packages>
```

Creating the pipeline

Azure DevOps provides pipelines that can be used to automate builds. There are two types of pipelines: YML and Classic. YML pipelines are available only when you use Git source control repositories. Classic pipelines must be used to build Team Foundation Version Control (TFVC) repositories. For more information, see Azure Pipelines.

This section describes the steps that are required in a pipeline to build X++ code. In the Dynamics365-Xpp-Samples-Tools GitHub repository, you can find a sample pipeline that can be imported into an existing Azure DevOps project.

Creating a basic build pipeline

A basic pipeline for compiling X++ requires only two steps:

1. Install the NuGet packages.
2. Build the solution or projects.

To simplify use of the extracted NuGet packages, consider using the **NuGet install** option and specifying the **-ExcludeVersion** NuGet command-line option. In that way, the extracted package paths can be used in the build, regardless of the version of the packages. Use the **NuGet Installer** task, and set the **Installation type** field to **Install**. Finally, specify the path of the packages.config and nuget.config files that you created earlier.

The following example of NuGet arguments will prevent a subfolder from being created for the package

versions and will extract the NuGet packages into **$(Pipeline.Workspace)\NuGets**.

```
-ExcludeVersion -OutputDirectory "$(Pipeline.Workspace)\NuGets"
```

To build X++ by using MSBuild, you must supply several arguments. In the pipeline step that builds the solution, you can specify these arguments in the **MSBuild Arguments** field.

ARGUMENT	DESCRIPTION
/p:BuildTasksDirectory	The path of the extracted Compiler Tools NuGet package, including the subfolders in the DevAlm folder.
/p:MetadataDirectory	The path of the X++ source code.
/p:FrameworkDirectory	The path of the extracted Compiler Tools NuGet package.
/p:ReferenceFolder	A semicolon-separated list of paths that contain binaries of X++ packages that are referenced and required for compilation (for example, Application Platform and Application Suite). If the code that will be compiled has multiple packages that reference each other, the output directory should also be included here.
/p:ReferencePath	A semicolon-separated list of paths that contain any non-X++ binaries that are referenced and required for compilation. You should include the location of the extracted Compiler Tools NuGet package, because it might contain required references.
/p:OutputDirectory	The path where the compiler will create folders and binaries.

The following example of MSBuild arguments assumes that the NuGet packages are installed in **$(Pipeline.Workspace)\NuGets**, the X++ source code is in **$(Build.SourcesDirectory)\Metadata**, and the output of the compiler should go in **$(Build.BinariesDirectory)**.

```
/p:BuildTasksDirectory="$(Pipeline.Workspace)\NuGets\Microsoft.Dynamics.AX.Platform.CompilerPackage\DevAlm"
/p:MetadataDirectory="$(Build.SourcesDirectory)\Metadata"
/p:FrameworkDirectory="$(Pipeline.Workspace)\NuGets\Microsoft.Dynamics.AX.Platform.CompilerPackage"
/p:ReferenceFolder="$(Pipeline.Workspace)\NuGets\Microsoft.Dynamics.AX.Platform.DevALM.BuildXpp\ref\net40;$(
Pipeline.Workspace)\NuGets\Microsoft.Dynamics.AX.Application.DevALM.BuildXpp\ref\net40;$(Build.SourcesDirect
ory)\Metadata;$(Build.BinariesDirectory)"
/p:ReferencePath="$(Pipeline.Workspace)\NuGets\Microsoft.Dynamics.AX.Platform.CompilerPackage"
/p:OutputDirectory="$(Build.BinariesDirectory)"
```

In the pipeline samples, variables for NuGet package names and paths are used to simplify these commands.

Creating a full pipeline that includes packaging

To be useful, the pipeline should include a versioning step and a packaging step. Before you can add these steps to a pipeline, the Dynamics 365 Finance and Operations Tools extension for Azure DevOps must be enabled and installed in the Azure DevOps account. For information about how to install an extension for an organization, see the Azure DevOps documentation.

A full pipeline should consist of at least the following steps:

1. Install the NuGet packages.
2. Update the model versions.
3. Build the solution or projects.

4. Install NuGet 3.3.0 or earlier on the agent. (This step is required for the step that creates the deployable package.)
5. Create the deployable package.
6. Publish the deployable package artifact as the build output.

For the deployable package to be created, NuGet must be readily available on the build agent. Therefore, the **NuGet tool installer** task in Azure DevOps must be run before the step that creates the package.

> **NOTE**
>
> Because of semantic versioning features in NuGet version 3.4 and later, make sure that the task installs version 3.3.0 or earlier. Currently, deployable package generation doesn't support semantic versioning.

Sample pipeline for X++ developers

In the Dynamics365-Xpp-Samples-Tools GitHub repository, you can find a sample pipeline that can be imported into an existing Azure DevOps project.

> **NOTE**
>
> Can you tell us about your documentation language preferences? Take a short survey.
>
> The survey will take about seven minutes. No personal data is collected (privacy statement).

Add license files to a deployable package in Azure Pipelines

2/18/2021 • 2 minutes to read • Edit Online

When you update an environment by using a deployable package, a license might be required for independent software vendor (ISV) or partner X++ solutions. ISVs can create pipelines to automatically include licenses in release or build pipelines. Customers can create their own pipelines to combine the ISV deployable package and the license file.

This topic assumes a working knowledge of Azure Pipelines.

> **NOTE**
>
> Before you can add these steps to a pipeline, the Dynamics 365 Finance and Operations Tools extension for Azure DevOps must be enabled and installed in the Azure DevOps account. For more information about how to install an extension for an organization, see Install extensions.

Adding the task to a pipeline

To add the task to your build for the YML or Classic pipeline, search the task list for **Add Licenses to Deployable Package**. The following table describes the options that are available for this task.

INPUT NAME	MANDATORY	DESCRIPTION
Search pattern for license files to add to the package	Yes	A list of license files on the build agent, or a search pattern for files on the build agent. To make the license files available on the build agent, you can add them to source control. Alternatively, they can be downloaded or generated in an earlier step of the pipeline. For more information, see File matching patterns reference.
Filename and path of the deployable package to update	Yes	The path and file name of an existing deployable package zip file that the license files should be added to.

> **NOTE**
>
> Can you tell us about your documentation language preferences? Take a short survey.
>
> The survey will take about seven minutes. No personal data is collected (privacy statement).

Create deployable packages in Azure Pipelines

2/18/2021 • 2 minutes to read • Edit Online

If you want to deploy customizations to an environment, a deployable package is required in Microsoft Dynamics Lifecycle Services (LCS). You can create this package by using Azure Pipelines during a build or release process.

This topic assumes a working knowledge of Azure Pipelines.

> **NOTE**
>
> Before you can add these steps to a pipeline, the Dynamics 365 Finance and Operations Tools extension for Azure DevOps must be enabled and installed in the Azure DevOps account. For more information about how to install an extension for an organization, see Install extensions.
>
> This Azure DevOps task requires that the X++ compiler tools be available on the agent. Either run this task on a build virtual machine (VM) agent, or use the Compiler Tools NuGet package. For more information about the NuGet package and how to install it in a pipeline, see Build automation using Microsoft-hosted agents and Azure Pipelines.

Add the task to a pipeline

To add the task to the build of your YML or Classic pipeline, search the task list for **Create Deployable Package**. The following table describes the options that are available for this task.

INPUT NAME	MANDATORY	DESCRIPTION
X++ Tools Path	Yes	The path of the location of the X++ tools. This location is either the **PackagesLocalDirectory\bin** folder location on a build VM, or the location of the extracted NuGet file of the Compiler Tools NuGet package.
Location of the X++ binaries to package	Yes	The path that contains the folders that contain all the binaries for the X++ packages (modules) that you want to include in the deployable package. If this task is used in a build pipeline, this folder is typically the same as the compiler output folder.
Search pattern for binaries to package	Yes	Provide a name matching pattern for X++ package (module) names inside the path that is specified in the **Location of the X++ binaries to package** option. You can also specify a list of names instead of search patterns, or you can specify exclusion filters so that, for example, test packages aren't included. For more information, see File matching patterns reference.

INPUT NAME	MANDATORY	DESCRIPTION
Filename and path for the deployable package	Yes	The path and file name of the deployable package. The output file is a zip file, and the file name typically includes version information to make the file easy to identify.

NuGet dependency

When this task is run on the build VM, NuGet is already available, and no action is required. However, when this task is run on hosted agents or other private agents, NuGet must be installed. In this case, Azure DevOps has the NuGet Tool Installer task that you can run before you run the task to create the package.

> **NOTE**
>
> Because of the introduction of semantic versioning in NuGet version 3.4 and later, you must install version 3.3.0 or earlier.

X++ model-versioning in Azure Pipelines

2/18/2021 • 2 minutes to read • Edit Online

During build automation, X++ model versions can be updated so that they match or are linked to the build number of the pipeline. These updates make it easier for customers to identify the version of the X++ packages that they are running. They also let developers track versions back to the build pipeline and the version of the source code files.

This topic assumes a working knowledge of Azure Pipelines.

> **NOTE**
> Before you can add these steps to a pipeline, the Dynamics 365 Finance and Operations Tools extension for Azure DevOps must be enabled and installed in the Azure DevOps account. For more information about how to install an extension for an organization, see Install extensions.

Add the task to a pipeline

To add the task to the build of your YML or Classic pipeline, search the task list for **Update Model Version**. The following table describes the options that are available for this task.

INPUT NAME	MANDATORY	DESCRIPTION
X++ Source Location	Yes	The path of a parent folder that contains X++ source code. The **Descriptor Search Pattern** option will be run in this path and subfolders. The default value, **$(Build.SourcesDirectory)**, points to the root of the source code repository.
Descriptor Search Pattern	Yes	Provide a file matching pattern to find the descriptor files inside the path that is specified in the **X++ Source Location** option. You can also specify a list of full paths of descriptor files instead of search patterns. For more information, see File matching patterns reference.
Lowest Layer to Update	Yes	When using search patterns, this task may find descriptors for ISV or partner code in your source control. Those descriptor versions should likely not be updated. This option allows you to define an additional filter to define the lowest layer that the task will update.

INPUT NAME	MANDATORY	DESCRIPTION
Version number in format #.#.#.# to update	Yes	The version number to write into the descriptors. Note that the format must consist of four digits that are separated by periods (.). By using the build ID or build number, you allow for traceability. Note that the default build number isn't in the correct format. You can change the format in the classic editor, under **Options** > **Build number format**. You can also change it by adding a `name:` tag at the top of the YML file. An example of a valid build number that uses the year, month, and date, and also the build count revision number, is `$(Date:yy.MM.dd)$(Rev:.r)`. For more information, see Configure run or build numbers.

Download assets by using Azure Pipelines

2/18/2021 • 2 minutes to read • Edit Online

You can automate the download of assets from the Asset library in Microsoft Dynamics Lifecycle Services (LCS) by using the **Deploy Lifecycle Services (LCS) Asset Download** task in Azure DevOps.

This topic assumes that you have a working knowledge of Azure Pipelines.

> **NOTE**
>
> Before you can add these steps to a pipeline, the Dynamics 365 Finance and Operations Tools extension for Azure DevOps must be enabled and installed in the Azure DevOps account. For more information about how to install an extension for an organization, see Install extensions.

Add the task to a pipeline

To add the task to the build of your YML or Classic pipeline, search the task list for **Dynamics Lifecycle Services (LCS) Asset Download**.

The following table describes the options that are available for this task.

INPUT NAME	MANDATORY	DESCRIPTION
LCS Connection	Yes	Select or create a service connection to LCS. For more information, see Create an LCS connection in Azure Pipelines.
LCS Project ID	Yes	Enter the ID of the project in LCS that contains both the asset to deploy and the target environment. You can find the project ID at the end of the URL of your project's dashboard.
Path to download to	Yes	Enter the path to download the asset to.

INPUT NAME	MANDATORY	DESCRIPTION
Search Pattern	Yes	Select the type of search pattern that should be used to find the asset in the Asset library in LCS. Depending on the value that you select, the following options are available: • **Asset ID (guid)** – If you select this value, in the **LCS File Asset Id(s)** field, enter the asset ID or a semicolon-separated list of asset IDs. Asset IDs are globally unique identifiers (GUIDs). • **Name** – If you select this value, in the **LCS File Asset Type** field, select the asset type. Then, in the **LCS File Asset Name** field, specify the name to search for. You can use an asterisk (*) as a wildcard character in the name. For example, you might enter **MyPackage***.

After a successful download, an output variable can be used to capture a list of the file paths. If there are multiple files, a semicolon-separated list of file paths is assigned to the output variable. For more information about output variables in Azure DevOps, see Use output variables from tasks.

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Upload assets by using Azure Pipelines

2/18/2021 • 2 minutes to read • Edit Online

You can automate the upload of assets to the Asset library in Microsoft Dynamics Lifecycle Services (LCS) by using the **Deploy Lifecycle Services (LCS) Asset Upload** task in Azure DevOps. This task is available only in **Releases** pipelines.

This topic assumes you have a working knowledge of Azure Pipelines.

> **NOTE**
> Before you can add these steps to a pipeline, the Dynamics 365 Finance and Operations Tools extension for Azure DevOps must be enabled and installed in the Azure DevOps account. For more information about how to install an extension for an organization, see Install extensions.

Add the task to a pipeline

To add the task to the build of your YML or Classic pipeline, search the task list for **Dynamics Lifecycle Services (LCS) Asset Upload**.

The following table describes the options that are available for this task.

INPUT NAME	MANDATORY	DESCRIPTION
LCS Connection	Yes	Select or create a service connection to LCS. For more information, see Create an LCS connection in Azure Pipelines.
LCS Project ID	Yes	Enter the ID of the project in LCS that contains both the asset to deploy and the target environment. You can find the project ID at the end of the URL of your project's dashboard.
Type of asset	Yes	Select the type of asset to upload.
File to upload	Yes	Enter the path of the file that you want to upload into the Asset library in LCS.
LCS Asset Name	No	Enter the name to show for the asset in the Asset library. If you don't enter a name here, the file name will be used.
LCS Description	No	Enter the description to show for the asset in the asset details.
Wait for Validation	No	For asset types that require validation, use this check box to instruct the task to wait until validation of the asset has either succeeded or failed.

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Deploy assets by using Azure Pipelines

2/18/2021 • 2 minutes to read • Edit Online

You can use the **Deploy Lifecycle Services (LCS) Asset Deployment** task in Microsoft Azure DevOps to automate the deployment of assets that are stored in the Asset library in Microsoft Dynamics Lifecycle Services (LCS) to specific environments. However, this task has the following limitations that you should consider:

- The task is available only in **Releases** pipelines.
- The deployment of software deployable packages to production environments can't be automated.
- Software deployable packages can't be deployed to build environments.
- Software deployable packages can't be deployed to local business data (LBD) environments on-premises.

This topic assumes that you have a working knowledge of Azure Pipelines.

> **NOTE**
> Before you can add these steps to a pipeline, the Dynamics 365 Finance and Operations Tools extension for Azure DevOps must be enabled and installed in the Azure DevOps account. For more information about how to install an extension for an organization, see Install extensions.

Add the task to a pipeline

To add the task to the build of your YML or Classic pipeline, search the task list for **Dynamics Lifecycle Services (LCS) Asset Deployment**. If your target environments include self-service environments, be sure to select task version 1.* or later.

The following table describes the options that are available for this task.

INPUT NAME	MANDATORY	DESCRIPTION
LCS Connection	Yes	Select or create a service connection to LCS. For more information, see Create an LCS connection in Azure Pipelines.
LCS Project ID	Yes	Enter the ID of the project in LCS that contains both the asset to deploy and the target environment. You can find the project ID at the end of the URL of your project's dashboard.
LCS Environment ID	Yes	Enter the ID of the target environment. The environment ID is a globally unique identifier (GUID) that you can find on the environment's details page, under **Environment Details** > **Environment ID**.

INPUT NAME	MANDATORY	DESCRIPTION
LCS File Asset ID	Yes	Enter the asset ID of the software deployable package to deploy. The asset ID is a GUID that you can find in the Asset library. Select the row of the asset that you want to deploy, and then, under **Additional Details**, look in the **Asset ID** field. Typically, this ID comes dynamically from other pipeline steps, such as the Dynamics Lifecycle Services (LCS) Asset Upload task.
Name for the update	Yes	Enter the name that is shown for the update in the environment history in LCS.
Wait for Completion	Cleared (No)	Use this check box to instruct the task to wait until the deployment of the asset has either succeeded or failed. If it's cleared (**No**), the task will only start the deployment. If the task is instructed to wait, a pipeline time-out might occur during long-running deployments. For more information about time-out options, see Timeouts.

Create an LCS connection in Azure Pipelines

2/18/2021 • 3 minutes to read • Edit Online

The Dynamics 365 Finance and Operations Tools extension for Microsoft Azure DevOps has several pipeline tasks that let you perform actions in Microsoft Dynamics Lifecycle Services (LCS). For example, you can upload assets, download assets, and service an environment. For the connection with LCS to work, you must set up a new service connection in Azure DevOps. This service connection provides the authentication details that are required to connect to LCS. For more information about service connections in Azure DevOps, see Service connections.

This topic assumes that you have a working knowledge of Azure Pipelines.

> **NOTE**
>
> Before you can add these steps to a pipeline, the Dynamics 365 Finance and Operations Tools extension for Azure DevOps must be enabled and installed in the Azure DevOps account. For more information about how to install an extension for an organization, see Install extensions.

Prerequisites

You must have the credentials for a user who has access to one or more LCS projects that you want to interact with from Azure DevOps. Make sure that this user has successfully signed in to LCS before, and has opened the dashboard for the projects that you want to interact with.

> **NOTE**
>
> LCS doesn't support service-to-service authentication. Therefore, only regular user credentials (that is, a user name and password) can be used. Because the pipelines don't run interactively, multifactor authentication must not be set up for the account that you use. We recommend that you set up a separate user account that has limited access and strong credentials that can regularly be rotated for security purposes.

To enable direct connections from Azure DevOps to LCS on a user's behalf, you must register an application in your Azure Active Directory (Azure AD).

1. Follow the instructions in Quickstart: Register an application with the Microsoft identity platform, and add a new redirect URI:
   a. Select **Public client/native (mobile & desktop)**.
   b. Enter any valid URI, such as `http://localhost`.
2. Add permissions to the application registration to access the LCS web APIs. Follow the instructions in Add permissions to access your web API. When you request the API permissions, select **APIs my organization uses**, and search for **Dynamics Lifecycle services**.
3. Make sure that the account that you will use has given consent for the application registration in Azure AD. Follow the instructions in Configure the way end-users consent to an application in Azure Active Directory. You can either enable a specific user or grant admin consent for the whole tenant.

Create the Dynamics Lifecycle Services service connection

You can create a new service connection either directly from a pipeline task or from your project's settings page.

For more information about how to create service connections, see Create a service connection. In the dialog box for the **Dynamics Lifecycle Services** service connection, provide the following information:

- **Authentication Endpoint** – The default value works for all Azure AD tenants in the Azure cloud. If your Azure AD is in a national cloud, see National clouds to find the correct authentication endpoint.
- **Lifecycle Services API Endpoint** – Provide the endpoint.
- **Username** – Provide the email alias for the user credentials.
- **Password** – Provide the password for the user credentials.
- **Application (Client) ID** – Provide the ID that was previously created for your application registration in Azure AD.
- **Service connection name** – Provide a meaningful name for the connection. This name will appear in the connection field for pipeline tasks that require an LCS connection.
- **Description** – Provide an optional description of this connection.

Update a legacy pipeline in Azure Pipelines

2/18/2021 • 2 minutes to read • Edit Online

> **NOTE**
> This documentation does not apply to the new build pipeline, even if you run it on the build virtual machine.

> Even though **Visual Studio 2017** is available on virtual machines deployed with version 10.0.13 or later, the build scripts needed to support unit testing using **VSTest** require version 10.0.15.

An **Azure Pipelines** pipeline explicitly specifies the versions of **Visual Studio** tools such as **MSBuild** and **VS Test**. To continue supporting newer versions of these products, new virtual machines will be deployed with newer versions of **Visual Studio** pre-installed. Any existing pipelines need to be manually updated to use the newer version.

Determine if your pipeline needs to be updated

Build and development virtual machines deployed with version 10.0.13 include **Visual Studio 2017**. Support for Visual Studio 2015 will be deprecated in the April 2021 release. If your build virtual machine does not include **Visual Studio 2017** you must plan to deploy a new build virtual machine with version 10.0.13 or later, or consider using the new hosted build pipeline.

If your build virtual machine has Visual Studio 2017 installed, you can use the newer versions of **MSBuild** and **VS Test**. If your pipeline was created by a virtual machine deployment prior to version 10.0.13, you will have to manually update the pipeline.

Finally, you can check your build pipeline on the **Build the solution** step. The **MSBuild Version** property indicates the version of **Visual Studio** in use.

MSBUILD VERSION	VISUAL STUDIO VERSION
MSBuild 14.0	Visual Studio 2015
MSBuild 15.0	Visual Studio 2017

Updating the Azure Pipelines pipeline

> **NOTE**
> To update an **Azure Pipelines** pipeline to use **Visual Studio 2017**, ensure your build virtual machine has been updated to version 10.0.15 or newer.

The following four properties, in three tasks in the pipeline, need to be updated.

TASK NAME	TASK PROPERTY	OLD VALUE	NEW VALUE
Build the solution	MSBuild Version	MSBuild 14.0	MSBuild 15.0
Database Sync	MSBuild Version	MSBuild 14.0	MSBuild 15.0
Execute Tests	Test platform version	Visual Studio 2015	Visual Studio 2017

TASK NAME	TASK PROPERTY	OLD VALUE	NEW VALUE
Execute Tests	Other console options	`/Platform:X64 /InIsolation /UseVsixExtensions:true`	`/Platform:X64 /InIsolation /TestAdapterPath:"$(VsixExtensionFold`

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

End-to-end scenario for the Fleet Management sample application

2/18/2021 • 8 minutes to read • Edit Online

This tutorial walks you through an end-to-end scenario that the Fleet Management sample application is designed to support.

In this tutorial, you'll take a tour of the Fleet Management sample. The overviews in this tutorial provide some background knowledge and contextual info. You'll walk through an end-to-end scenario that this sample application is designed to support. This is information that you should have before proceeding to other tutorials.

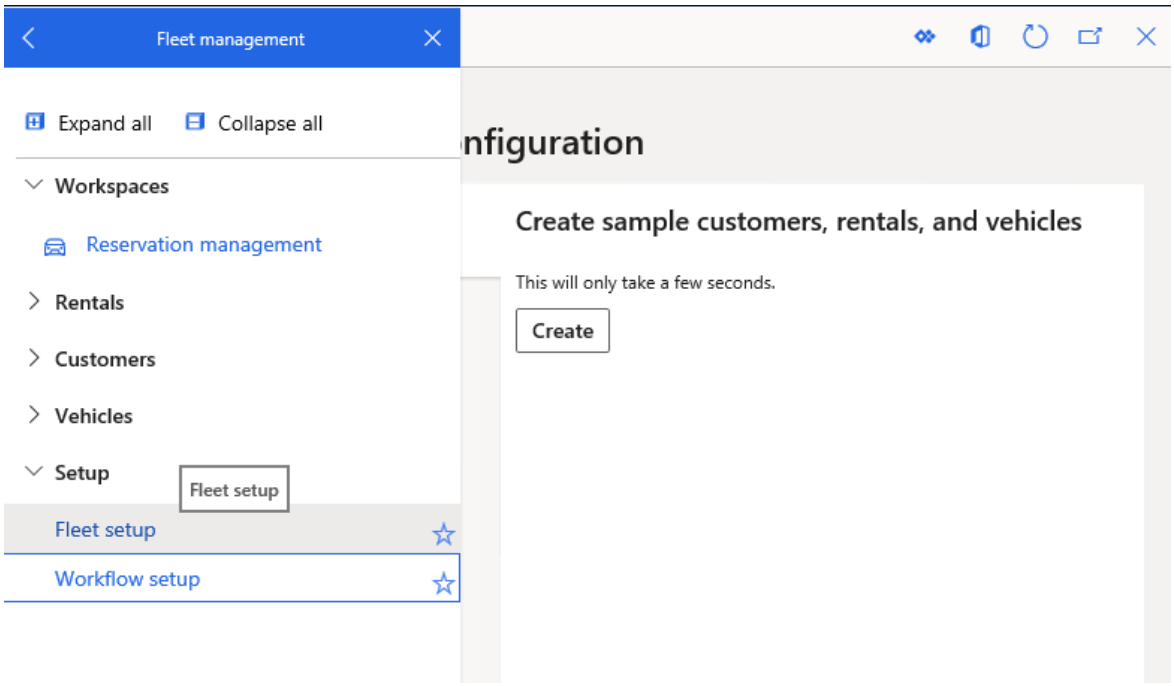
Prerequisite

- You must first be provisioned as an end user before you start this tutorial.
- This tutorial mainly explores the FleetManagement Migrated project and the application that it builds.

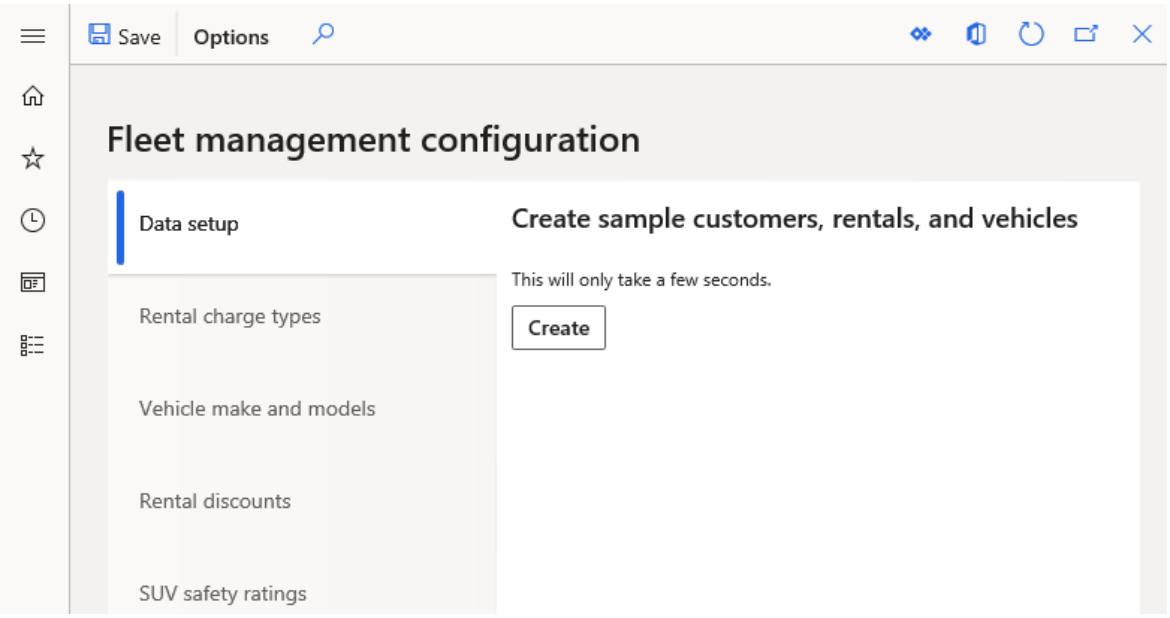
Installing the demo data

To work with the sample, you must install the provided demo data.

1. In the virtual machine (VM), open Internet Explorer and navigate to the application's base URL.
2. Sign in.
3. On the dashboard, open the navigation pane and go to **Fleet Management** > **Setup**> **Fleet setup**.



4. On the **Data setup** tab, select **Create**.



5. If you're prompted to reload the demo data, click **Yes**.
6. When the data is finished loading, select **Close**.

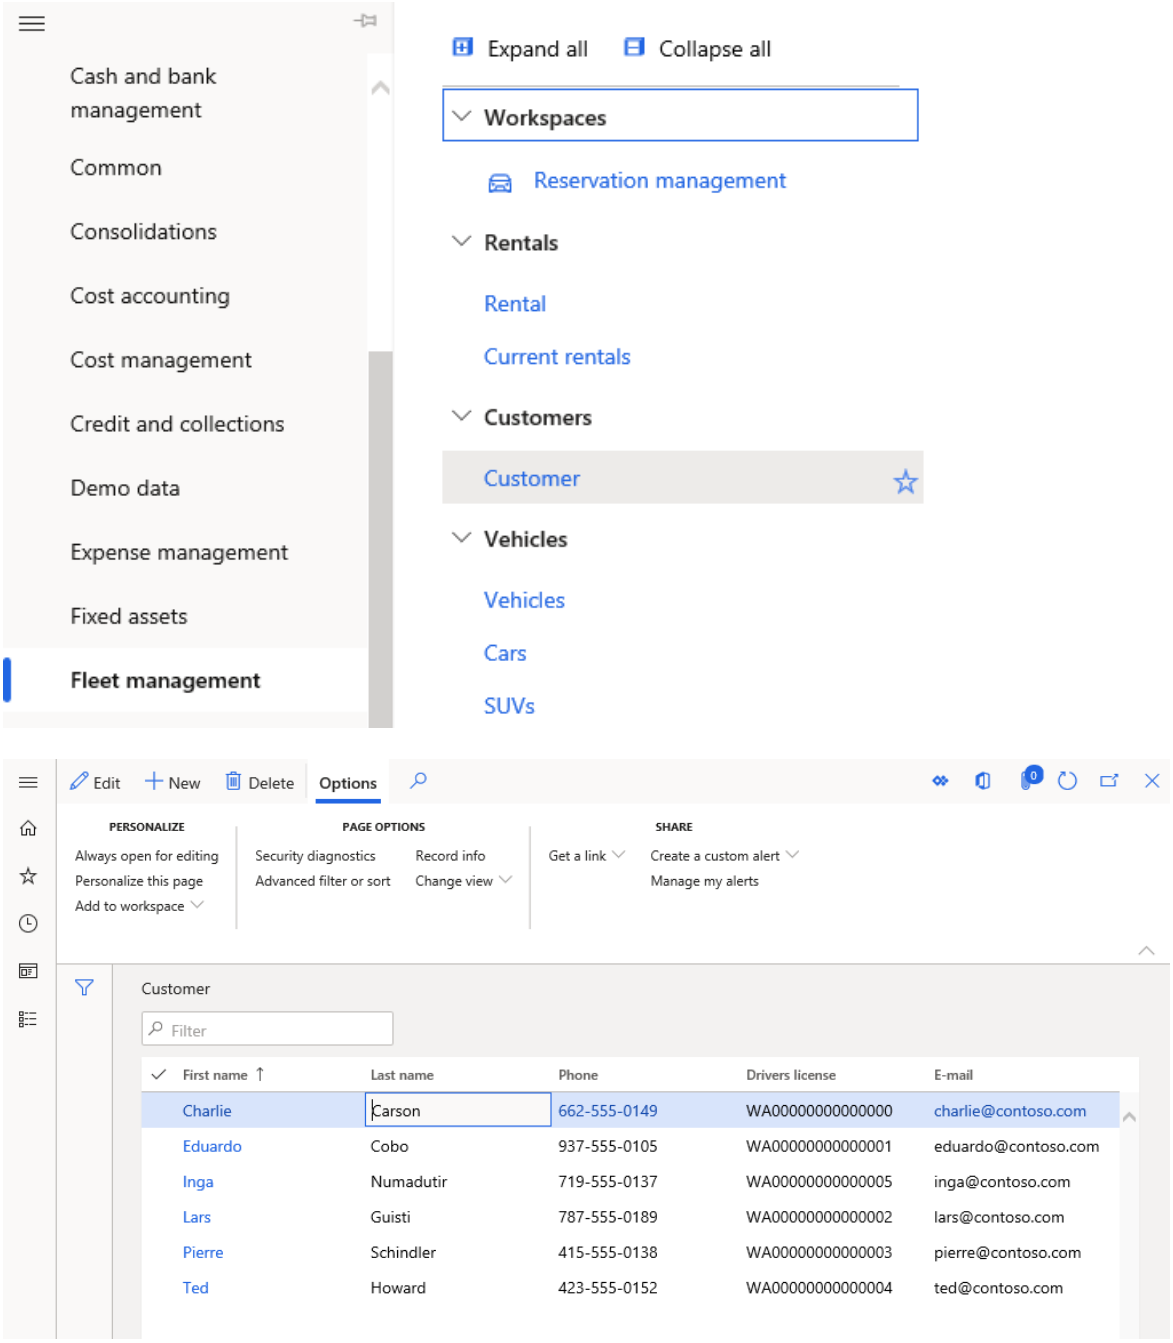
Use the Fleet Management application to rent a vehicle

Remember that you're working with the migrated app in this section. The forms that you see are directly ported from the Microsoft Dynamics AX 2012 version of the sample. Although they have been modified and restyled, they have not been reimagined.

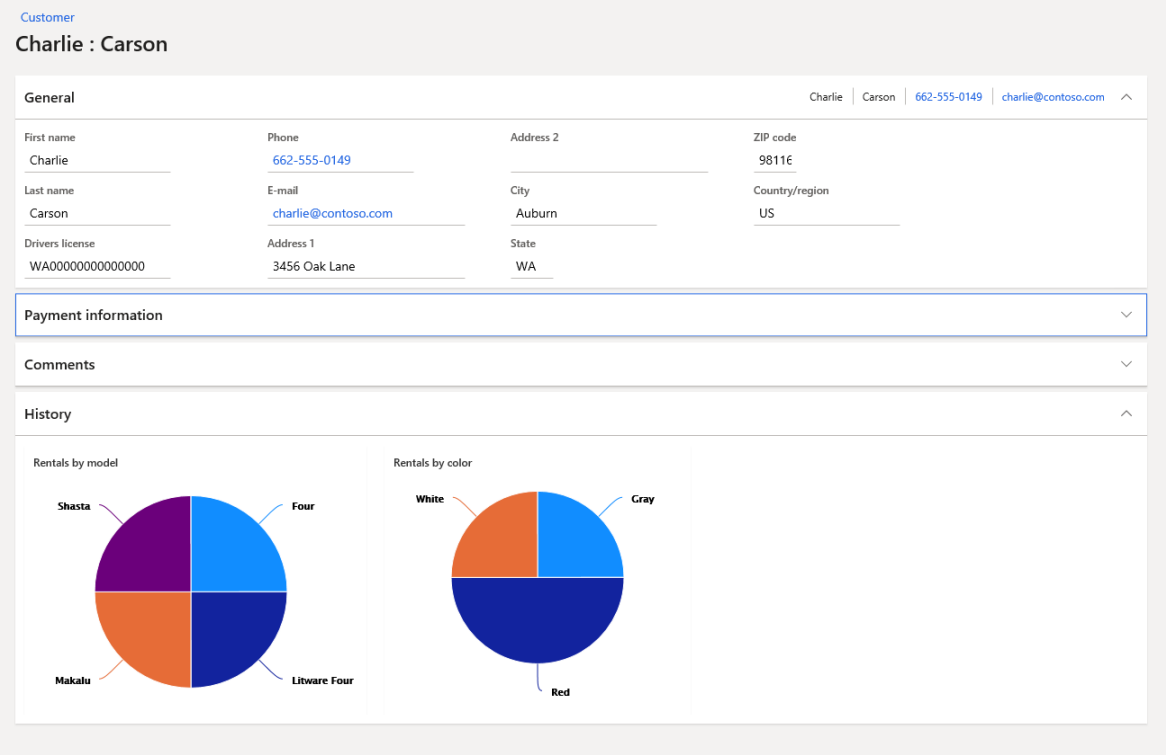
1. Open Internet Explorer, and sign into the Finance and Operations application.
2. To return to the **Dashboard**, select the product name in the top-left corner of the page.

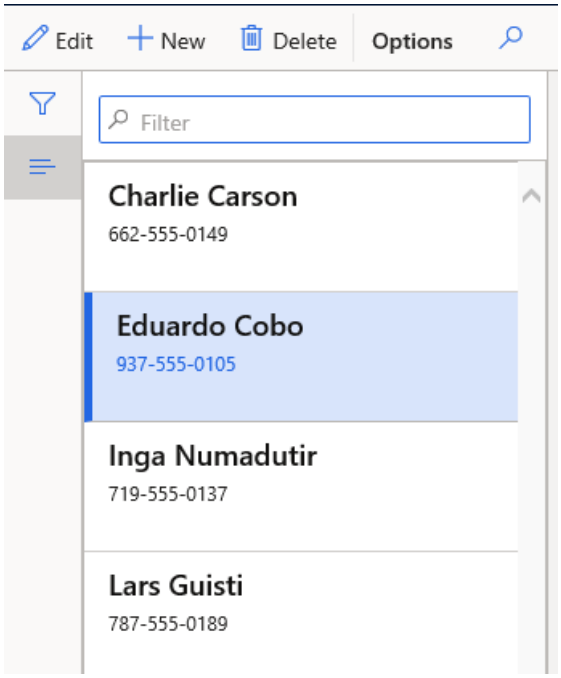
   The dashboard is the main working hub. You can see the various tiles, organized into sections, which lead to parts of the application. The dashboard is designed for horizontal scrolling, which is an optimization for working well on modern devices. The button to the right of the dashboard shows the navigation bar.
3. From the Dashboard, open the navigation bar and go to **Fleet Management** > **Customers** > **Customer**.



4. To switch to the **Details** view, select a value in the **First Name** column. This view shows detailed information for a single customer.

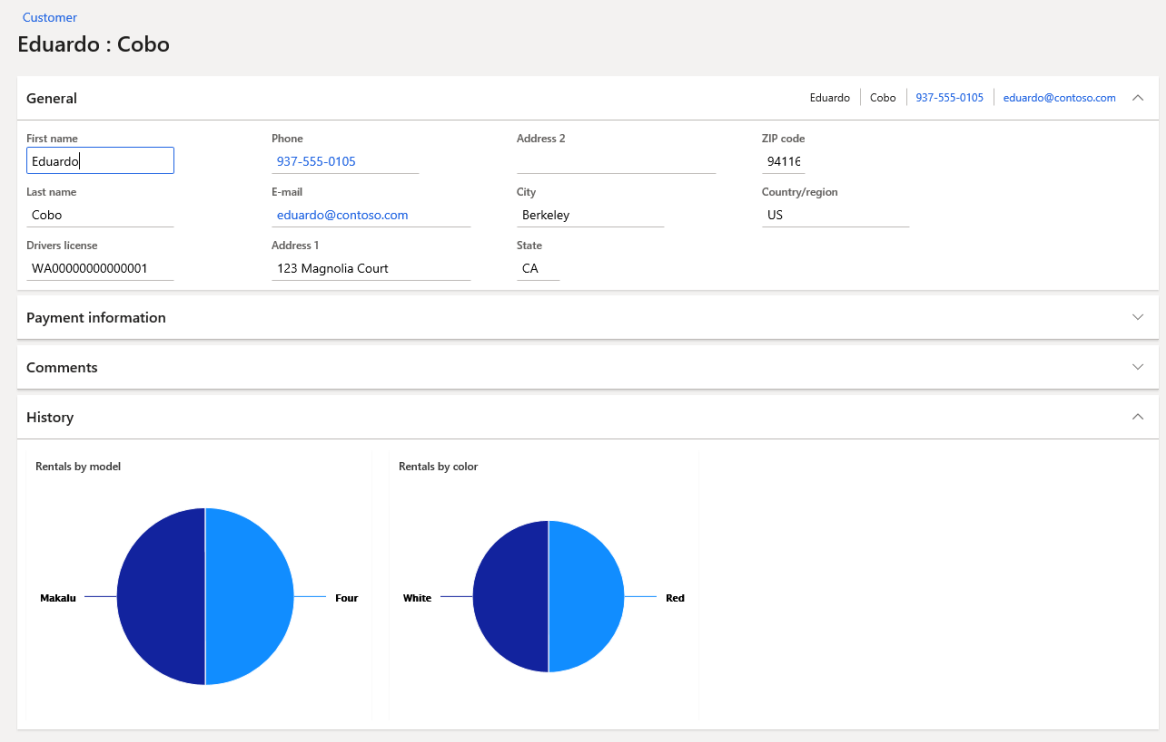


5. Click **Show list** to show the navigation list.



6. Click the various customer names in the navigation list in the side pane, and watch as the detailed information about each customer changes.

7. Select the customer **Eduardo Cobo**. You'll notice the charts update to indicate Eduardo's previous rental preferences.



8. Hover over the pie slices to see the details. You'll notice that, in the past, Eduardo has often rented red SUVs. This might give the sales clerk a cue to look for available red SUVs the next time Eduardo makes a reservation. This is a simple example of proactively providing insights.

9. Add yourself as a customer.

   - On the Action Pane, click **New**.

   - Fill in the form to add yourself as a customer. Make sure that you provide your name, a 16-digit number in the credit card field, and address information, at a minimum. **Note**: You don't have to take any action to save a new record.

10. Create a new rental.

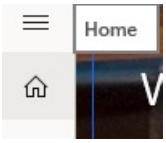
    a. On the navigation bar, go to **Fleet management** > **Rentals** > **Rental**.
    b. In the **Rental** form, on the Action Pane, click **New.**
    c. In the **Vehicle** field, select a vehicle.
    d. In the **Customer** field, select your name.
    e. In the **To** field, pick an end date.
    f. In the **Start** field, enter **35,000**.
    g. In the **Pickup** field, enter **Full**.
    h. When you are done, click **Save**.

11. Start the rental period.

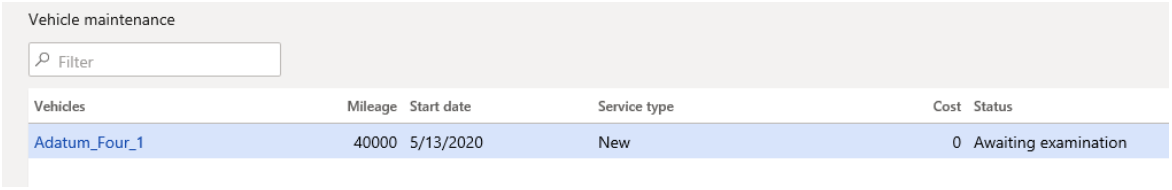
    a. On the Action Pane, click **Start rental**.
    b. In the dialog box, verify the values in the fields and click **OK**.

Use Fleet Management to run a workflow

1. Click the **Home** icon to return to the dashboard.

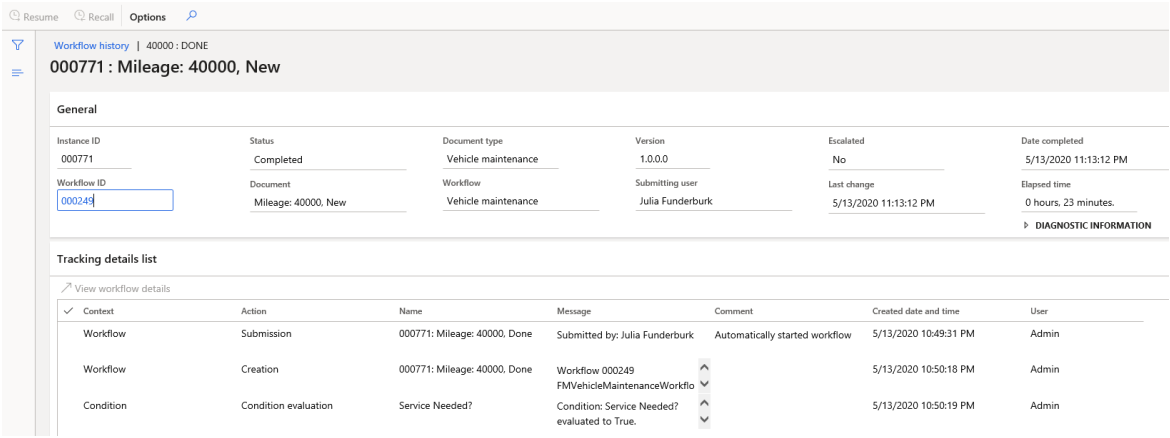


2. Find the **Reservation Management** tile and select it to open the Reservation Management workspace.
3. Click **Current rentals**.
4. On the **Rentals** form, click the ID of your rental.
5. On the Details view of the **Rentals** form, on the Action Pane, click **Complete rental**.
6. In the **New mileage** field, enter **40,000**, and then click **OK**.
7. Click the **Home** icon to return to the dashboard.
8. On the navigation bar, navigate to **Fleet management** > **Vehicles** > **Vehicle Maintenance**. In the **Vehicle Maintenance** form, the **Status** field shows that your rental is awaiting examination by the service department.



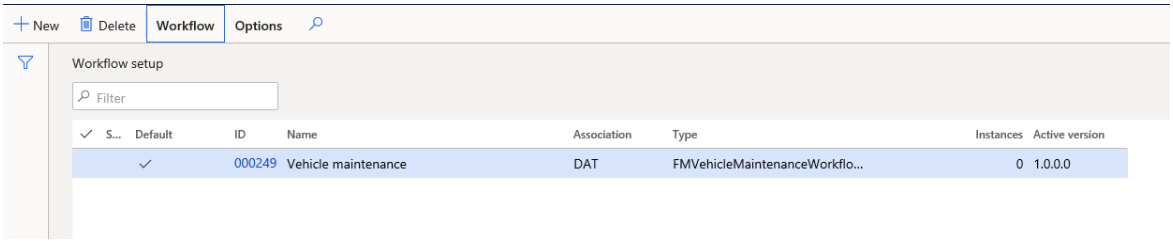
> **NOTE**
>
> You might need to wait up to two minutes for the batch framework to change the status of the vehicle. On the Action Pane, click **Refresh** periodically to update the view, until you see the status change. Keep in mind that a different person usually handles each step in a workflow; the brief delay introduced by the batch framework is not an issue in a real-world application.

9. Select the row that contains your rental. On the Action Pane, click **Workflow**, and then click **Examination complete**. You may need to refresh the page to get the full set of options under Workflow.
10. Enter a comment, and then click **Examination complete**.
11. You might again need to wait up to two minutes for the batch framework to process the change. On the Action Pane, click **Refresh** periodically, until you see the **Status** field change. Notice that the vehicle now has a status of **Awaiting Service**.
12. Optionally, you can continue to repeat these workflow steps to take the vehicle through the service and cleaning phases. After cleaning is completed, the final status is **Done**.
13. Click **Workflow**, and then click **View history**. The **Workflow history** form provides information about the vehicle workflow.
14. Click **Tracking details** to see the activities.



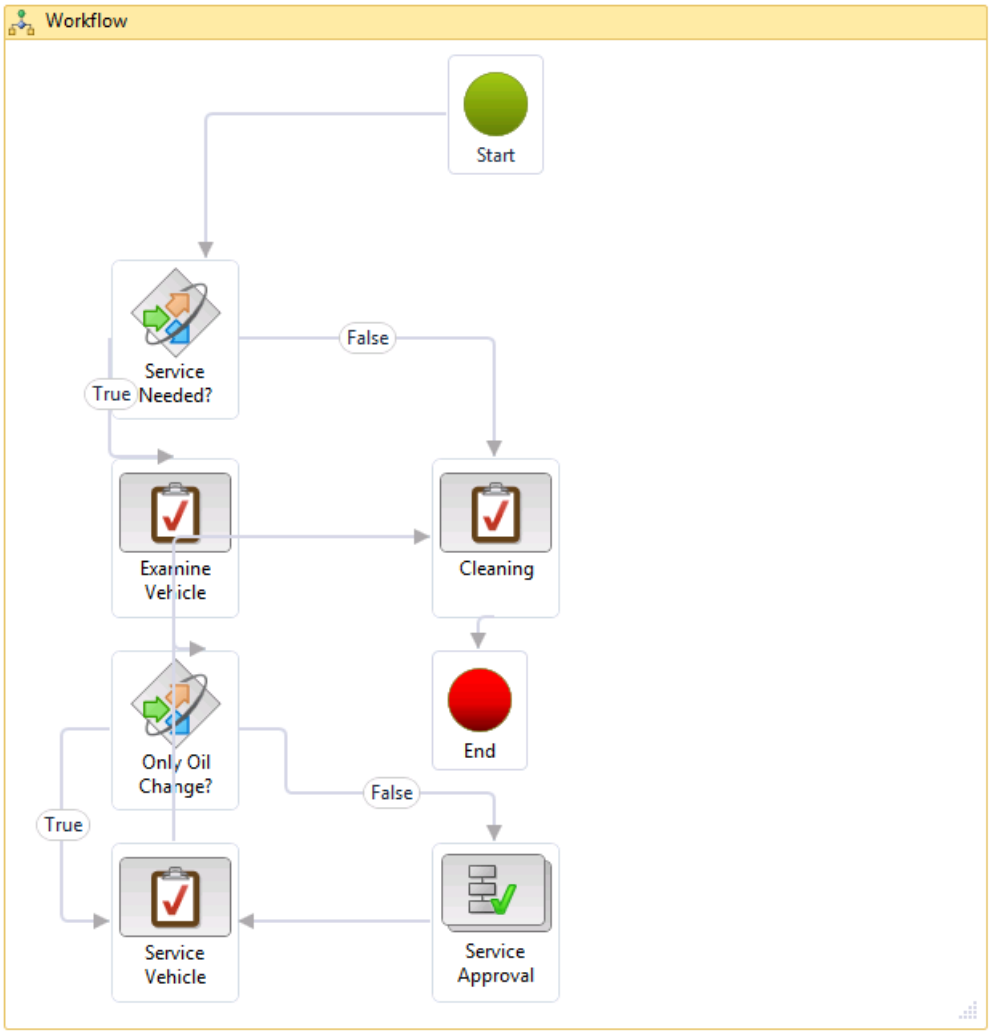
To view the setup behind the workflow

1. On the dashboard, navigate to **Fleet Management** > **Setup** > **Workflow setup**. The **Workflow Setup** page shows the list of workflows.



2. In the **Workflow ID** column, click the ID of your vehicle maintenance workflow.

3. Accept any prompts that ask you for permission to run code. After a short wait, the workflow editor opens. This step works on the one-box environment, but not in the cloud. You can view the workflow diagram in the workflow editor. The following illustration shows the workflow.



4. When you are done, close the **Workflow** window.

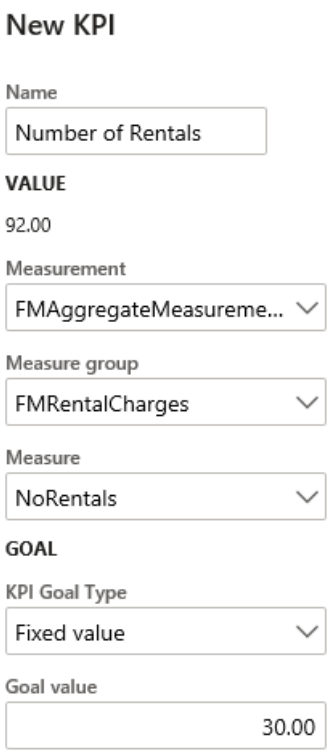
Create a new KPI definition

The web client enables users who have appropriate permissions to modify KPI definitions that have been modeled and deployed by developers. Users also have the ability to create new KPI definitions in the client. In this walkthrough, you create a new KPI definition in the client.

1. Open the **Reservation Management** workspace. On the navigation bar, go to **Fleet Management > Workspaces > Reservation Management**.
2. Notice the Total revenue KPI tile shown on the bottom left of the workspace. Click the **Total Revenue KPI** tile. Details of the total revenue KPI tile along with charts indicating top and bottom contributors to revenue will be shown on screen.
3. Next, you will define a new KPI to monitor the number of rentals.
4. On the Action Pane, click **New**. The **New KPI** dialog will open.
5. Enter following values for the new KPI definition.

FIELD	VALUE
Name	Number of Rentals
Measurement	FMAggregateMeasurements

FIELD	VALUE
Measure group	FmRentalCharges
Measure	NoRentals
KPI Goal Type	Fixed Value
Goal value	30



6. Click **Save**.

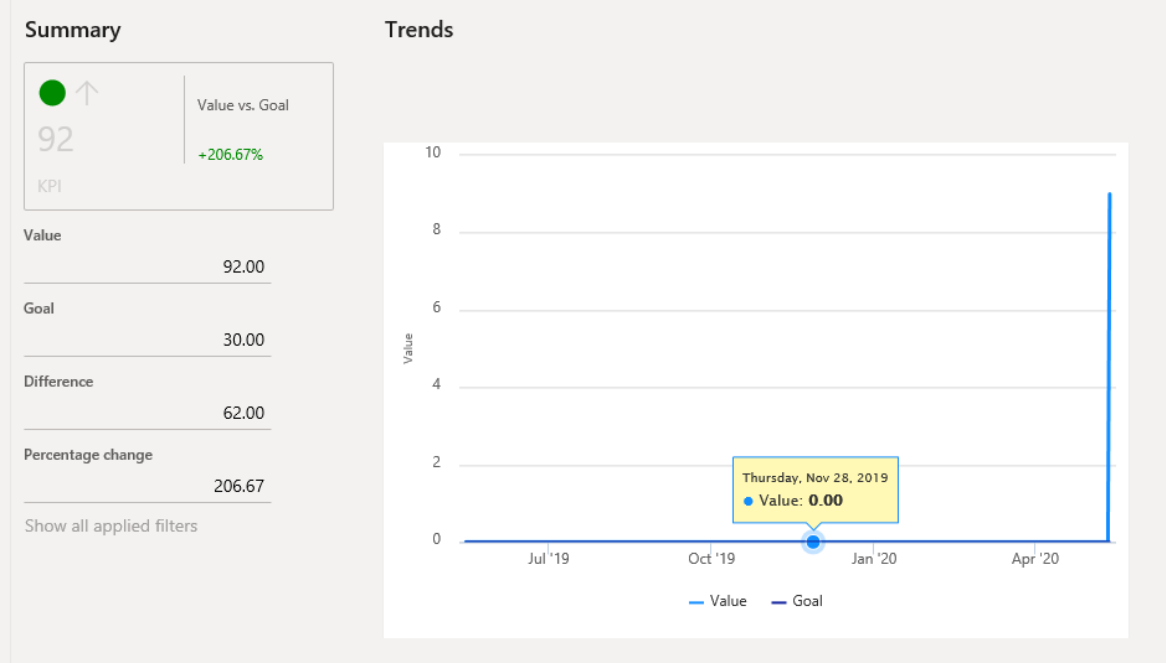
> **NOTE**
> If the **Save** button isn't visible in the **New KPI** dialog box, use a higher screen resolution so that you can see the entire dialog. You can see the KPI details page that contains details about the KPI that you created. You can make changes in the **Details** section. You will modify the default threshold values so that if the value is less than 90% of the goal, the KPI will show red and if the value is over 110% of the goal, the KPI will show green.

7. Click **Edit**.

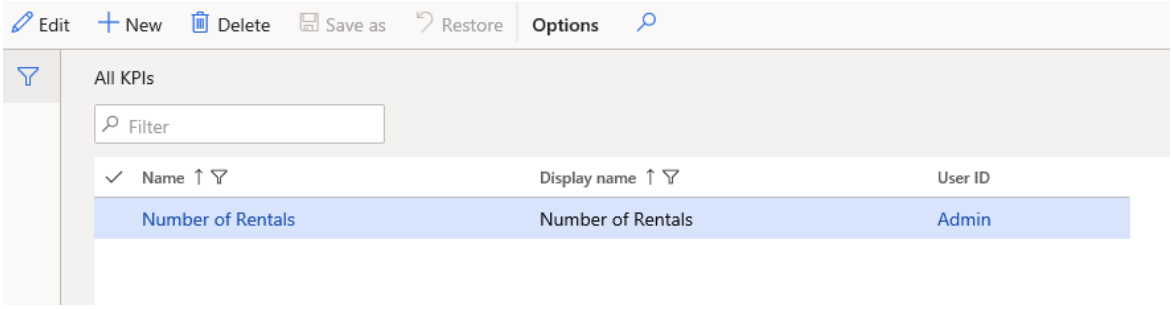
8. Scroll to the right of the screen, and modify the values in the thresholds fields as follows.

PROPERTY	VALUE
Bad if less than	90
Good if more than	110

9. In the application bar, click **Save**.



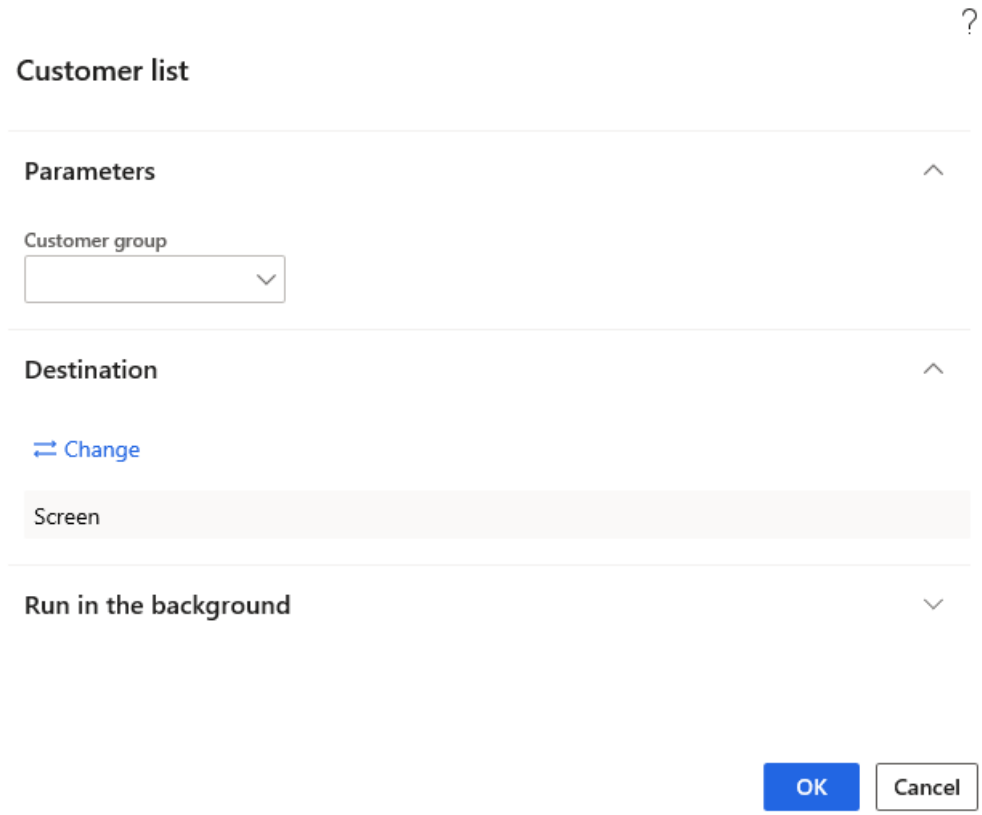
10. Click the form caption to return to the grid view.
11. Click the **Name** column header, change the filter operator to **contains**, and update the filter field value to **Number**. You will see the new KPI is available in the list.



Launch an operational report

In this tutorial, you'll launch an operational report that contains a list of customers who are currently renting vehicles.

1. Use the dashboard to open the **Reservation management** workspace.
2. On the right side of the page, under **Reports** click **Customer list**. Do not enter anything in the parameter for **Customer group**.



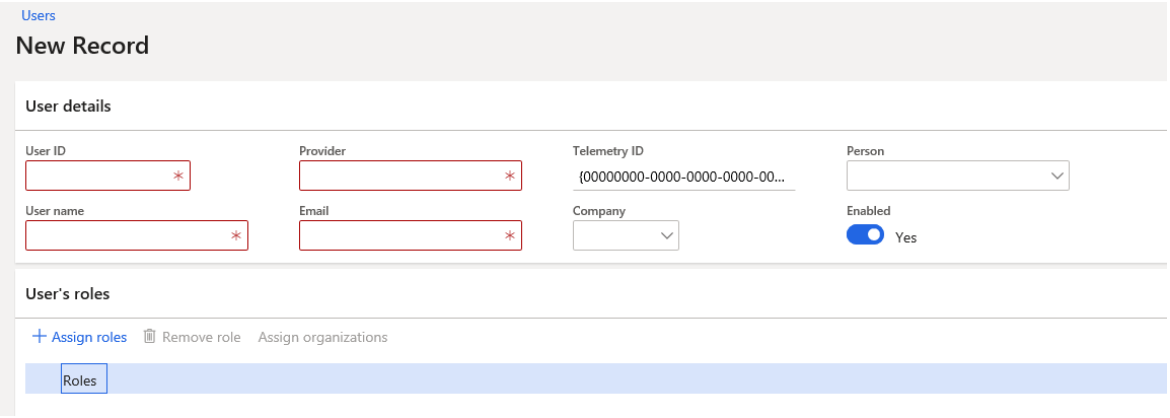
3. Click **OK** to close the dialog box. The report will be rendered and show the list of customers. The report may take a minute to render.

Secure access using the role-based security system

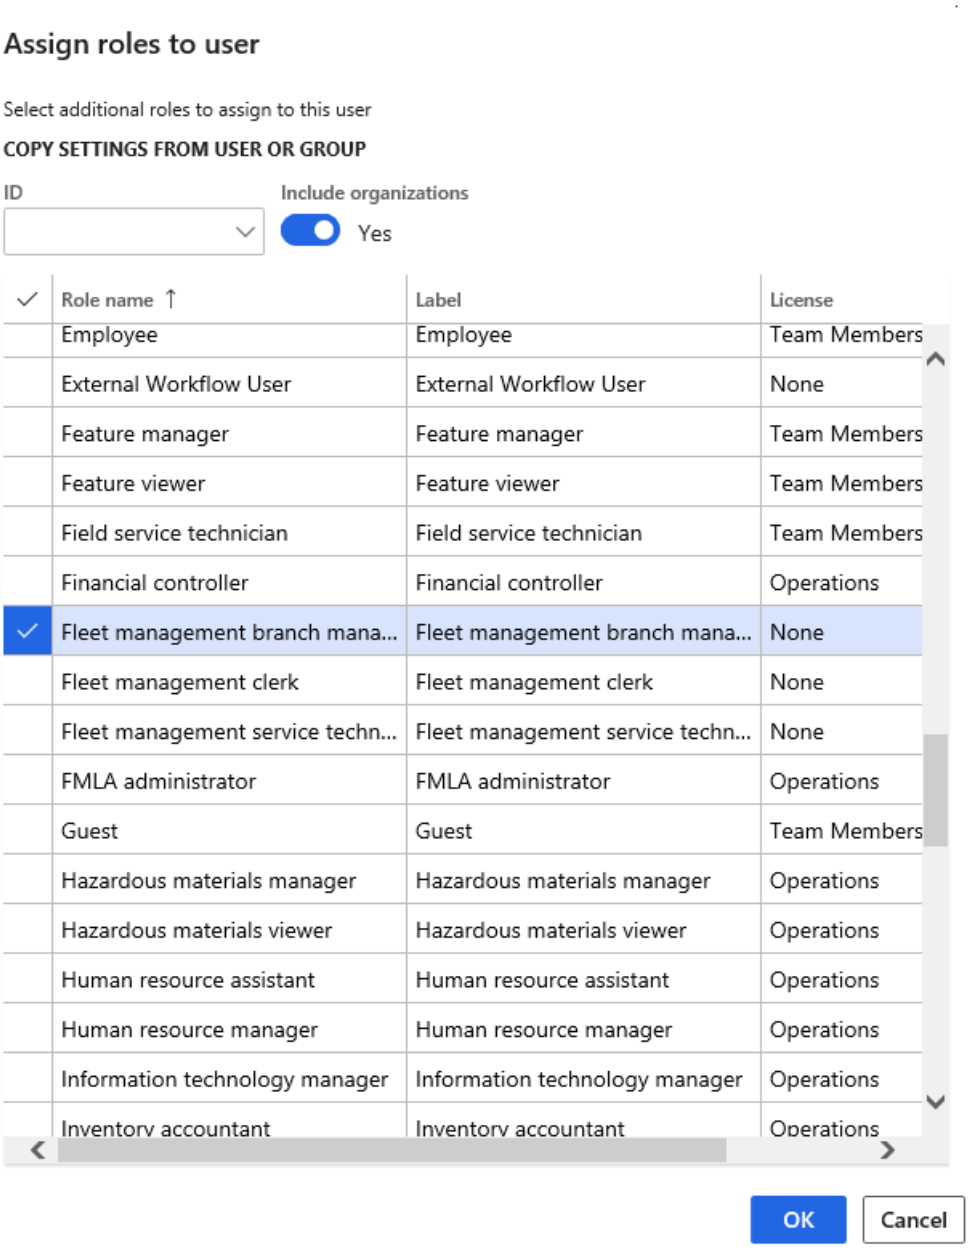
In this tutorial, you'll access the system as a user that has been assigned a different security role. This tutorial requires that you have created at least one additional end user.

1. On the dashboard, in the **System administration** section, click **Users** and then **Users**.
2. On the Action Pane, click **New**.
3. Enter the following field information.

PROPERTY	VALUE
User ID	Eight character unique ID
User name	The first name of the user
Provider	`urn:Federation:MicrosoftOnline`
Email	Use an email alias that you can login with for testing.
Company	`DAT`
Enabled	Verify that this slider is set to **Yes**.



4. Click **Assign Roles**.



5. Select **Fleet management branch manager**, and then click **OK**.
6. Click the user name on the top right, and then click **Sign Out**. You'll be redirected back to the sign-n page
7. Sign in using the credentials for the user who you assigned the security role to in the steps above.
8. Notice that in the dashboard, this user can see only items that are related to the branch manager security role. Items that system administrators can see are now hidden.

9. Click **Sign out** to sign out of the session.

Fleet Management sample application

2/18/2021 • 2 minutes to read • Edit Online

This topic is an overview of the Fleet Management sample application.

The Fleet Management sample application has been provided to showcase development and foundation capabilities. Fleet Management represents a solution that an ISV might create for a car-rental agency. Fleet Management data includes vehicles which are available for renting, and customers who can rent and return these vehicles. Employees can also run a maintenance workflow on these vehicles.

For some tutorials, you will need to create the FleetManagement solution if it is not on your computer. The steps to create it are listed in Tutorial: Create a Fleet Management solution file out of the Fleet Management models in the AOT.

For some tutorials, you must download the Fleet Management tutorial code and other artifacts from https://github.com/Microsoft/FMLab.

Fleet Management is provided as a Visual Studio solution that demonstrates platform capabilities, such as:

- Forms
- Workflow
- Security
- Labels
- Resources
- Data
- Business Intelligence
- Extensions

The Fleet Management solution includes two separate projects: one for the base model and the other one for extensions to the base model. The project named FleetManagement Migrated demonstrates how a migrated application might appear after migrating code from Dynamics AX 2012. This version shows how forms that have been migrated from Microsoft Dynamics AX 2012 R3 work on a web client. These forms have been created using automated migration tools and some other manual migration steps in Visual Studio. These forms bind to X++ tables and use the X++ programming model. The project named FleetManagement Discounts (or FleetManagementExtension) demonstrates how to use extensions to customize an application. This project extends the Fleet Management sample by extending controls and tables, handling data events, and replacing business logic using a plug-in. The tutorials that accompany this article provide a more-detailed look at the Fleet Management sample. These include a Fleet Management tutorial, End-to-end scenario for the Fleet Management sample application, and a tutorial that walks through extensions, Customize model elements through extension.

Additional resources

Using the Fleet Management sample

Customize model elements using extensions

Develop and customize home page

Download the FMLab sample code

Create the FleetManagement solution

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Development tools in Visual Studio

2/18/2021 • 2 minutes to read • Edit Online

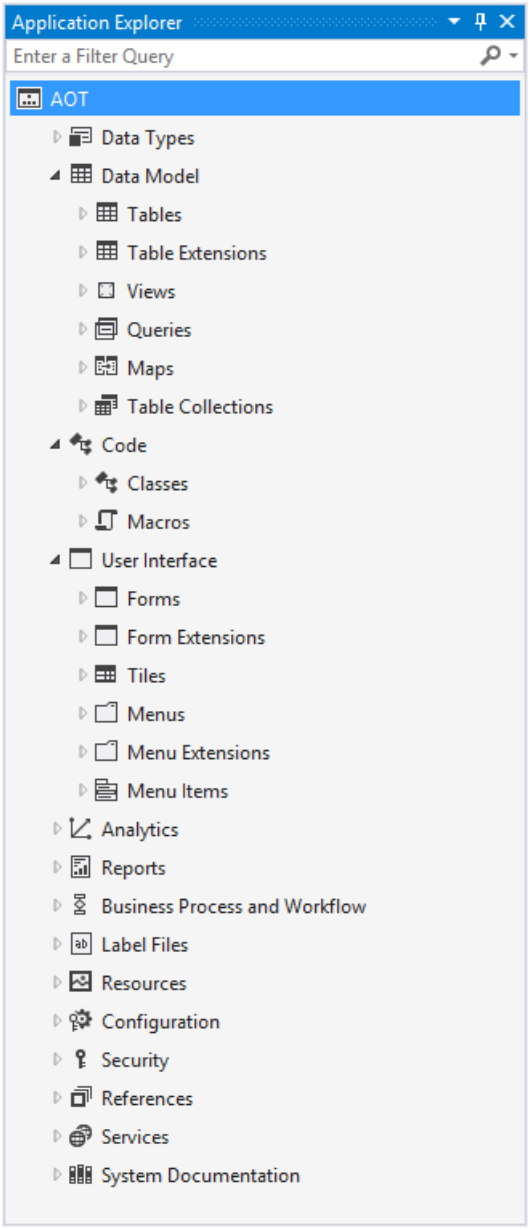
What are the development tools?

A notable change from Microsoft Dynamics AX 2012 is that the Finance and Operations applications do not include a rich-client application (ax32.exe). From a development perspective, this means that the Microsoft Dynamics AX 2012 development environment, MorphX, is no longer used. In its place, the application development is carried out exclusively in Visual Studio. The development tools support all of the development tasks, including debugging and local testing scenarios. A primary goal of the development experience is to keep familiar Microsoft Dynamics AX 2012 concepts, and seamlessly adapt them to the Visual Studio framework and paradigms.

Visual Studio is the exclusive integrated development environment (IDE) for development. All of your application development work will be performed with it. This section is an overview of the main features that are added to Visual Studio when the development tools are installed.

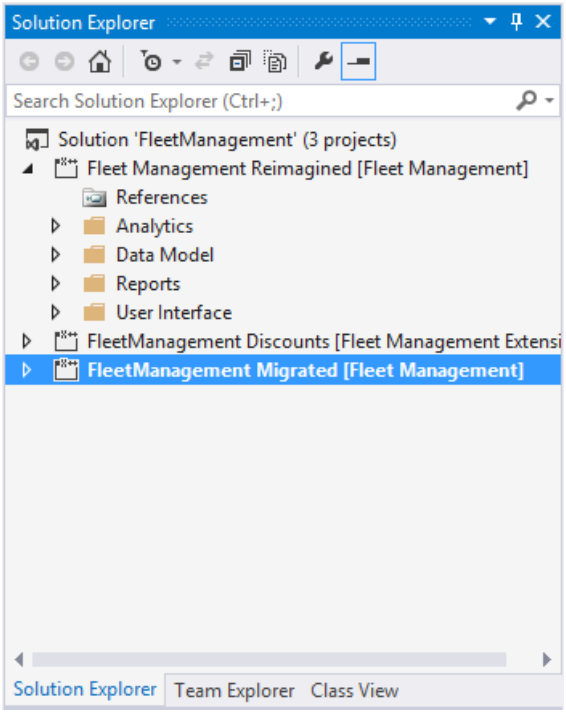
Application Explorer

In Visual Studio, the model store is represented by the Application Explorer. On the **View** menu, click **Application Explorer** to open it. The Application Explorer corresponds to the Application Object Tree (AOT) that you may be familiar with in Microsoft Dynamics AX 2012. Use the Application Explorer to browse and interact with the elements in the model store that define the applications. The following illustration shows the Application Explorer. For more details, see Application Explorer.



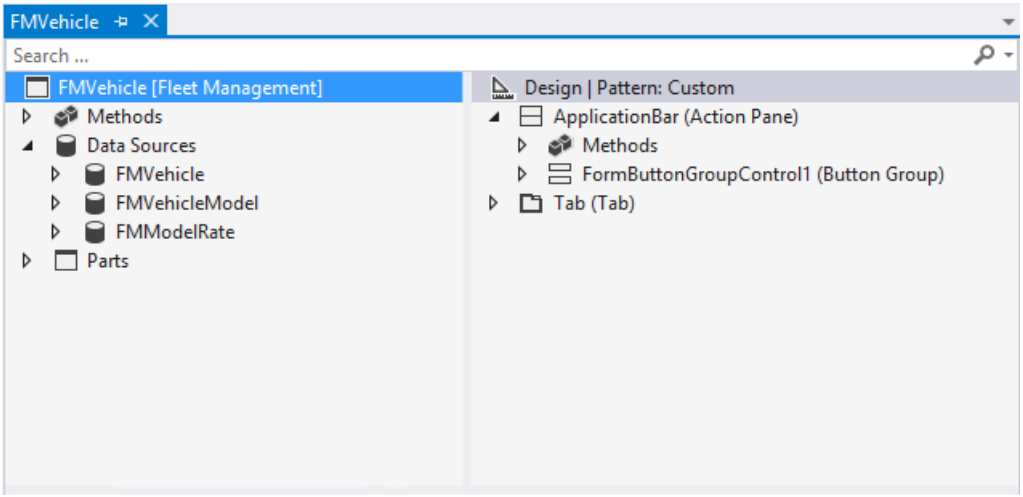
The project template

Even a simple application can have a large number of elements in its model. The **Operations Project** template has been added to Visual Studio to help you organize and manage the elements that you are working with for a model. You will use the project to design, build, and test model elements. It's common to have several projects within a single Visual Studio solution. The following illustration shows three projects in a Visual Studio solution. For more details, see Finance and Operations project type in Visual Studio.



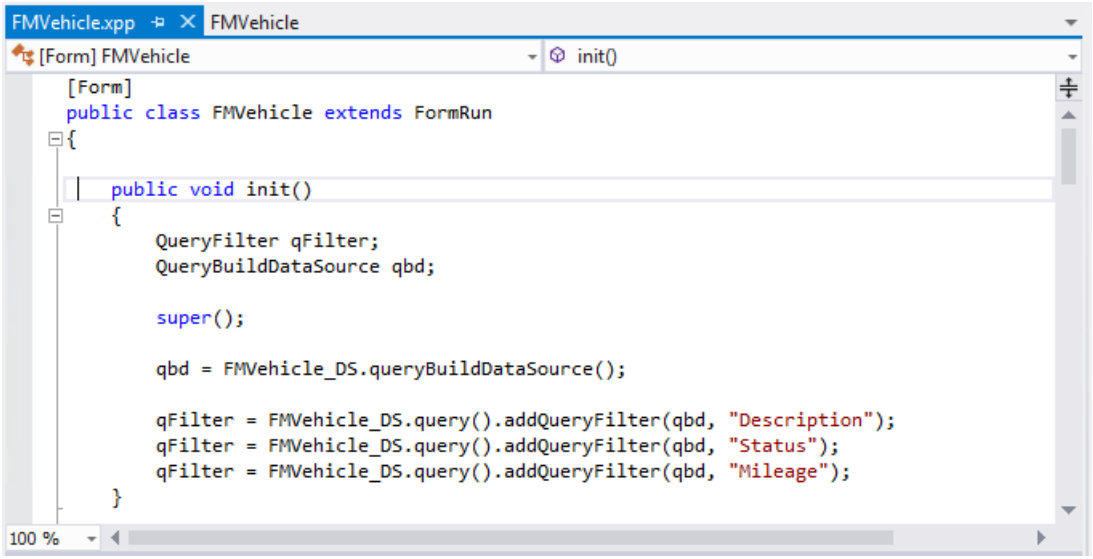
Element designers

The Visual Studio tools contain designers for each kind of element in the application. You will use these designers when you create or modify elements. The following illustration shows the element designer for a form element. For more details, see Element designers.



Code editor

The X++ code is written in the code editor for Visual Studio. The standard features that a developer expects from the code editor are supported. For example, sections of code are collapsible. IntelliSense provides guidance as you write or modify code. For more details, see Code editor features.



Dynamics 365 menu

The tools add the **Dynamics 365** menu to Visual Studio. Several tools that you will use during the development process are found here. For example, the tools for managing models are accessed from the menu.

Development tools tutorial

2/18/2021 • 7 minutes to read • Edit Online

This tutorial tours the Fleet Management solution in Visual Studio and introduces you to the development tools.

In this tutorial, you'll take a tour of the Fleet Management solution in Visual Studio. You'll see how a project is organized in the Visual Studio development environment. Much of what you'll see uses standard Visual Studio features, plus you will notice that we've added some new customized features. Along the way we'll point out some of these new and customized features and how they ease development. This tutorial will focus on:

- Visual Studio projects and their features.
- Files used in development.

Prerequisites

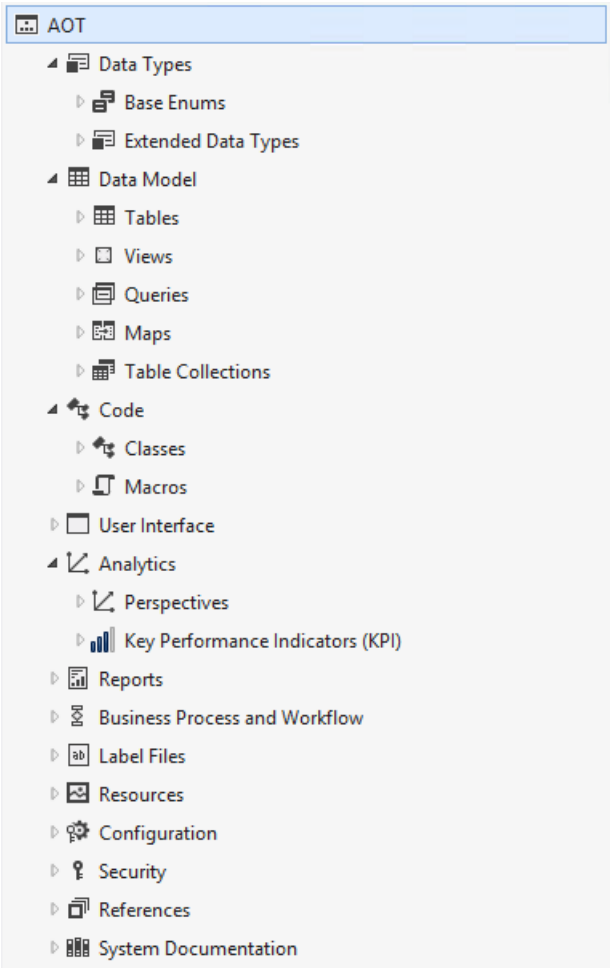
This tutorial requires you to access the environment using Remote Desktop and to be provisioned as an administrator for the instance.

Setup

1. Start Visual Studio using **Run as an administrator**.
2. On the **File** menu, point to **Open** and then click **Project/Solution**.
3. Browse to the **Desktop,** and then open the **FleetManagement** folder. If the solution file is not on your computer, the steps to create it are listed in Tutorial: Create a Fleet Management solution file out of the Fleet Management models in the AOT.
4. Select the solution file named **FleetManagement**. The file type listed is Microsoft Visual Studio Solution (**SLN** file).
    - The fleet management solution file is available on the downloadable
    - VHD.
5. Click **Open**. The solution may take some time to load.

View the FleetManagement model

1. On the **View** menu, click **Application Explorer**. **Application Explorer** opens in Classic view. This view provides a familiar view of the **Application Object Tree** (**AOT**), which is similar to what you see in MorphX. The new AOT categorizes model element types a little differently than Microsoft Dynamics AX 2012. For example:
    - Items that were previously found in the **Data Dictionary** node are now under **Data Model** or **Data Types**.
    - Classes and macros are under **Code**.
    - Forms, menus, and other GUI elements are under **User Interface**.
    - Business intelligence components are under **Analytics**.



2. In **Application Explorer**, right-click **AOT**, and then click **Model view**.

   Model view organizes programmable objects according to their model. For these tutorials, the application suite models have been removed. The core foundation and platform components have been separated from the application suite. This separation is what allowed the application suite models to be removed.

3. Double-click **Fleet Management**, or click the arrow to expand the model's tree node. Model view provides a familiar way to work with a set of programmable objects. It's similar to what you saw in Classic view, but the tree displays only the objects that are part of that particular model.

4. Double-click **User Interface**, and then double-click **Forms** to expand the forms node. In the Fleet Management sample, the names of forms and other programmable objects are prefixed with "FM" so that they're easy to identify. The name of each object is followed by the name of its layer, which in this case is "isv," and then by the name of the model it belongs to, which is "Fleet Management."

5. You can continue to expand the nodes in the tree. For example, double-click **FM Rental** to view the parts, data sources, and methods for the form.

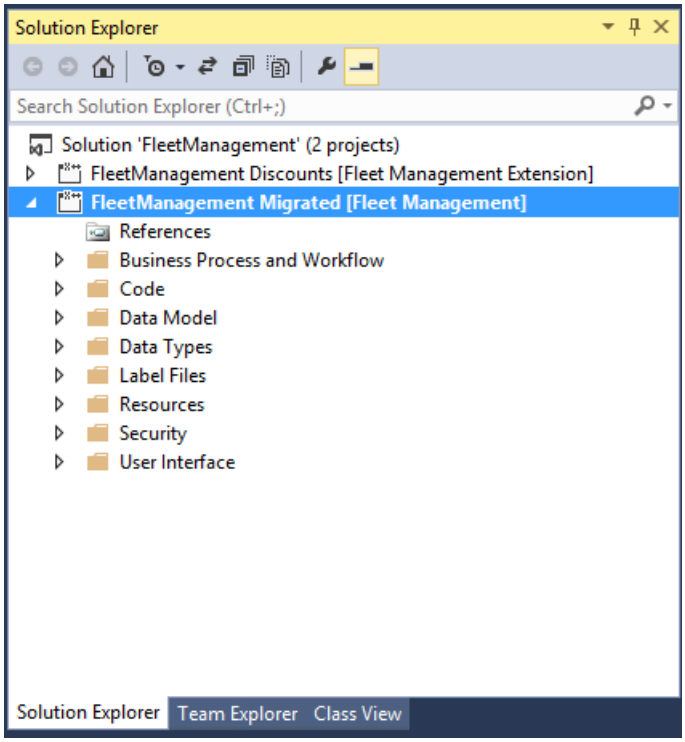
6. From **Application Explorer**>, you can open the Visual Studio code editor and view the source code for the form. For example, right-click **FMRental**, and then click **View code**.

7. You can also open the **Form Designer**. For example, right-click **FMRental**, and then click **Open designer**. You can expand the tree nodes in the **Form Designer** to see and edit the form metadata.

8. You can also preview the form in the **Preview** pane. Click on a control in the preview to it in the Form Designer. Similarly, click on a control in the Form Designer to highlight it in the form preview.

View the FleetManagement solution and its projects

This section of the tutorial describes the Fleet management projects and solution. Projects enable you to build your model elements (compile, synchronize the database, generate RDL files, etc.), test your application, and debug your code. We recommend that you don't make a change to a model element unless it's a part of a project; otherwise, your changes may not be compiled until you do a full build of your models, which can be a lengthy operation. In **Solution Explorer**, you can see the sample projects, two of which are named **FleetManagement Discounts** and **FleetManagement Migrated**. These projects are contained in a single Visual Studio solution, named **FleetManagement**.

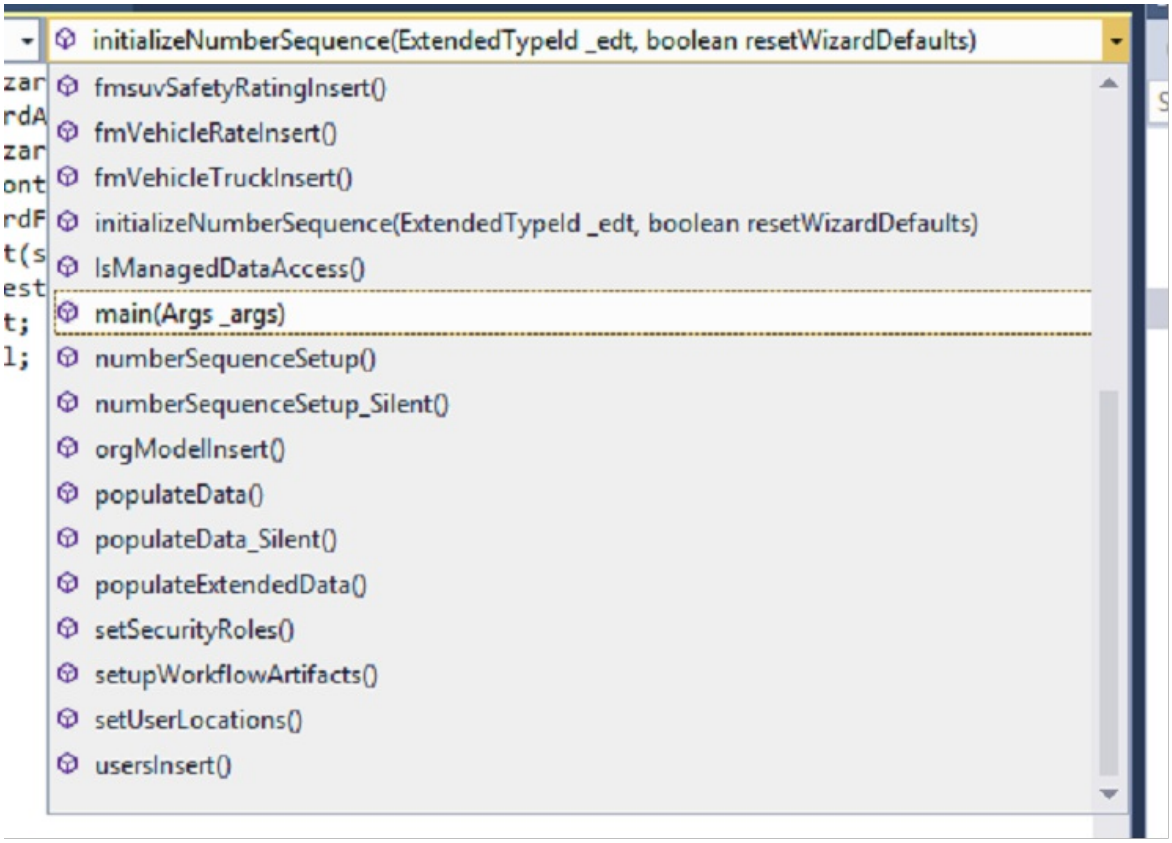


1. In **Solution Explorer**, right-click **Fleet Management Migrated**, and then click **Properties**.
2. In the **Property Pages** dialog box, review the listed properties. In the **Startup Object** field, you can see the name of the first form that runs when you run or debug your project. You can see that the **Startup Object type** field is set to **Form**. You can also view the model name and its layer. A project always belongs to one model.
3. Don't change anything in this dialog box right now. Click **Cancel** to close it.

View the source file for a model element

The code in a solution is stored as XML. The following instructions show you how to view the code in Visual Studio and the source XML in Internet Explorer.

1. In **Solution Explorer**, be sure that the **Fleet Management Migrated** project node is expanded.
2. Double-click **Code**, and then double-click **Classes**, to open the folder that contains the list of classes for the **Fleet Management Migrated** project.
3. In the list of classes, double-click **FMDataHelper** to open the code editor. Here, you can see the implementation of the **FMDataHelper** X++ class.
4. Scroll down in the code to locate the **main** method. **Tip**: You can also go the main method using the method navigation menu located on the top right of the code editor window.



If this class is set as the startup object of the project, the **main** method will be the execution entry point when you run or debug the project.

```
FMDataHelper.xpp
FmDataHelper                                    main(Args _args)
public class FmDataHelper
{
    #define.FMSvcTechUserId('FMSvcTec')
    #define.FMClerkUserId('FMClerk')
    #define.FMManagerUserId('FMMgr')
    #define.FMSvcTechUserGrpId('FMSvcTech')
    #define.FMClerkUserGrpId('FMClerk')
    #define.FMManagerUserGrpId('FMManager')

    /// <summary>
    /// Create a number sequence reference for the default scope.
    /// </summary>
    /// <param name = "_edt">The extended data type of the number seqeunce.</param>
    private static void initializeNumberSequence(ExtendedTypeId _edt, boolean resetWizardDefaults)
    {
        NumberSequenceReference sequenceReference;
        NumberSequenceTable sequence;
        NumberSeqDatatype dataTypeObject;
        NumberSequenceDatatype dataTypeRecord;
        NumberSeqScope scope;

        if (_edt)
        {
            sequenceReference = NumberSequenceTable::autoCreate(_edt);
            if (sequenceReference && resetWizardDefaults)
            {
                ttsbegin;
                sequence = NumberSequenceTable::find(sequenceReference.NumberSequenceId, true);
100 %
```

5. In Windows, open **File Explorer**, and then browse to the following folder: C:\Packages\FleetManagement\FleetManagement\AxClass

6. Double-click the file named FMDataHelper.xml. If you're prompted to choose a program to open the file with, click **More options**, and then click **Internet Explorer**. Otherwise, open it in Notepad.

```
C:\Packages\FleetManagement\FleetManagement\AxClass\FmDataHelper.xml
C:\Packages\FleetManage...

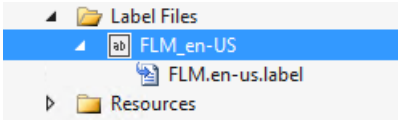
<?xml version="1.0" encoding="UTF-8"?>
- <AxClass xmlns:i="http://www.w3.org/2001/XMLSchema-instance">
    <Name>FmDataHelper</Name>
  - <SourceCode>
    - <Declaration>
        <![CDATA[ public class FmDataHelper { #define.FMSvcTechUserId('FMSvcTec') #define.FMClerkUserId('FMClerk') #define.FMManagerUserId
        ('FMMgr') #define.FMSvcTechUserGrpId('FMSvcTech') #define.FMClerkUserGrpId('FMClerk') #define.FMManagerUserGrpId('FMManager') } ]]>
      </Declaration>
    - <Methods>
      - <Method>
          <Name>initializeNumberSequence</Name>
        - <Source>
            <![CDATA[ /// <summary> /// Create a number sequence reference for the default scope. /// </summary> /// <param name =
            "_edt">The extended data type of the number seqeunce.</param> private static void initializeNumberSequence(ExtendedTypeId _edt,
            boolean resetWizardDefaults) { NumberSequenceReference sequenceReference; NumberSequenceTable sequence;
            NumberSeqDatatype dataTypeObject; NumberSequenceDatatype dataTypeRecord; NumberSeqScope scope; if (_edt)
            { sequenceReference = NumberSequenceTable::autoCreate(_edt); if (sequenceReference && resetWizardDefaults) { ttsbegin;
            sequence = NumberSequenceTable::find(sequenceReference.NumberSequenceId, true); if (sequence) { dataTypeObject =
            NumberSeqDatatype::construct(); dataTypeObject.find(_edt); scope = NumberSeqScopeFactory::createDefaultScope
            (dataTypeObject); dataTypeRecord = NumberSequenceDatatype::find(dataTypeObject.parmRecId()); sequence.AllowChangeDown =
            dataTypeRecord.WizardAllowChangeDown; sequence.AllowChangeUp = dataTypeRecord.WizardAllowChangeUp;
            sequence.AnnotatedFormat = dataTypeRecord.wizardAnnotatedFormat(scope, dataTypeRecord.wizardHighest, true);
            sequence.Continuous = dataTypeRecord.WizardContinuous; sequence.FetchAheadQty = dataTypeRecord.WizardFetchAheadQty;
            sequence.Format = dataTypeRecord.wizardFormat(scope, dataTypeRecord.WizardHighest, true); sequence.Highest =
            dataTypeRecord.WizardHighest; sequence.Lowest = dataTypeRecord.WizardLowest; sequence.Manual =
            dataTypeRecord.WizardManual; sequence.NextRec = 1; sequence.update(); } ttscommit; } } } ]]>
          </Source>
        </Method>
      - <Method>
          <Name>main</Name>
        - <Source>
            <![CDATA[ public static void main(Args _args) { FmDataHelper::cleanupBrokenNumberSequences();
            FMDataHelper::ConfigureTotalsEngine(); FmDataHelper::populateData_Silent(); } ]]>
          </Source>
        </Method>
      - <Method>
          <Name>ConfigureTotalsEngine</Name>
        - <Source>
            <![CDATA[ public static void ConfigureTotalsEngine() { FMParameters FMParam = FMParameters::find(true); ttsbegin;
            FMParam.TotalsEngine = "Default"; FMParam.update(); ttscommit; } ]]>
          </Source>
        </Method>
```

In this file, you can see XML code that contains the metadata that describes the **FMDataHelper** class. For example, you can see that the class named **FMDataHelper** contains a set of methods. You can see the code that implements the **intializeNumberSequence** method for example, which is contained by an XML element. The <![CDATA]> tag ensures that the contained text isn't interpreted or changed by the XML parser. This metadata contains the source code that you viewed in the Visual Studio code window. When you develop a solution, you always work with code that's stored as XML. This means that the code files are stored on your computer, not in the database. There isn't an active connection to an application

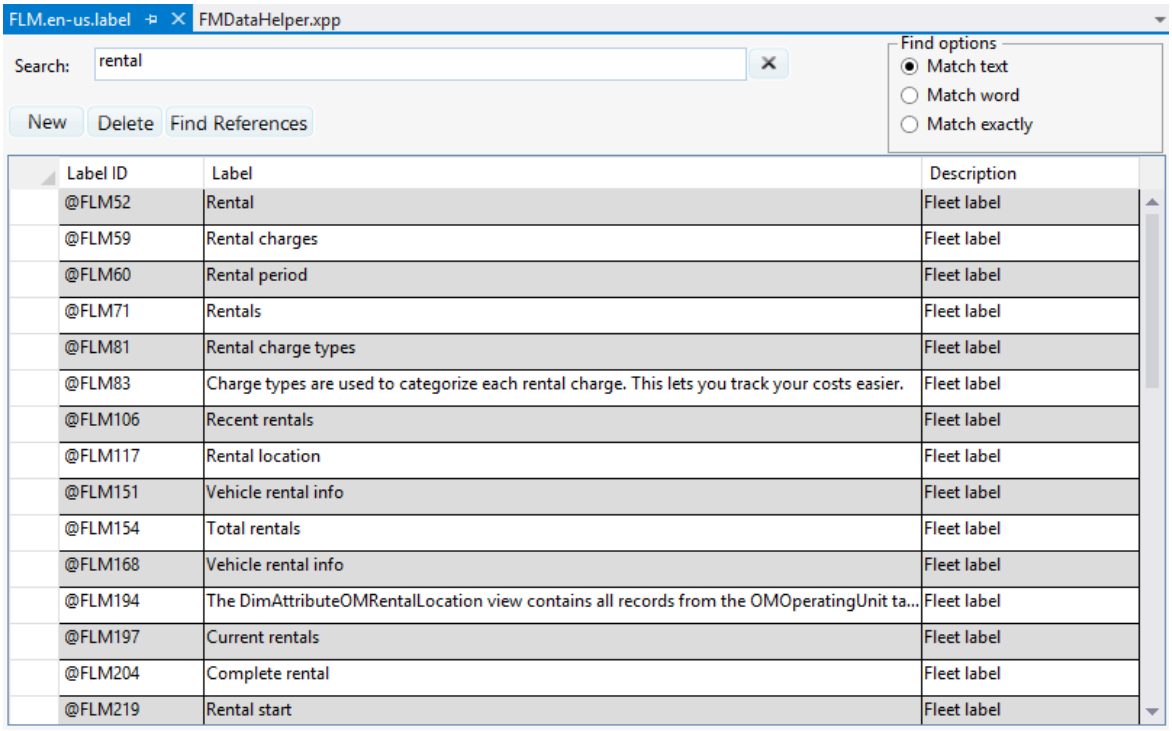
object server (AOS) while you develop your application. To avoid data loss, we recommend that you maintain your project files in a source code control system, such as Visual Studio Team Foundation Server. Although it's helpful to know how and where the source code files are stored, don't modify the XML files directly. **Always use Visual Studio to modify the source code for your projects.**

7. Close the window that **FMDataHelper.xml** file.

8. In **Solution Explorer**, double-click **Label Files** in the **FleetManagement Migrated** project to open the folder to view the labels for the project, and then double-click on the **FLM_en-US** node to open the label editor.



In the label editor **Search** box, enter "rental." As you type, you'll see the list of labels for the Fleet Management sample that contain the word "rental." You can double-click in any cell that can be edited to change its contents, and then save the label file.

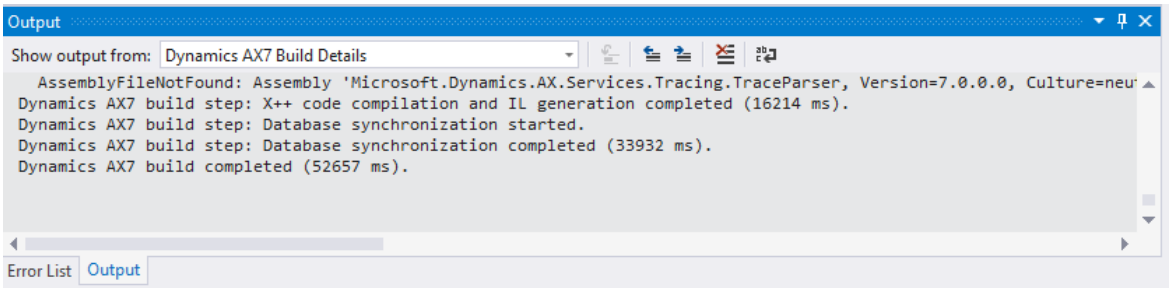


Label ID	Label	Description
@FLM52	Rental	Fleet label
@FLM59	Rental charges	Fleet label
@FLM60	Rental period	Fleet label
@FLM71	Rentals	Fleet label
@FLM81	Rental charge types	Fleet label
@FLM83	Charge types are used to categorize each rental charge. This lets you track your costs easier.	Fleet label
@FLM106	Recent rentals	Fleet label
@FLM117	Rental location	Fleet label
@FLM151	Vehicle rental info	Fleet label
@FLM154	Total rentals	Fleet label
@FLM168	Vehicle rental info	Fleet label
@FLM194	The DimAttributeOMRentalLocation view contains all records from the OMOperatingUnit ta...	Fleet label
@FLM197	Current rentals	Fleet label
@FLM204	Complete rental	Fleet label
@FLM219	Rental start	Fleet label

Build the FleetManagement migrated project

1. In the **Solution Explorer**, right-click **Fleet Management Migrated**, and then click **Rebuild**.

2. In the **Output** window, in the **Show output from** list, click **Build**. Verify that the build completed without compilation errors. Wait for the build to complete. The final build message in the **Output** window says, "... build completed." the final build message in the status bar (at the bottom left corner of Visual Studio) says "Ready."



3. On the **View** menu, click **Error List** to see the list of best-practice warnings. We've deliberately left some warnings in the build to demonstrate this feature.
4. Double-click any warning message to view the code or resource that caused the warning.
5. In the **Window** menu, click **Close All Documents** to close all open documents.

Application checker

2/18/2021 • 2 minutes to read • Edit Online

The application checker tool is a set of technologies that allow you to gain insight into your application code (both source and metadata) in ways that have not been possible before. The technology is based on representing both source code and metadata in XML and providing rich search facilities by using the XQuery language to express declarative queries over the source code. The current implementation runs inside a BaseX repository, which runs locally on the developer's box.

For information about how to install and use the application checker, see Dynamics365FO-AppChecker.

Application Explorer

2/18/2021 • 6 minutes to read • Edit Online

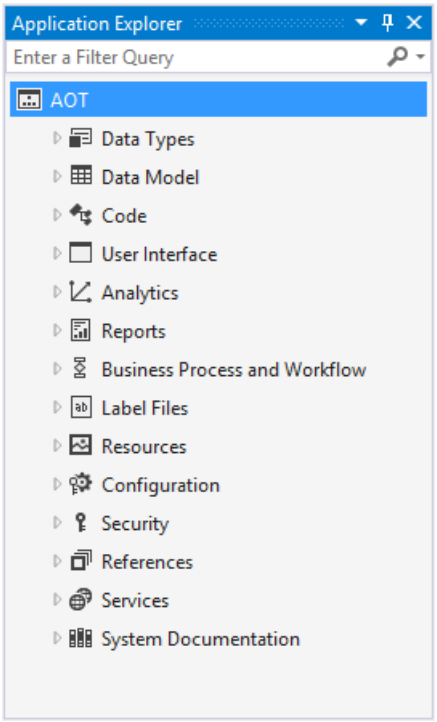
This topic reviews Application Explorer, and the various views and filtering methods in it. The topic also describes how to work with elements in Application Explorer.

Application Explorer

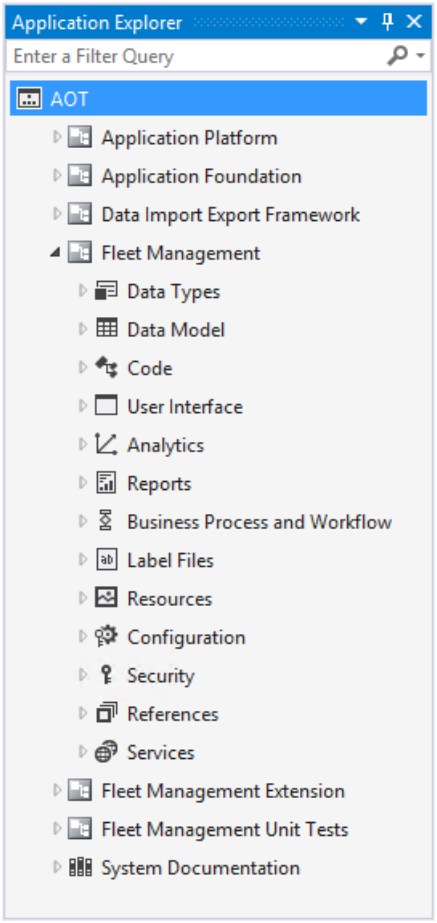
Application Explorer is the tool that you use to find the elements that you want to add to a project so that you can work with them. To access Application Explorer, on the **View** menu, click **Application Explorer**. An important difference between Application Explorer and the Application Object Tree (AOT) in the MorphX environment of Microsoft Dynamics AX 2012 is that you don't use Application Explorer to add or edit model elements. Instead, you use it to view elements, view code, find references to a selected element, and add elements to a project. To create, design, edit, and build model elements, you must use a Finance and Operations project.

Application Explorer views

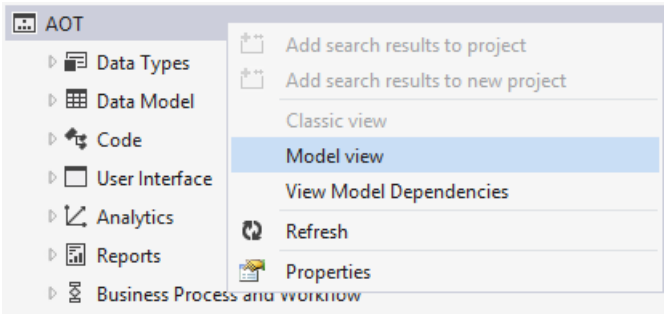
The content in Application Explorer can be organized in two ways. In the *classic view*, all the elements from every model are grouped according to type. This view resembles the way that the AOT was organized in Dynamics AX 2012. The following illustration shows the classic view.



The second view is called the *model view*. In this view, each model is listed separately. The elements within each model are grouped, as in the classic view. The following illustration shows the model view. Notice that the node for the Fleet Management model is expanded, and that the elements in the model are arranged as they would be in the classic view.



To switch to the model view, right-click the **AOT** node, and then click **Model view**. To switch back to the classic view, right-click the **AOT** node, and then click **Classic view**.

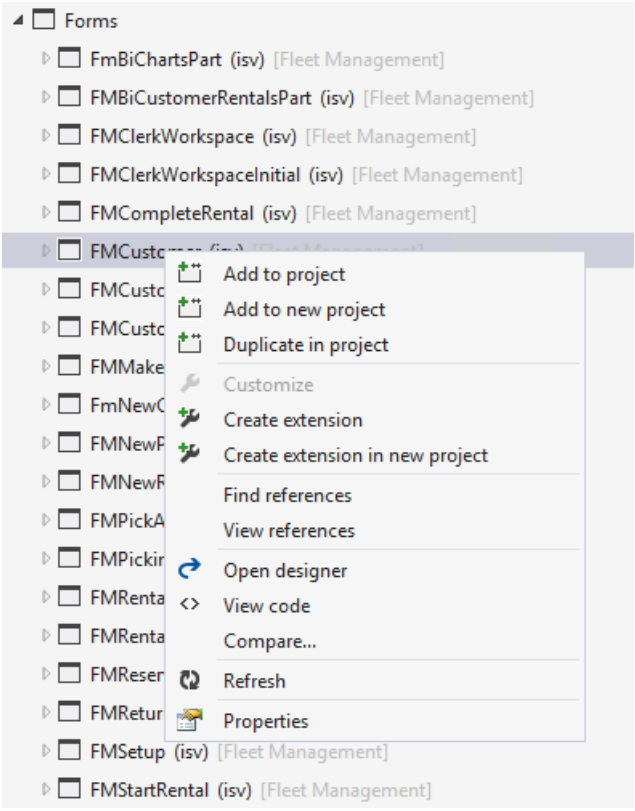


Working with elements

To work with elements, you must select them in the Application Explorer:

- To select one element, click it.
- To select a contiguous group of elements, hold down the Shift key while you click through the group of elements.
- To select noncontiguous elements, hold down the Ctrl key while you click the individual elements.

After you select the elements, right-click the selection to view the actions that you can perform. The following illustration shows the actions that are available for a form element.



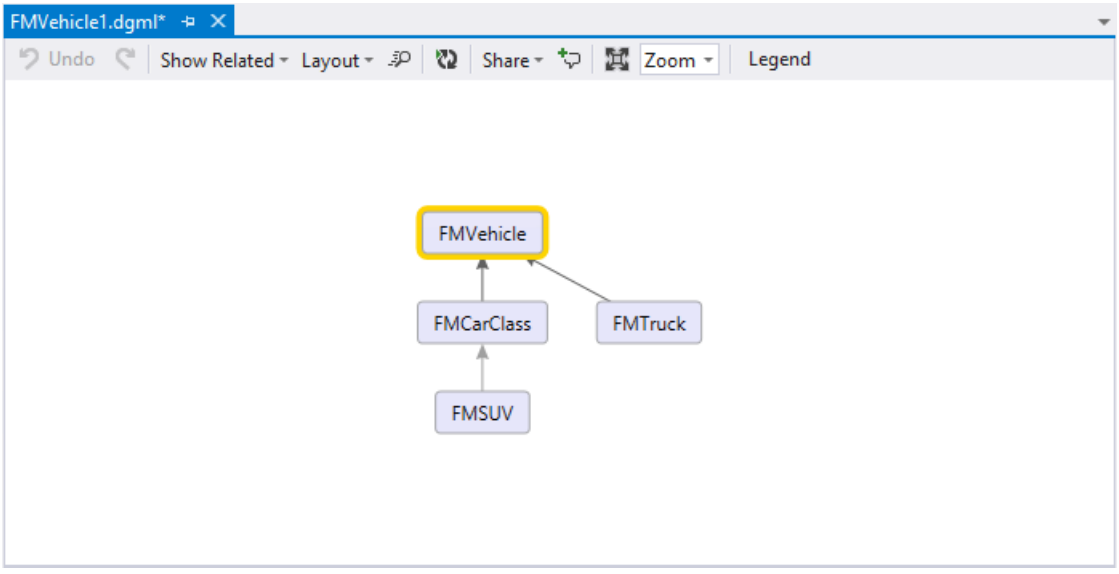
The actions that are available depend on the elements that you've selected. The following are some of the common actions that you can perform for elements in Application Explorer. **Note:** When the selected node is an element that exists in more than one model (in the case of overlayering customizations), the selected element will depend on the view that Application Explorer is currently in:

- If Application Explorer is in **model view**, the selected element is the element that belongs to the Application Explorer model that it appears under.
- If Application Explorer is in **classic view**, the selected element depends on the current context and the selected project in Solution Explorer. For example, if **Add to project** is the selected action, the selected element will be the element that belongs to the model of the current project, when applicable.

ACTION	DESCRIPTION
Add to project	Add the selected element or elements to the current project.
Add to new project	Add the selected element or elements to a new project.
Duplicate in project	Create a copy of the selected element or elements in the current project.
Customize	Create a customized version of the element. Click **Customize** when you want to do overlayering (customization) of an existing element. The model that you're using for your current project must be in the same package as the selected element, and it must belong to a higher layer than the element that you want to customize. When you click **Customize**, a new "customization" model element file is created and is added to your project.
Create extension	Create an extension for the element. A new extension model element (.Extension) is added to the current project in Solution Explorer. This is the preferred way to work with existing elements.

ACTION	DESCRIPTION
Create extension in new project	Create an extension for the element as part of a new project. You define the new project when the **New Project** dialog box opens.
Find References	Find all of the X++ code and other elements that reference the selected element.
View references	Create a diagram that shows the other elements that reference the selected element.
Open designer	Open the element designer for the element of that type, so that you can view the element. Although you can modify the element, this is typically done when the element is part of a project.
View code	Open the code editor, where you can view and edit the X++ code for the element.
Refresh	Update the metadata for the element.
Compare	Compare the element with the XML representation of the element that you select. Typically, you will compare an element with a different version of the element from a source code control repository.
Properties	Open the **Properties** dialog box in Visual Studio, so that you can see the property settings for the element.

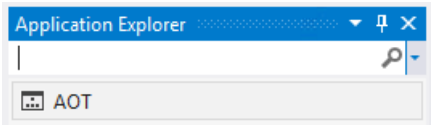
Some elements have unique commands that let you perform actions for that type of element. For example, table elements have two commands that provide additional information about the table. The first is the **View hierarchy** command. When you right-click a table element and click this command, you will see a graphical representation of the table hierarchy that the table is part of. For example, the following illustration shows the table hierarchy for the FMVehicle table.



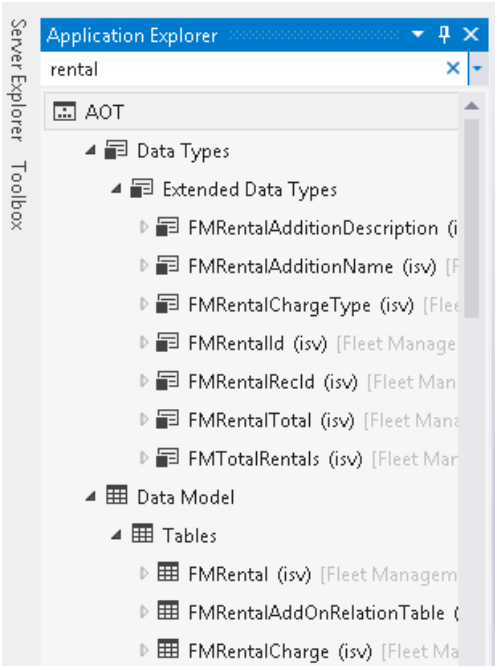
A similar hierarchy tool is available for classes. The second command is **Open table browser**. When you click this command, the data from the table is displayed as a list in the program.

Filtering Application Explorer

Application Explorer can contain a very large number of elements. This can make it difficult to find the specific element or elements that you want to work with. However, Application Explorer can filter the elements, based on a query that you supply. To filter the elements that are displayed, you can enter a query in the search bar at the top of Application Explorer.



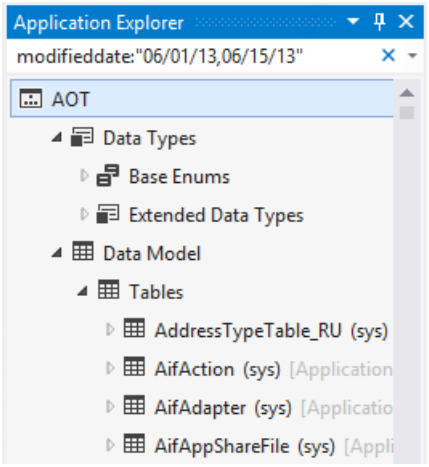
To apply a simple filter, just type the text that you want to filter by, and then click the **Filter** button at the end of the search bar. For example, if you want to find all of the elements that have a name that contains the word "rental," enter **rental** as the search term.



To clear the filter and return to the complete view, click the **Clear filter** button (X) in the search bar. Notice the drop-down arrow at the end of the search bar. If you click this arrow, you will see a list of filter options that you can use to refine the filter:

- Filter By Type
- Filter By Model
- Filter By Name
- Filter By Modified Date
- Filter By Extension Point

When you select one of these options, a predefined criterion is added to the search bar. You supply the specific values for the criteria. This feature can provide powerful search capabilities. For example, if you want to find the elements that were modified within a specific period, select **Filter By Modified Date**, and specify the start and end dates.



Previously used filters are listed in the drop-down list at the end of the search bar. You can also perform actions on the filtered results that are displayed in Application Explorer. Right-click the **AOT** node, and then select one of the following actions to perform on the results.

ACTION	DESCRIPTION
Add search results to project	Add the elements from the filter results to the current project.
Add search results to new project	Add the elements from the filter results to a new project.

These actions can be used only when the filter results are limited to a single model. Your query must contain the **model:** "*Model Name*" criterion to limit the filter to a specific model.

Build and debug projects

2/18/2021 • 11 minutes to read • Edit Online

In this tutorial, you'll learn about using the tools in Visual Studio to analyze and debug code in the Fleet Management application. You'll go through a simple developer scenario in which you will set breakpoints, modify some code, and build the result.

Prerequisites

Previous experience with code and Visual Studio is helpful to get the full benefit of this tutorial. This tutorial requires you to access the environment using Remote Desktop and that you be provisioned as an administrator on the instance.

Key concepts

- The debugger in Visual Studio is used to analyze and debug code for your projects.
- The standard features of the Visual Studio debugger are available to use when you're examining the running application. These features include modifying values of variables, setting breakpoints, and so on.
- IntelliSense and other features of Visual Studio are vital to efficient code editing and comprehension.
- Development is an iterative process. After making modifications to the code, the project will be built, and changes can be tested.

Scenario

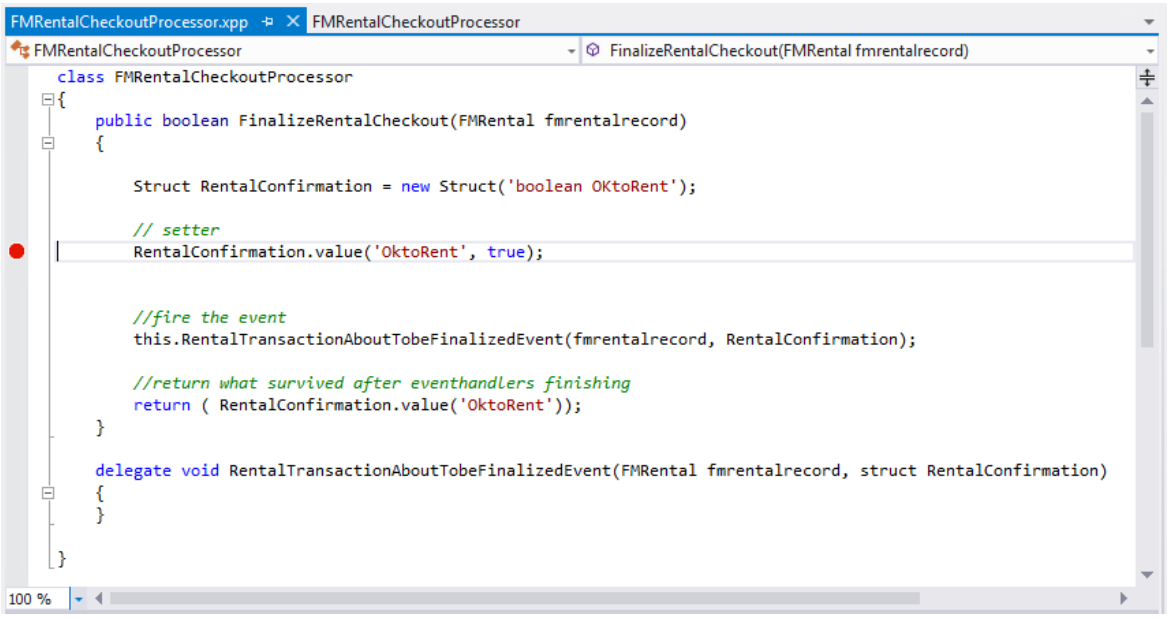
The rental company has had unfortunate events when customers rent cars using credit cards that are past the expiration dates. You, the developer, are tasked with revising the application to help prevent this situation. You'll identify the problem by using the debugger in Visual Studio. After the problem is identified, you'll edit some code to implement a fix. Finally, you'll build the project and validate that the fix was successful.

Run to a breakpoint

1. On the desktop, double-click the Visual Studio shortcut to open the development environment.
2. Open the FleetManagement solution. On the **File** menu, point to **Open**, and then click **Project/Solution**.
3. Browse to the desktop, and then open the **FleetManagement** folder. If the solution file is not on your computer, the steps to create it are listed in Tutorial: Create a Fleet Management solution file out of the Fleet Management models in the AOT.
4. Select the file named **FleetManagement**. The file type listed is SLN File.
5. Click **Open**. Loading the solution may take some time.
6. Make the **FleetManagement** project the startup project. In **Solution Explorer**, right-click the **Fleet Management** project, and choose **Set as StartUp Project** in the context menu.
7. In **Solution Explorer**, double-click the **Fleet Management** project to display its content.
8. Double-click the **Code** folder, and then double click the **Classes** folder of the Fleet Management project. Locate the **FMRentailCheckoutProcessor** class. Right-click this class, and then click **Open**. Alternatively, you can use the solution explorer search bar at the top of the solution explorer window. As you enter the name in the search bar, you'll see the corresponding artifacts selected in the solution

explorer. You can now see the X++ code for the class. This class has a method named **FinalizeRentalCheckout**.

9. Place a breakpoint in this method on the line following the first comment. To do this, click in the margin to the left of the line of code where you want the debugger to pause execution. You can also click anywhere in the line of code, and then press F9. The following illustration shows a breakpoint, which is displayed as a red-filled circle in the margin.



The FinalizeRentalCheckout method is called when a rental transaction is saved. This method calls the delegate named RentalTransactionAboutTobeFinalizedEvent. You can implement an event handler method, which is called by this delegate. The method that calls the delegate passes a parameter, named RentalConfirmation, which contains a value that indicates whether the rental should be allowed or blocked. If the rental is allowed, the value contains "true"; if it's blocked, the value contains "false". An event handler can change this value, based on any test the developer chooses to implement in code. In this case, we'll modify the code to test the expiration date of the credit card.

10. Press F5 to start the application for debugging, or, on the **Debug** menu, click **Start Debugging**. It's important that you start the application in one of these ways. If you don't, the Visual Studio debugger won't start, so you won't hit any of the breakpoints you've set. **Note**: The debugger needs to relate code position to source positions. It does this through consuming PDB files produced alongside the assemblies and net modules. The debugger will load symbols from the PDB files as described in the settings in the global tools settings. To open the options page containing the setting that controls which symbols load, go to the **Tools** menu and choose **Options**. In the **Microsoft Dynamics 365 for Finance and Operations** group, select the **Debugging** page. If this option is selected, the system will load symbols from only the PDB files related to the artifacts in the current solution. This reduces the startup time significantly, so be sure it's selected for this lab. Be aware that when this option is selected, it won't be possible to see source code from entities outside of the current solution. After a few moments, the browser will start and display the startup object that was selected in the project.

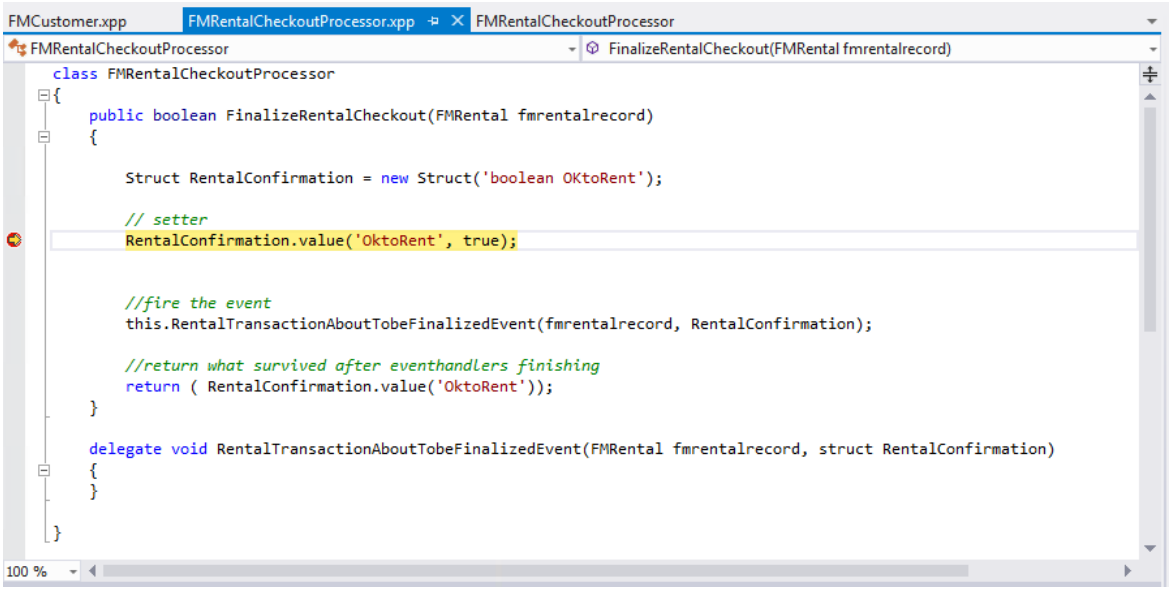
11. The **Current Rentals** page will open.

    a. In the Action Pane, click **Edit**.

    b. When the page is displayed, click **Show list** in the **Show/Hide** list (or press **Ctrl+F8**).

12. Make a change to any existing rental. For example, click **Edit**, and change the time that the rental period started.

13. Click **Save** to force a validation of the rental record. The method in which you placed a breakpoint is called. Execution pauses at the line of code that contains the breakpoint.



While the application is paused at a breakpoint, you can examine the application state. Use the same techniques that you typically would for any application developed with Visual Studio. For example, place the cursor over a variable or a parameter to see its value in a tooltip.

```
class FMRentalCheckoutProcessor
{
    public boolean FinalizeRentalCheckout(FMRental fmrentalrecord)
    {
        Struct RentalConfirmation = new Struct('boolean OKtoRent');

        // setter
        RentalConfirmation.value('OktoRent', true);

        //fire the event
        this.RentalTransactionAboutTobeFinalizedEvent(fmrentalrecord, RentalConfirmation);

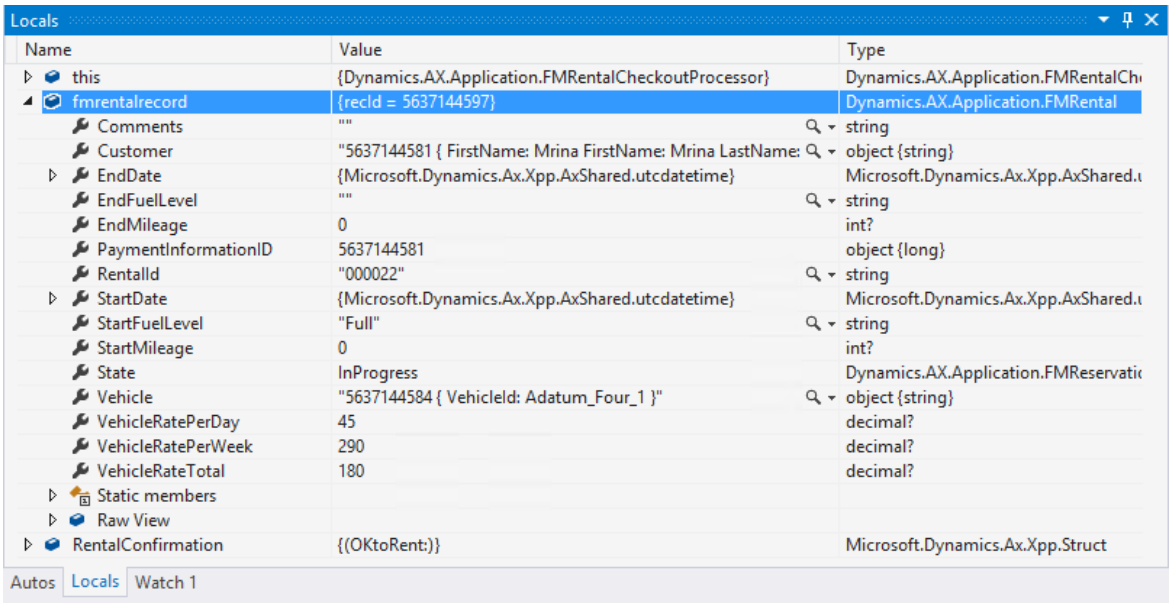
        //return what survived after eventhandlers finishing
        return ( RentalConfirmation.value('OktoRent'));
    }

    delegate void RentalTransactionAboutTobeFinalizedEvent(FMRental fmrentalrecord, struct RentalConfirmation)
    {
    }

}
```

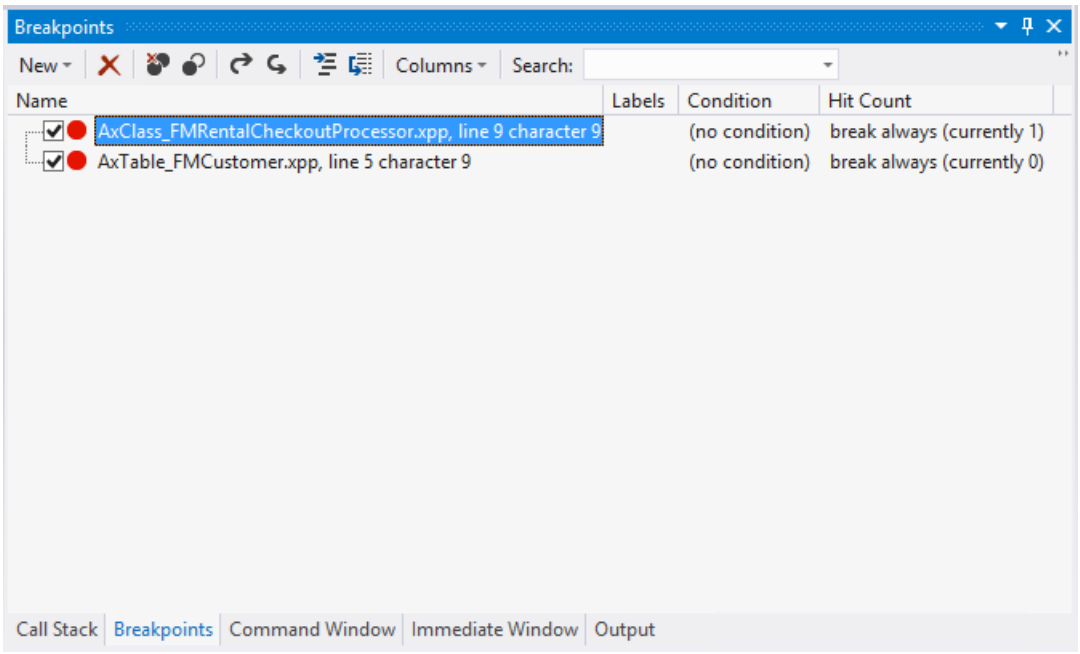
{recId = 5637144597}

14. The other debugging tools in Visual Studio are available as well. For example, the **Locals** window shows all of the local variables for the location where execution has stopped. Click the **Locals** tab at the bottom of Visual Studio, and expand the **fmrentalrecord** variable. You will see the internal state of the record, showing the values of all the fields in the record.



Notice the value of the **Vehicle** property of the **fmrentalrecord** variable. This property is a foreign key field in the **FMRental** table. The debugger allows us to peek into the related record in the FMVehicle table. It shows values that belong to the **AutoIdentification** field group.

15. The **Breakpoints** window lists all of the breakpoints that have been set. Click the **Breakpoints** tab to see its content.



16. Press F10 a few times to step through the code, line-by-line, and use the full complement of debugger features. Notice that the **Locals** window updates the values of variables immediately with each statement that's executed.

17. On the toolbar, click **Continue**, or press F5

18. Close Internet Explorer to close the **Fleet Management** application. Visual Studio will exit the debugging mode. An alternative is to choose **Stop Debugging** from the **Debug** menu. This will leave Internet Explorer open, allowing the next debugging session to start faster.

Add the validation code

In the **FinalizeRentalCheckout** method, you saw that the developer added code to call the delegate that's used to determine the validity of the rental. To solve the problem of expired credit cards, you'll add an event handler,

which you'll use to verify that the credit card isn't expired. To simplify the lab, the handler will be added in the same file that contains the delegate. Use the following code as inspiration. Rather than copying and pasting the code, type it in manually to see the IntelliSense features in action. These features add to the high level of productivity that Visual Studio users expect.

```
[SubscribesTo(classstr(FMRentalCheckoutProcessor),
    delegatestr(FMRentalCheckoutProcessor, RentalTransactionAboutTobeFinalizedEvent))]
public static void RentalFinalizedEventHandler(FMRental rentalrecord, Struct rentalConfirmation)
{
    FMPaymentInformation paymentInfo;
    date ccExpiryDate, lastDayOfExpiryMonth;
    str s;

    select firstonly * from paymentInfo where paymentinfo.RecId == rentalRecord.PaymentInformationId;

    if (paymentInfo)
    {
        // Check if the payment info is valid
        // For now, we will check if the credit card is expired
        // Credit cards expire on the last day of the month indicated
        ccExpiryDate = mkdate(1, str2int(paymentInfo.ExpirationMonth), paymentInfo.ExpirationYear);
        lastDayOfExpiryMonth = endmth(ccExpiryDate);

        if (lastDayOfExpiryMonth < today())
        {
            rentalConfirmation.value('OktoRent', false);
            s = "Credit card validation failed for rental ";
        }
        else
        {
            s = "Credit card validation succeeded for rental ";
        }

        info (s + rentalrecord.RentalId);
    }
    else
    {
        rentalConfirmation.value('OktoRent', false);
        info ("No Credit card available for " + rentalrecord.RentalId);
    }
}
```

The preceding code is straightforward. The method is marked as handler for the relevant delegate by using the **SubscribesTo** attribute, as shown. In the code, the customer record is retrieved, and then the credit card date is compared to today's date. If the expiration date of the credit card is in the past, the event handler sets a value in the **RentalConfirmation** structure to signal that the customer isn't eligible to rent a vehicle. The idea is that any number of handlers can subscribe to the delegate. If any handler determines that a rental should not proceed, it sets the **OkToRent** flag to false. A superior implementation might refrain from doing any analysis if it determines that the **OkToRent** flag has already been set to false.

1. Be sure that you're working in the FMRentalCheckoutProcessor.xpp file. Begin by adding the new event handler definition to the FMRentalCheckoutProcessor class. Add the following code on an empty line just above the brace (}) that marks the end of the class definition.

   ```
   public static void RentalFinalizedEventHandler(FMRental rentalrecord, Struct rentalConfirmation)
   {

   }
   ```

2. Add the attributes to the beginning of the event handler. These attributes indicate which delegate the event handler is subscribing to.

```
    [SubscribesTo(classstr(FMRentalCheckoutProcessor),
        delegatestr(FMRentalCheckoutProcessor, RentalTransactionAboutTobeFinalizedEvent))]
        public static void RentalFinalizedEventHandler(FMRental rentalrecord, Struct
                                                                        RentalConfirmation)
    {

    }
```

3. Now, add the code that checks the credit card expiration value. The completed method should look similar to the following code.

```
[SubscribesTo(classstr(FMRentalCheckoutProcessor),
    delegatestr(FMRentalCheckoutProcessor, RentalTransactionAboutTobeFinalizedEvent))]
public static void RentalFinalizedEventHandler(FMRental rentalrecord, Struct rentalConfirmation)
{
    FMPaymentInformation paymentInfo;
    date ccExpiryDate, lastDayOfExpiryMonth;
    str s;

    select firstonly * from PaymentInfo where paymentinfo.RecId == rentalRecord.PaymentInformationId;

    if (paymentInfo)
    {
        // Check if the payment info is valid
        // For now we will check if the credit card is expired
        // Credit cards expire on the last day of the month indicated
        ccExpiryDate = mkdate(1, str2int(paymentInfo.ExpirationMonth), paymentInfo.ExpirationYear);
        lastDayOfExpiryMonth = endmth(ccExpiryDate);

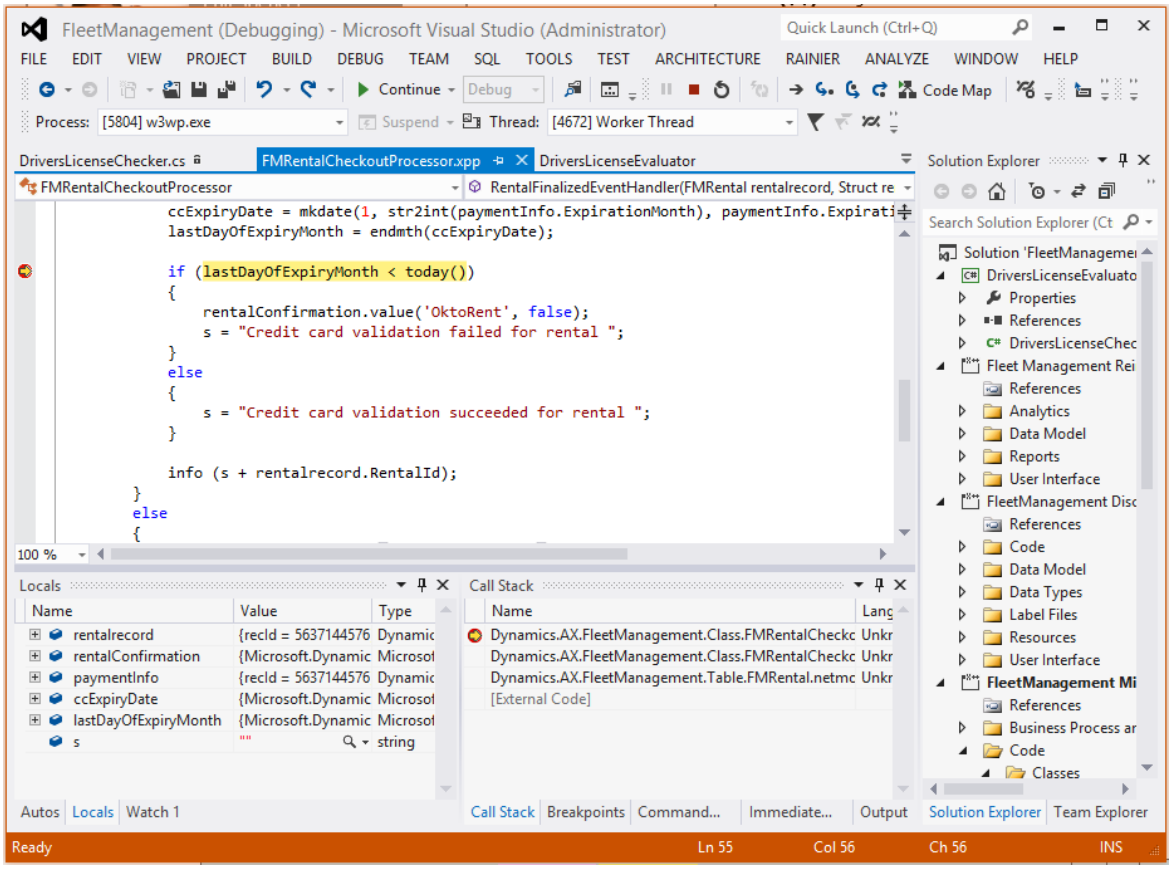
        if (lastDayOfExpiryMonth < today())
        {
            rentalConfirmation.value('OktoRent', false);
            s = "Credit card validation failed for rental ";
        }
        else
        {
            s = "Credit card validation succeeded for rental ";
        }

        info (s + rentalrecord.RentalId);
    }
    else
    {
        rentalConfirmation.value('OktoRent', false);
        info ("No Credit card available for " + rentalrecord.RentalId);
    }
}
```

4. Make sure the handler and the delegate are separated by exactly one blank line.
5. On the toolbar in Visual Studio, click **Save**.
6. After you're satisfied with the code, build the code for the Fleet Management project. To do this, in **Solution Explorer**, right-click the **FleetManagement** project name, and then click **Build**. You may see errors or warnings if the code isn't correct. If so, correct the code, and build again until all warnings and errors have been resolved. You're now ready to validate that the revision works as intended.
7. On the **Debug** menu, click **Delete All Breakpoints**.
8. Place a new breakpoint in the event-handler method at the line that contains the following statement:

```
if (lastDayOfExpiryMonth < today())
```

9. Start the Fleet Management sample with debugging active by pressing F5.
10. Browse to the **Current rentals** page, as described starting in step 11 of the previous section. Select one of the reservations, and click **Edit**.
11. In the **Customer** drop-down list, select Adrian Lannin from the list, and then click **Save**. Execution pauses at the breakpoint that you set in the event-handler method.
12. Press F10 three times to step through the code block.



13. To see the code map for the call stacks, right-click in the code editor, and then click **Show Call Stack on Code Map**. You may want to add a comment to the call stack, step through the code, and watch as the code map changes accordingly.
14. Press F5 to continue. You'll see that the customer has been disallowed.
15. In the same rental, change the customer name to Phil Spencer, and then click **Update**. This time, the transaction is allowed.
16. Close Internet Explorer.
17. Comment out the **SubscribesTo** attribute on the **RentalFinalizedEventHandler** method. This step ensures that the credit card test will no longer run as you work on the remaining tutorials.

Best practices

Earlier in this tutorial, you had the opportunity to add code to the project and build the solution with your changes. The build process may not have been successful, requiring you to refer to the error window. Using this window, you can get to the error by clicking on the line that describes the error. You may have noticed some diagnostic messages that don't represent compilation errors. These are diagnostics from the **Best Practice** checker. This tool will check for instances where the developer has violated a known best practice, and display a

warning when one is found. The Best Practice rules apply to both code constructs and metadata. Each software development organization is likely to have its own set of best practices that they enforce. They may want to disregard some of the existing best practice checks. To support this, the set of reported best practice diagnostics can be modified by the individual developer. To demonstrate this, complete the following steps:

1. On the **View** menu, click **Error List**. You should see a small number of best practice warnings.
2. On the **Dynamics 365** menu, click **Options**. In the **Dynamics 365** group, choose **Best Practices**.
3. In the **Model** drop-down list, make sure that the **Fleet Management** model is selected. The best practice rules apply to a particular model.
4. Mark the selections for some of the sets of Best Practice rules. For example, if you select the entry for **CodeStyleRules**, best practice guidelines for variables will be examined. After you've updated the selections, click **OK**.
5. Rebuild the Fleet Management project by right-clicking the project name and then clicking **Rebuild**. You'll notice that the violations of the best practice rules that you specified appear in the **Error list** window.

Build operations

2/18/2021 • 6 minutes to read • Edit Online

This topic reviews the process to build projects and full build of model packages.

The elements of a model must be built so that they can be used by the application. You can build the elements in a project. You can also build all the elements in a model. The following actions are performed during a build operation:

- Metadata validation
- X++ code validation
- Best practice checks
- Report RDL generation
- Compilation, IL generation, and creation of the .NET assemblies
- Label assembly generation and deployment of other resource files
- Database synchronization

Build a project

When you build a project, only those elements that are new or that have changed are built. To build a project, follow these steps.

1. In Solution Explorer, select the project.
2. On the **Build** menu, click **Build <project name>** to start the build process. Alternatively, right-click the project in Solution Explorer, and then click **Build**.

During the build process, you might notice that some elements that are built aren't part of the project. This behavior is required because of the way that assemblies are created. When you build an element, you're actually building the .NET module that the element is included in. A single .NET module contains multiple model elements, and a single assembly contains multiple .NET modules. The assembly can be created only if all the .NET modules in the assembly have been built and are up to date. If any elements in any of the .NET modules for an assembly haven't been built or aren't up to date, they will be built, even if they aren't included in the current project.

> **NOTE**
>
> If you delete an element from a project, you must rebuild the project or perform a full build on the model before the deletion takes effect.

Rebuild a project

If you want to build all the elements in a project, regardless of whether they have changed, you must perform a rebuild operation. To rebuild a project, follow these steps.

1. In Solution Explorer, select the project.
2. On the **Build** menu, click **Rebuild <project name>** to start the rebuild process. Alternatively, right-click the project in Solution Explorer, and then click **Rebuild**.

Synchronizing the database at each build

A project property lets you specify that the synchronize operation for the database should be performed every time that you build the project. This can be useful when you're making changes to the table structure for an application. Each time that you build, you will know that the database is synchronized with the tables as they are defined in the project. For information about how to set project properties, see Finance and Operations project type in Visual Studio. If your application has a large number of tables, and you aren't yet testing the application, you can set the **Synchronize database on build** property to **false**. This change will reduce the time that is required to build the project. Then, when you begin testing, be sure to set this property back to **true**. If you must manually synchronize the tables in a project, you can right-click the project in Solution Explorer and then click **Synchronize <project name> with database**. To synchronize the entire database, which can be a long process, on the **Dynamics 365** menu, click **Synchronize database**.

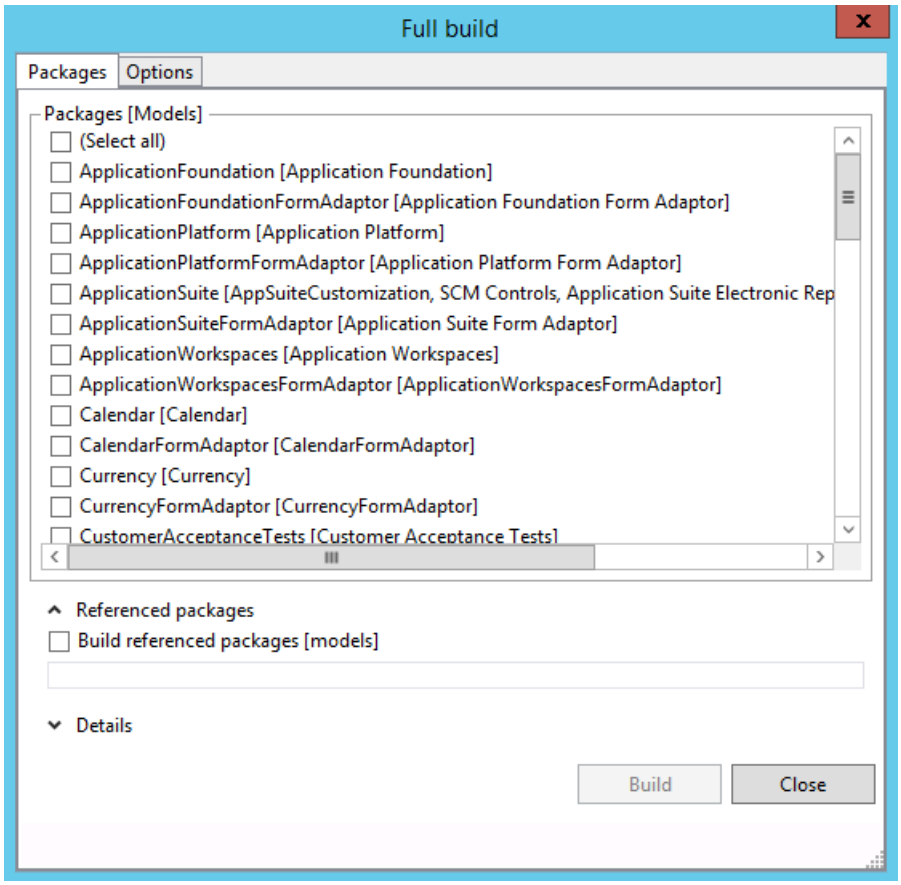
> **NOTE**
> If you try to synchronize the database before you have fully compiled assemblies, the Visual Studio database synchronization tool will display a message that synchronization has completed successfully, when in fact, the synchronization was not successful.

Tables and views cannot be synchronized against the database until they are fully compiled. After you complete a full build of the Application Platform, Application Foundation, and Application Suite, you can complete a Database Synchronization from the Dynamics 365 menu in Visual Studio.

Build a model's package

You might want to build all the elements in a specific model. To do this, you must perform a full build on the package that the model belongs to. Follow these steps.

1. On the **Dynamics 365** menu, click **Build models**.
2. In the **Packages** list, select the package(s) to build.
   - Package names are listed alphabetically.
   - Models belonging to the package are shown in brackets.
3. If you want to build the dependent packages first, select **Build referenced packages**. Any dependent package that must be built will be listed.



4. On the **Options** tab, review the options for the build process. The following options are available.

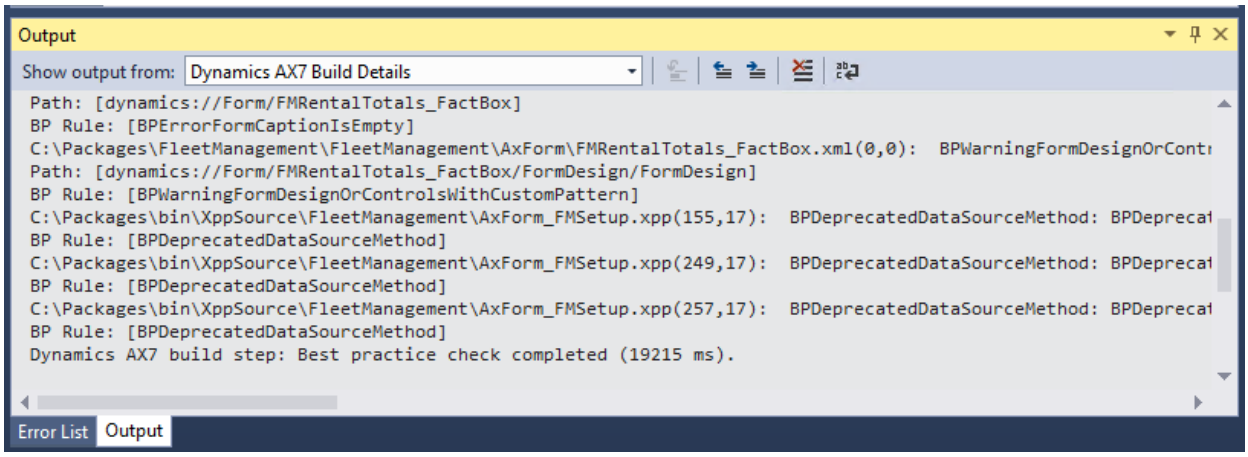
OPTION	DESCRIPTION
Build Pre-Compiled Forms	Static HTML is generated for each form during the build process. This allows faster rendering of forms at run time.
Build Reports	Reports are built.
Build Aggregate Measurements	Aggregate measurements are build.
Run Best Practice Checks	Best practice checks are performed during the build process.
Synchronize Database	The schema of the SQL database is updated during the build process (after compilation of the metadata and source code), so that it matches the metadata.
Build cross reference data	The data for the cross-reference feature is updated during the build process. Cross reference data enables developers to find references to code and metadata during development.

5. Click **Build** to start the build process.

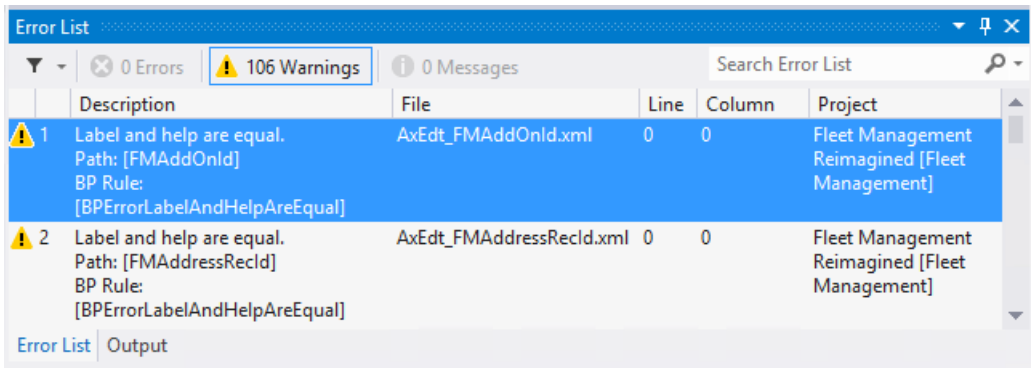
6. Expand the **Details** tab to follow details of the build process.

Build results

After a build operation is completed, you will see the results in Microsoft Visual Studio. The **Output** pane in Visual Studio shows the status of the build. You can use the **Show output from** field to switch between the standard build information and the build details.



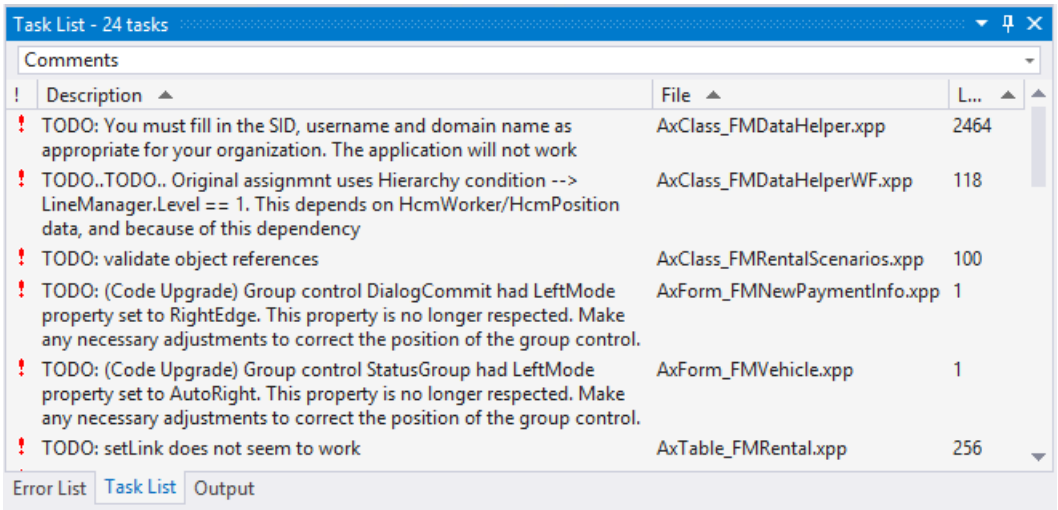
The **Error List** pane in Visual Studio shows the build errors and warning that occurred during the build process. If you see any build errors, you must fix them and then build again, so that valid assemblies can be created for the application. Many of the warnings that appear in the **Error List** pane are best practice checks that inform you of revisions that you should make to your application so that it conforms to the best practices for application development. Ideally, you should address all the best practice warnings for an application.



You can double-click most errors and warnings to see the source of the issue. The element designer or code editor will open, where you can see what property setting or code is causing the error or warning. The **Task List** pane in Visual Studio shows tasks that have been flagged with "TODO" comments in code. For example, the following comment indicates that some object references still require validation.

```
// TODO: validate object references
```

When the code is built, these "TODO" comments appear in the **Task List** pane. To view the **Task List** pane, on the **View** menu, click **Task List**.



To make resolution easier, you can add the elements that are affected by the error or task to the current project

or to a new project. In the **Error List** pane or the **Task List** pane, select the rows for the errors or tasks that you want to fix, right-click, and then click **Add to project** or **Add to new project**. This saves you the effort of finding the affected elements in the application.

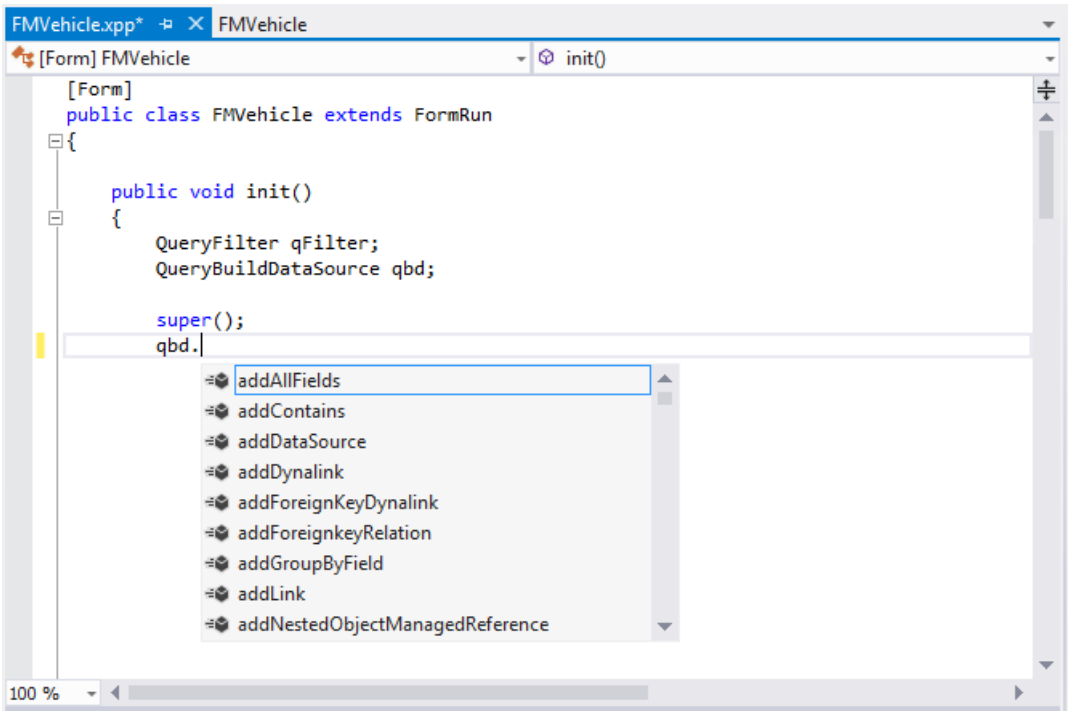
Code editor features

2/18/2021 • 2 minutes to read • Edit Online

This topic describes the code editor for Visual Studio.

Code editor

You use the code editor in Microsoft Visual Studio to write the X++ code for your applications. The X++ language is fully integrated into the Visual Studio environment. As you write your X++ code, you will see the familiar features of the Visual Studio code editor. For example, IntelliSense is displayed to help you write the code. You can also navigate to methods and classes in the code editor by using the navigation drop-down menus at the top of the code editor window.



Other features, such as collapsible sections, are also available.

Opening the element designer

You can open the element designer that corresponds to the current X++ source code by right-clicking in the code editor and then selecting **Open Designer**.

Create models and data model elements overview

2/18/2021 • 5 minutes to read • Edit Online

In this tutorial, you'll use Visual Studio's Dynamics 365 menu to create a new model named **Fleet Management tutorial**. You'll also create and edit new model elements.

Prerequisites

This tutorial requires that you have access to an environment, and that you be provisioned as an administrator

Keywords

- **Model** - You configure your model to refer to two other models. This enables your model to reference metadata and code elements that are in other packages.
- **Project** - You create a project and then associate your project to your new model. You add elements to your project, which are also added to your model. Specifically, you add an extended data type (EDT). You also add a table that you populate with fields and a method.
- **Designer** - Each time you add an item to your project, a designer is displayed that is tailored to the item type you selected. The **Properties** window adjusts each time a different node of the designer is highlighted. You make updates in the designers and in the **Properties** window.
- **EDT** - Extended data type.

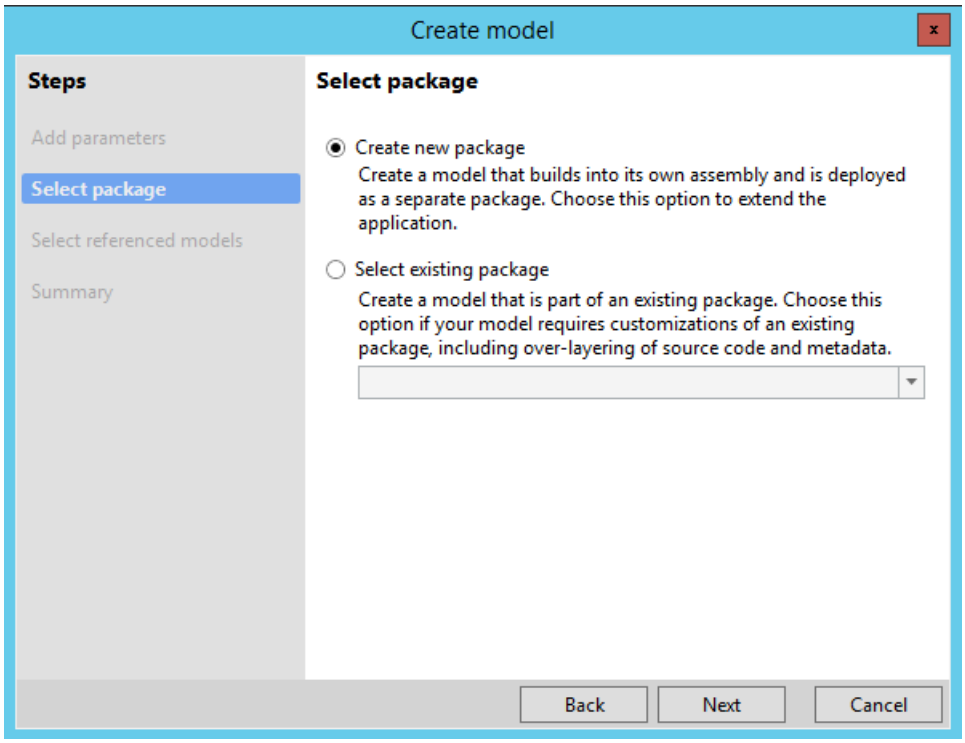
Create the Fleet Management tutorial model

1. Start Visual Studio using **Run as administrator**.
2. From the **Dynamics 365** window, select **Model Management > Create model** to open the **Create model** wizard.
3. Enter the following values for model parameters.

PROPERTY	VALUE
Model name	FleetMgmntTutorial
Model publisher	Microsoft Corp
Layer	isv
Model description	This tutorial shows how to build the Fleet Management application by using the Microsoft Dynamics AX development tools.
Model display name	Fleet Management Tutorial

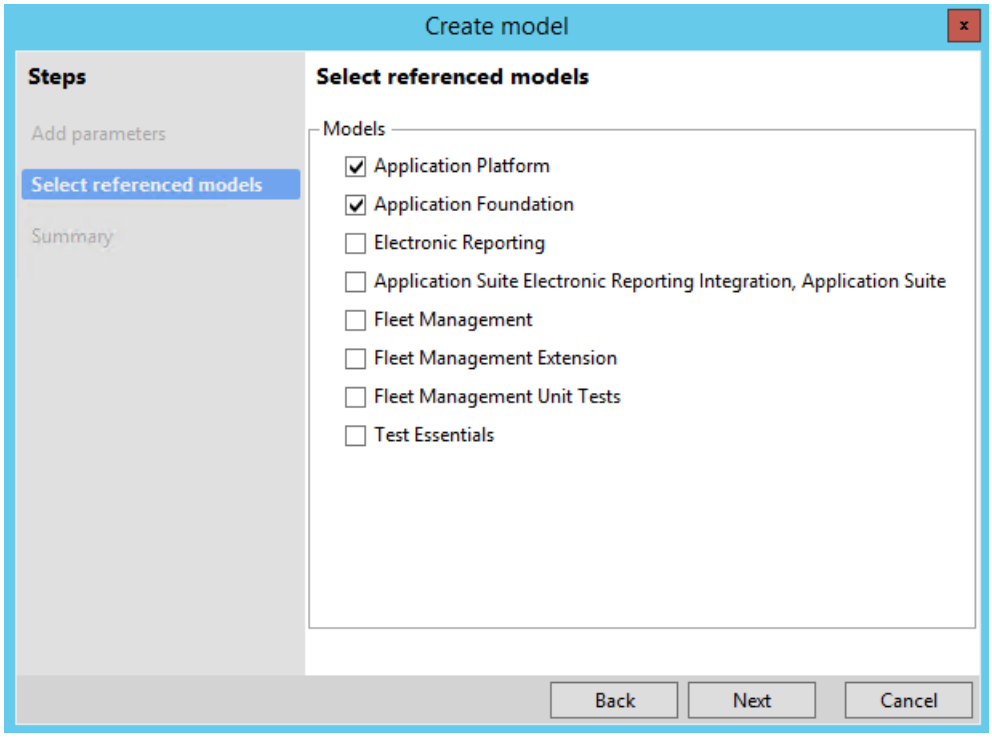
> **NOTE**
>
> Your model name must be **FleetMgmntTutorial**. Don't use any other name. In other tutorials, you'll overwrite model elements in this model by importing a project. If the model you create in this tutorial isn't named **FleetMgmntTutorial**, you may not be able to correctly import the project in other tutorials.

4. Click **Next** to advance to the next page, and then select **Create New Package**. The model you're creating will have its own package and build its own .NET assembly.



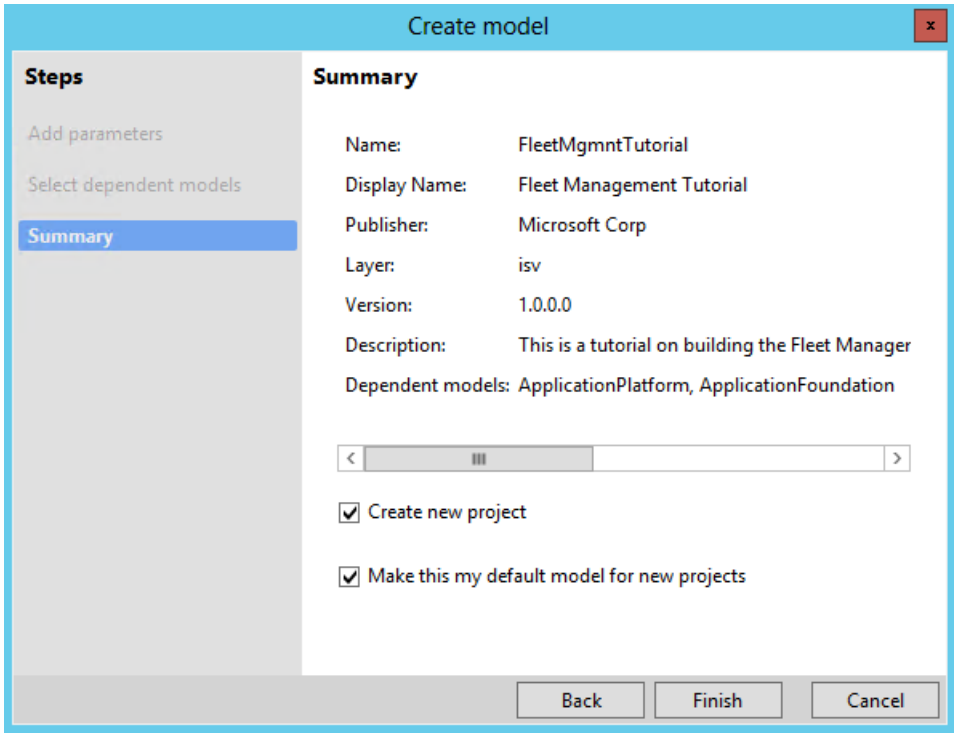
5. Click **Next** to advance to the **Select referenced models** step.

6. Select **Application Platform** and **Application Foundation** as referenced models.



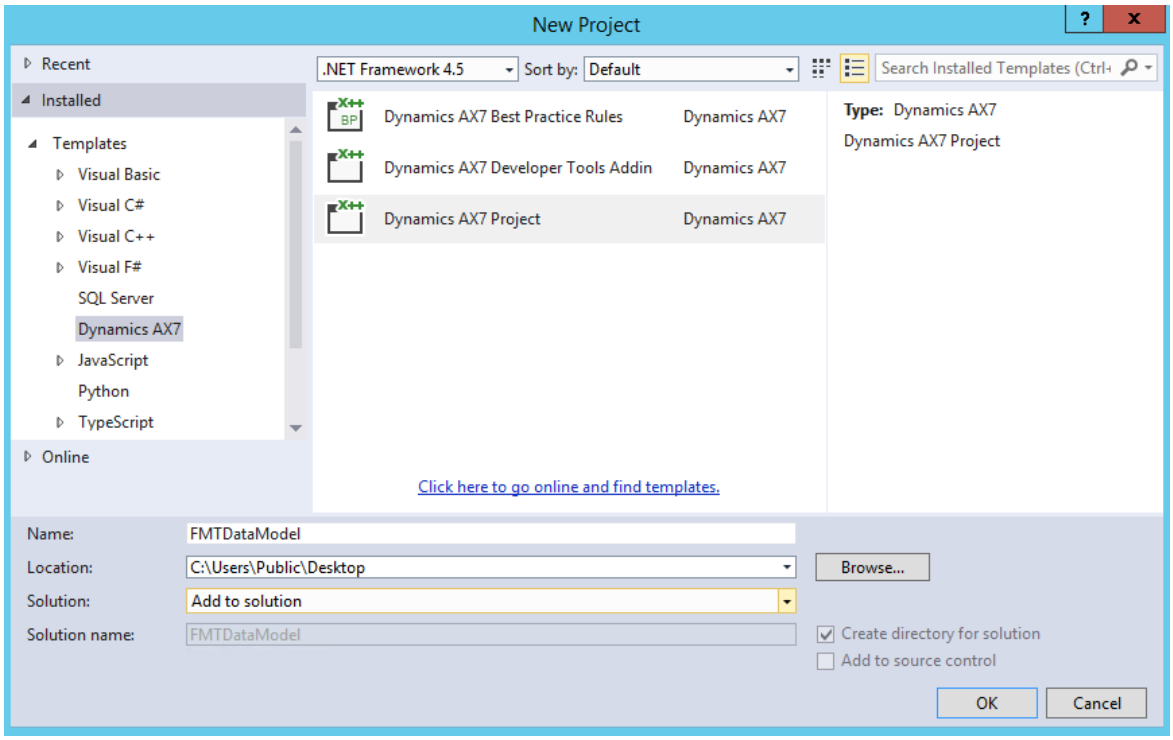
> **IMPORTANT**
>
> Verify that you've selected the correct referenced models.

7. Click **Next** to advance to the **Summary** step.
8. Verify the information on the summary page, and then select the **Create new project** and **Make this my default model for new projects** check boxes.



9. Click **Finish**. The **New Project** dialog box opens.
10. Under **Templates**, select **Dynamics 365**.
11. Select the **Unified Operations** template.
12. Enter the following values in the fields in the dialog box.

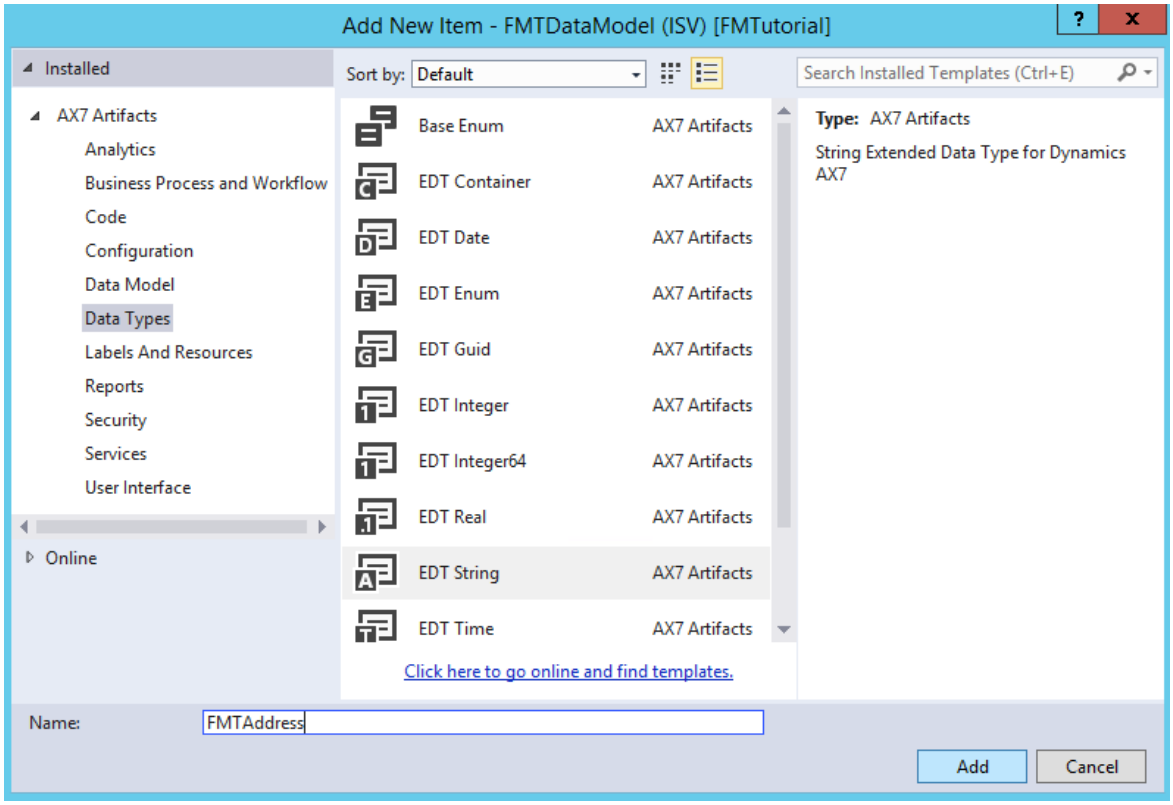
PROPERTY	VALUE
Name	FMTDataModel
Location	C:\FMLab
Solution	Add to solution



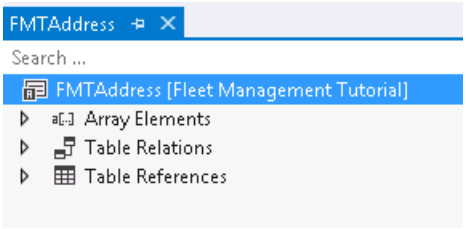
13. Click **OK** to create the project.

Create the FMTAddress extended data type

1. In **Solution Explorer**, right-click **FMTDataModel**, point to **Add**, and then click **New Item**.
2. Under **Dynamics 365 Items**, select **Data Types**.
3. Click **EDT String** to select the new item type.
4. In the **Name** field, enter **FMTAddress**, and then click **Add**.

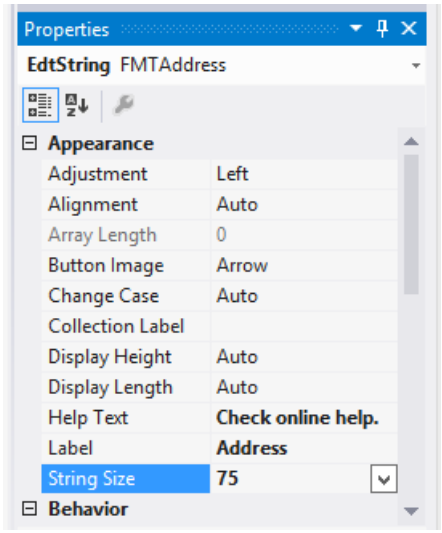


This adds a new EDT model element to the project, and opens the EDT designer for the new element, as shown in the following illustration.



5. Select the root node of **FMTAddress** in the designer.
6. In the **Properties** window, in the **Appearance section**, set the following properties.

PROPERTY	VALUE
Help Text	Check online help.
Label	Address
String Size	75

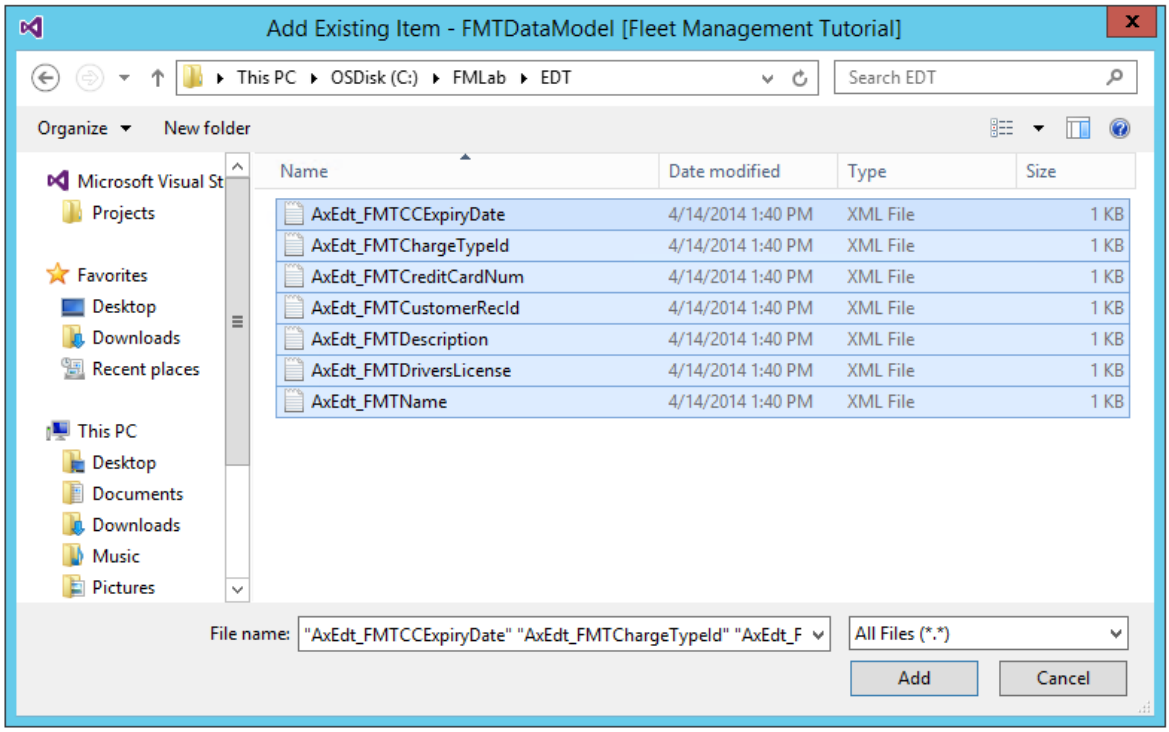


7. Press **Ctrl+S** to save the EDT.

Add existing model

Add the other required model element files to the current model and project. You can do this quickly by using the **Add existing item** feature.

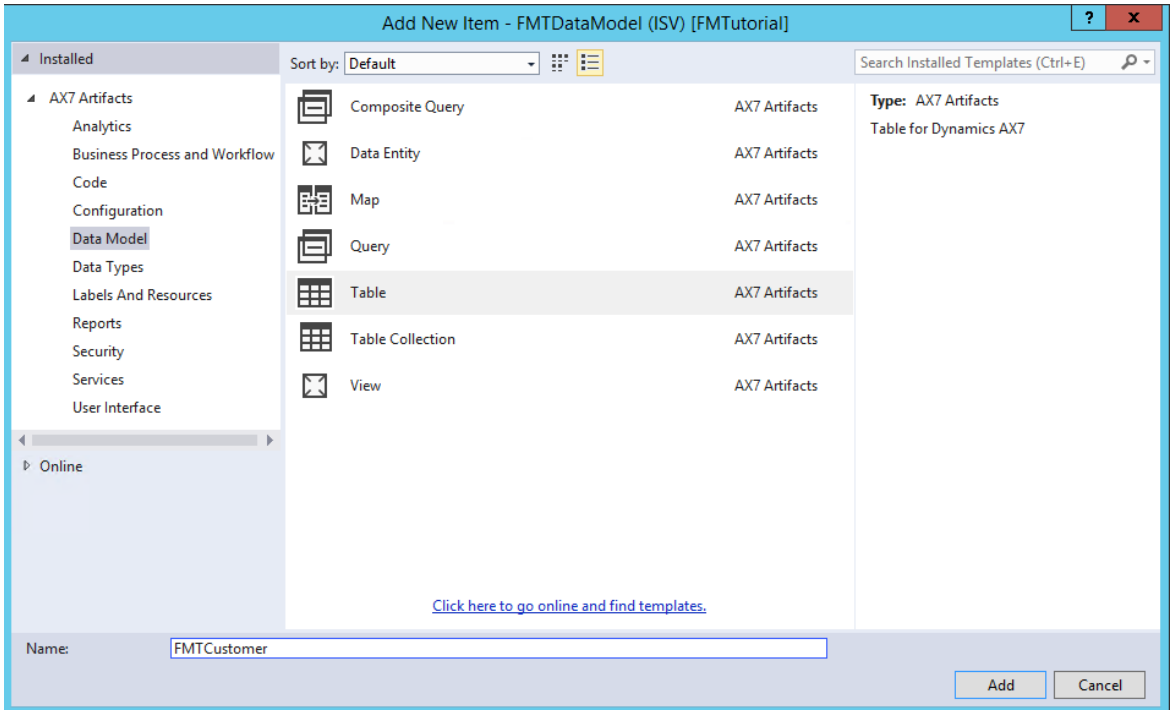
1. In the **Solution Explorer**, right-click **FMTDataModel**, point to **Add**, and then click **Existing Item**.
2. Browse to C:\FMLab\EDT\.



3. Press **Ctrl+A** to select all of the files, and then click **Add**.

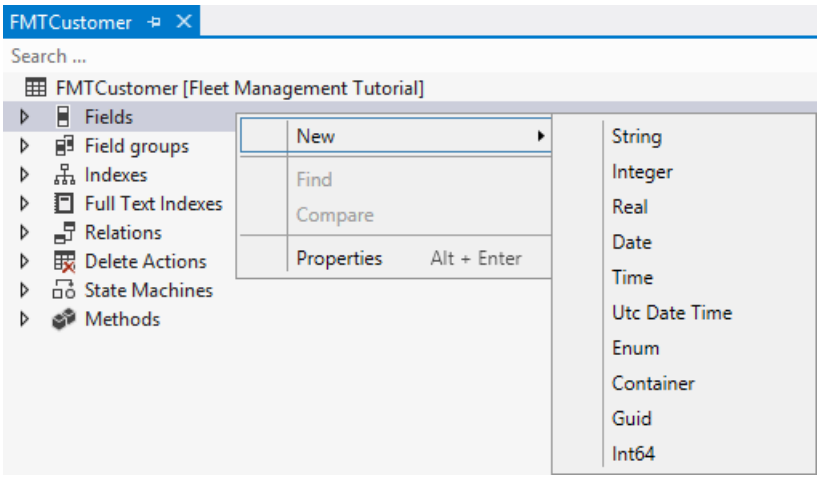
Create the FMTCustomer table

1. In **Solution Explorer**, right-click **FMTDataModel**, and then click **Add > New Item**.
2. In the left pane, expand **Installed**, expand **Dynamics 365 Items** and then click **Data Model**.
3. In the list of artifacts, select **Table**.
4. In the **Name** field, enter **FMTCustomer**, and then click **Add**. The table designer opens.



Add fields to the FMTCustomer table

In the table designer for FMTCustomer, you now add several fields to the table.

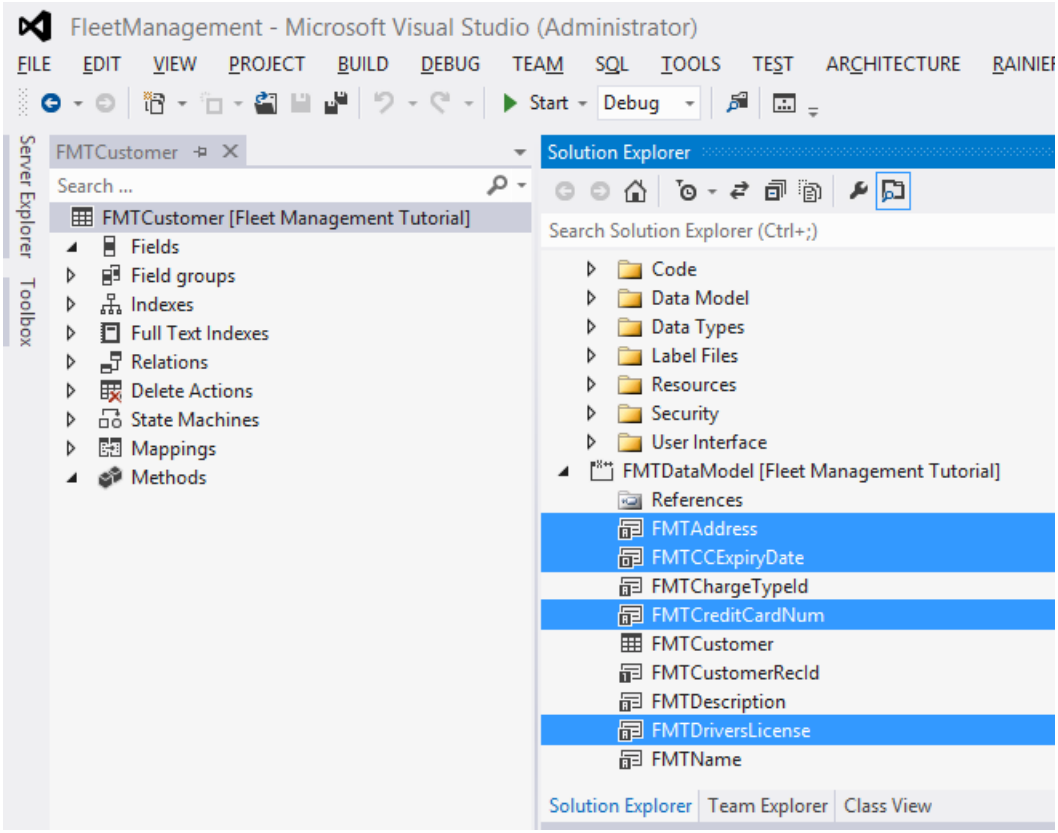


1. To add each field, right-click **Fields**, click **New**, and then select a type. As you add each field, you must specify the field name and certain other values in the **Properties** window, as described in the following table.

TYPE	FIELD NAME	PROPERTY VALUES
Date	CCExpiryDate	Extended Data Type = FMTCCExpiryDate
String	Address	Extended Data Type = FMTAddressHelp Text = Help text for the address field.
String	CellPhone	Extended Data Type = Phone
String	CreditCardNum	Extended Data Type = FMTCreditCardNum
String	DriversLicense	Extended Data Type = FMTDriversLicense
String	Email	String Size = 80Label = Email
String	FirstName	Extended Data Type = FirstName
String	LastName	Extended Data Type = LastName
String	License	String Size = 100Label = License
String	Thumbnail	String Size = 100Label = Thumbnail

TIP

For all new fields in the table that reference an EDT, you can create the field by simply dragging the EDT element from **Solution Explorer** or **Application Explorer** and dropping it on the **Fields** node of the **FMTCustomer** table in the designer.



2. Press **Ctrl+S** to save the new fields on the table.

Add fields to field groups

1. Prepare to add some of the fields to the **AutoSummary** field group by selecting the fields in the following list. To select multiple fields, hold down the Ctrl key while you click each field:

   - **Address**
   - **CCExpiryDate**
   - **CellPhone**
   - **CreditCardNum**
   - **DriversLicense**
   - **Email**
   - **FirstName**
   - **LastName**

2. Expand the **Field Groups** node.

3. Drag the selected fields to the **AutoSummary** node

4. Use the same technique to add the fields **FirstName**, **LastName**, and **CellPhone** to the **AutoReport** field group.

5. Save the table.

Add a method

1. Add the X++ method named **fullName** to the **FMTCustomer** table by right-clicking the **Methods** node, and then clicking **New Method**.

2. In the code editor, replace the default method code with the following code.

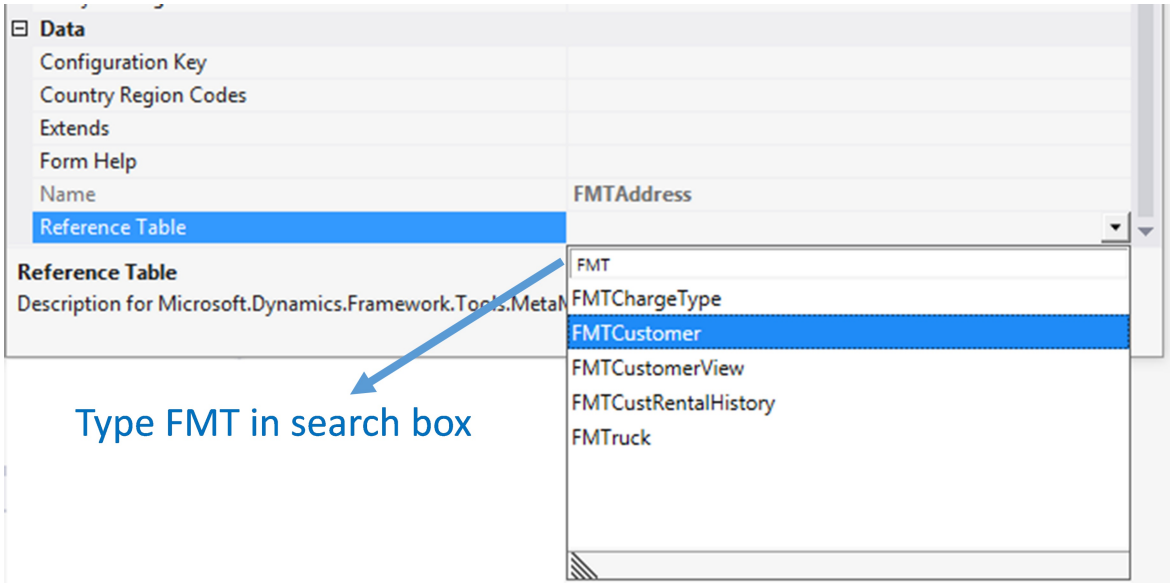
> **TIP**
>
> When you type “this.”, choose the field from the IntelliSense list.

```
public display FMTName fullName()
{
    return this.FirstName + ' ' + this.LastName;
}
```

3. Save the code.

Update the FMTAddress EDT

1. In **Solution Explorer**, expand the **FMTDataModel** project.
2. Right-click **FMTAddress**, and then click **Open**. The **EDT designer** opens.
3. In the **EDT designer**, select **FMTAddress**.
4. In the **Properties** window, in the **Reference Table** field, select **FMTCustomer**. **Tip:** Click the drop-down list, and then type the prefix "FMT" in the search box. This filters the drop-down list to only show tables that contain "FMT" in their name. Select the **FMTCustomer** table from the list of filtered entries.



5. Save the EDT.

Build the FMTDataModel project and the Fleet Management tutorial model

1. In **Solution Explorer**, right-click **FMTDataModel**, and then click **Rebuild**.
2. To do a full build of the entire model, on the **Dynamics 365** menu, click **Build models**.
3. Clear the check box for all models except for **Fleet Management Tutorial**.
4. On the **Options** tab, select the **Run Best practice checks** check box. Note that other options available.
5. On the **Models** tab, click **Build**.
6. Click **Close** in the dialog box.
7. On the **Window** menu, click **Close All Documents**, to close all open documents.

Turn off model customization and deprecate functionality

2/18/2021 • 6 minutes to read • Edit Online

This article describes the process of disabling customization of a model. By following this process, you make it ineligible for over-layering. Developers will still be able to extend that model. This article also describes how you can deprecate obsolete functionality.

Typically, you build an application in models that depend on other models. At the very least, your models will depend on the Application Platform model that is provided. Finance and Operations applications run on the Microsoft Azure cloud platform. In other words, it runs off-premises, in data centers that are managed by Microsoft. Because we can't support changes from a large number of vendors in the fundamental models, your applications can no longer over-layer artifacts in those models. Therefore, to build your applications, you must use extensions instead of over-layering. Even though all the artifacts in the models that you depend on are available for documentation purposes, you can't compile someone else's intellectual property and run it in the cloud.

Locking customizations

Transitioning a model from over-layering to extensions involves three steps:

1. You set a property that causes instances of over-layering to be flagged as warnings. This step is sometimes known as "soft-locking."
2. You have a period when you can burn down the warnings by using extensions instead of over-layering.
3. When you have resolved all the warnings, it's time to make over-layering a hard error that causes compilation to fail. This step is known as "hard-locking." When a model is hard-locked, the tooling that is required for over-layering can't be used for that model. Additionally, you can't have more than one model in a given package.

Currently, there is no tooling that you can use to manipulate the property that disables customizations. Instead, you must add the **Customization** XML element to the model descriptor file, as shown in the following example. You can find the model descriptor file at ...\<packages>\<package name>\Descriptor\<model name>.xml.

```
<?xml version="1.0" encoding="utf-8"?>
<AxModelInfo xmlns:i="http://www.w3.org/2001/XMLSchema-instance">
<Customization>DoNotAllow</Customization>
<Description>My cool locked application</Description>
...
<</AxModelInfo>
```

There are three levels of customization settings:

- **Allow customizations** – If the **Customization** element is omitted, or if it's provided but the text **Allow** is used inside it, there are no restrictions.
- **Soft-locking** – If you require soft-locking, use the text **AllowAndWarn** inside the **Customization** element.
- **Hard-locking** – To disable customization of the model, use the text **DoNotAllow** inside the **Customization** element, as shown in the preceding example.

> **NOTE**
>
> Elements in the descriptor file must be listed in alphabetical order.

Backward compatibility of the platform

There is a requirement that your application must continue to run even if a newer version of a dependent platform model is installed. Therefore, we enforce strict requirements for backward compatibility on all the changes that we make in those platform models. We can clarify this point through an example. For this example, you have a base model M that has the following class.

```
public void DoSomething(int arg)
{
    // Do great stuff
}
```

In your model that depends on model M, you want to take advantage of all the great functionality that the **DoSomething** class offers. Therefore, you have the following code.

```
{
    var c = new SomeClass();
    c.DoSomething(42);
}
```

Later, your vendor (perhaps Microsoft) releases a new, updated version of the model that you depend on (model M). When this model is released, we must support the public interface, because things must run without recompilation. Suppose that we changed the method signature by adding another parameter, as shown here.

```
public void DoSomething(int arg, str anotherArg)
{
    // Do greater stuff
}
```

In this case, we break the app. The common language runtime (CLR) can't call the method, because the parameter profile that is assumed in the call isn't the same as the parameter profile of the callee (the calling code provided one parameter, but two are now required). Therefore, it's a good idea to limit what is publicly consumable. If something is private, nobody can use it from outside your model. However, another option is to make the artifact internal. If you apply the **internal** modifier to a class or method, the artifact is visible only inside your model and can't be reached from the outside. Essentially, you must assume that anything that isn't internal or private will be used from outside your model. Therefore, you must support it forever. Never make anything public or protected unless it absolutely must be public or protected, and use interfaces to hide implementation details that aren't relevant outside the boundary of your model. There is no way to mark metadata (as opposed to code) with the internal visibility specifier.

Testing internal functionality

By limiting the surface area of your model, you help guarantee that you will be able to fix issues in your models that do not allow customizations, and that the application will run smoothly. However, you might argue that, by making things internal, you limit the ability to test your code. To remedy this situation, you can inform your test packages about the packages that they should test. In other words, the test packages can access internal things. To implement this solution, you edit the descriptor file, as shown in the following example.

```
<?xml version="1.0" encoding="utf-8"?>
<AxModelInfo xmlns:i=http://www.w3.org/2001/XMLSchema-instance>
<InternalsVisibleTo xmlns:d2p1="http://schemas.microsoft.com/2003/10/Serialization/Arrays">
<d2p1:string>ExternalPackageName</d2p1:string>
</InternalsVisibleTo>
...
</AxModelInfo>
```

You can provide any number of external packages by including them in the **InternalsVisibleTo** element. This information is provided for the package that contains the code to test, not for the package that contains the testing code. In other words, the package determines who it shares information with. **Note:** The elements under **AxModelInfo** must be in alphabetical order.

Deprecating functionality

Deprecating methods

Sometimes, you no longer want to support source code that is public. As we mentioned earlier, you should not remove an artifact from the code unless that artifact is private or internal, because there might be users who rely on it. Instead, you can use the **SysObsoleteAttribute** attribute to specify that consumers should no longer use that artifact. We recommend that you mark things as obsolete in two phases:

1. Specify that using the artifact is flagged as a warning.
2. After one or more release cycles, make using the artifact an error.

In the following example, the **DoSomething** method is defined in the first release of a model.

```
class SomeApi
{
    void DoSomething()
    {
        // Do great stuff
    }
}
```

In the second release, you've determined that there is a better way to accomplish something. Therefore, you add the new implementation and make the old implementation obsolete.

```
class SomeApi
{
    [SysObsolete("Use DoSomethingNew instead", false)]
    void DoSomething()
    {
        // Do great stuff
    }

    void DoSomethingNew()
    {
    }
}
```

All your existing customers will continue to call the old version. This situation is fine, but the customers won't be able to take advantage of the benefits of the new version. Anyone who codes against your class will receive a build warning together with the message that you provided in the **SysObsolete** attribute argument. Presumably, these clients will update their code so that it uses the new method. As time passes, more clients will move to the new version. Therefore, at some point, it will make sense for you to make coding against the method a hard error.

```
class SomeApi
{
    [SysObsolete("Use DoSomethingNew instead", true)]
    void DoSomething()
    {
        // Do great stuff
    }

    void DoSomethingNew()
    {
    }
}
```

Again, for the reasons that we mentioned earlier, you may never be able to get rid of the old method completely, because it was not made private or internal.

Deprecating metadata

For deprecating model elements (tables, data entities, EDTs, Enums, ...etc.), use the property **IsObsolete** that is available on all model element types. **IsObsolete** is also available on table, view, and data entity fields. When you set **IsObsolete** to Yes, references to that element or field will cause compilation warnings.

Customization Analysis Report (CAR)

2/18/2021 • 11 minutes to read • Edit Online

This article describes how to generate a Customization Analysis Report for your model. It also describes some best practice rules that are included in the report, and provides suggestions for fixing errors and warnings that are associated with these rules.

What is the Customization Analysis Report?

The Customization Analysis Report is a tool that analyzes your customization and extension models, and runs a predefined set of best practice rules. The report is one of the requirements of the solution certification process. The report is in the form of a Microsoft Excel workbook.

How to generate the report

To generate the Customization Analysis Report, run the following command in a development environment.

```
xppbp.exe -metadata=<local packages folder> -all -model=<ModelName> -xmlLog=C:\BPCheckLogcd.xml -module=
<PackageName> -car=<reportlocation>
```

Example

```
xppbp.exe -metadata=C:\Packages -all -model="MyAppSuiteCustomizations" -xmlLog=C:\temp\BPCheckLogcd.xml -
module="ApplicationSuite" -car=c:\temp\CAReport.xlsx
```

The xppbp.exe tool is located in c:\packages\bin or I:\AosService\PackagesLocalDirectory\bin.

Issues List

This section describes all best practice rules (errors, warnings, or informational messages) that can appear on the **Issues List** page of the report and provides suggestions for fixing the issues. Issues are of the **metadata** or **code** type. For all **code** issues, keep in mind that, if the warning or error occurs in a method that you've overlaid, the lines of code that violate the rule might belong to a model in a lower layer. In that case, you're not responsible for fixing warnings and errors in code that isn't yours.

BPCheckPackReturnsConnull

DESCRIPTION	THIS RULE APPLIES TO ALL CLASSES THAT IMPLEMENT THE SYSPACKABLE INTERFACE. IT MAKES SURE THAT THE PACK METHOD DOESN'T RETURN CONNULL().
Error message	Container pack method returns connull in a Runbase derived class
Issue type/severity	Code/Warning
How to fix it	Update the return value of the **Pack** method, or return **Super()** when applicable.

BPCheckParametersModified

DESCRIPTION	THIS RULE FAILS IF A PARAMETER OF A METHOD IS MODIFIED INSIDE A METHOD.
Error message	Parameter 1% in method %1 are modified inside the method
Issue type/severity	Code/Warning
How to fix it	Refactor your code. Parameters must be modified by the caller, not within the called method.

BPCheckSQLCode

DESCRIPTION	THIS RULE FAILS IF YOUR X++ CODE CONTAINS DIRECT SQL CODE.
Error message	SQL code found in method %1
Issue type/severity	Code/Warning
How to fix it	Refactor your code to use X++ to access the database.

BPCheckNestedLoopInCode

DESCRIPTION	THIS RULE FAILS IF IT FINDS A WHILE SELECT LOOP NESTED WITHIN A LOOP.
Error message	Nested data access loop found in %1 method
Issue type/severity	Code/Warning
How to fix it	Refactor your code to use joins instead of nested data access loops. If you can't refactor the code without altering the business logic of your method, document an exception when you submit your Customization Analysis Report to Microsoft.

BPCheckInsertMethodInLoop

DESCRIPTION	THIS RULES FAILS IF IT FINDS A CALL TO THE METHOD INSERT NESTED INSIDE A LOOP. WE RECOMMEND THAT YOU USE INSERTRECORDLIST. THIS RULE DOESN'T APPLY TO INMEMORY TABLES.
Error message	Insert method can be replaced with RecordInsertList in method %1
Issue type/severity	Code/Warning
How to fix it	Refactor your code to use set-based operations, such as **InsertRecordList**.

BPCheckSelectwithJoin

DESCRIPTION	THIS RULE FAILS IF IT FINDS NESTED SELECT STATEMENTS THAT AREN'T JOINED.
Error message	Nested select statement in %1 method can be joined

DESCRIPTION	THIS RULE FAILS IF IT FINDS NESTED SELECT STATEMENTS THAT AREN'T JOINED.
Issue type/severity	Code/Warning
How to fix it	Refactor your code to use joins instead of a nested **select** statement. If you can't refactor the code without altering the business logic of your method, document an exception when you submit your Customization Analysis Report to Microsoft.

BPFunctionCallwithSelect

DESCRIPTION	THIS RULE FAILS IF A FUNCTION CALL IS FOUND WITHIN A SELECT STATEMENT.
Error message	Function call found in select statement in method %1
Issue type/severity	Code/Warning
How to fix it	Assign the function's return value to a local variable before you call the **select** statement, and use the local variable in the **select** statement.

BPCheckinvalidExecuteQuery

DESCRIPTION	THIS RULE FAILS IF A CALL TO ADDRANGE IS FOUND AFTER A CALL TO SUPER() IN THE EXECUTEQUERY METHOD.
Error message	Add range after super() should not be added in ExecuteQuery method for form %1
Issue type/severity	Code/Warning
How to fix it	Refactor your code to avoid this pattern.

BPCheckInvalidInitFormMethod

DESCRIPTION	THIS RULE MAKES SURE THAT YOU DON'T INITIALIZE FORM CONTROLS AND DATA SOURCES IN A FORM'S INIT METHOD BEFORE YOU CALL SUPER(). IT FAILS IF IT FINDS A STATEMENT THAT USES ELEMENT OR THIS BEFORE THE CALL TO SUPER() (THIS.AMETHOD() OR ELEMENT.AMETHOD()). AN INFORMATIONAL MESSAGE IS SHOWN ONLY FOR SOME ALLOWED PATTERNS, SUCH AS INITIALIZING NUMBER SEQUENCES (NUMBERSEQPREINIT).
Error message	Form element statements should not be used before super() in init method of form %1
Issue type/severity	Code/Info or Warning
How to fix it	Refactor your code to access form controls and data after the call to **super()**. If your code doesn't initialize any form control and doesn't access any form data sources before **super()**, document an exception when you submit your Customization Analysis Report to Microsoft.

BPCheckEmptyLoop

DESCRIPTION	THIS RULE FAILS IF IT FINDS LOOPS THAT HAVE NO STATEMENTS.
Error message	Empty loop found in method %1 in class %2
Issue type/severity	Code/Warning
How to fix it	Remove the loop from your code.

BPCheckLockQueryRange

DESCRIPTION	THIS RULE FAILS IF THE CODE CALLS ADDRANGE IN THE INIT METHOD OF THE FORM, AND DOESN'T SET THE RANGE AS LOCKED OR HIDDEN.
Error message	Range should be locked or hidden in form %1
Issue type/severity	Code/Warning
How to fix it	Add **QueryBuildRange.status(RangeStatus::Locked)** or **QueryBuildRange.status(RangeStatus::Hidden)** after the call to **AddRange**.

BPCheckSkipStatementValidation

Description	This rule reports an informational message if it finds a set-based operation that doesn't have **Skip** statements. • When **update_recordset** is found, the rule checks for **skipDataMethods(true)**. The rule applies only when the **update** method on the table is overridden. • When **insert_recordset** is found, the rule checks for **skipDataMethods(true)**. The rule applies only when the **insert** method on the table is overridden. • When **delete_from** is found, the rule checks for **skipDeleteActions(true)**. The rule applies only when the **insert** method on the table is overridden. This is an informational message that highlights the need to call **skip** methods to take full advantage of the performance gains of set-based operations. If **skip** methods are not used, the execution falls back to a row-by-row operation.
Error message	Set-based operation must invoke Skip statements in method %1 in class %2; otherwise, execution will fall back to a row by row operation.
Issue type/severity	Code/Information
How to fix it	Use **skipDataMethods(true)** or **skipDeleteActions(true)** when applicable.

BPCheckNoTTSTryBlock

DESCRIPTION	THIS RULE FAILS IF IT FINDS A TRY STATEMENT WITHIN A TTS BLOCK THAT ISN'T HANDLED CORRECTLY.
Error message	Tts block with Try statement does not explicitly catch exceptions in method %1

DESCRIPTION	THIS RULE FAILS IF IT FINDS A TRY STATEMENT WITHIN A TTS BLOCK THAT ISN'T HANDLED CORRECTLY.
Issue type/severity	Code/Warning
How to fix it	Use the code example that follows this table.

The following examples show when the rule will fail or pass. Use these examples as guidelines to refactor your code.

```
ttsbegin;
try {
}
// fail
catch {
}
try {
}
// pass
catch(Exception::UpdateConflict) {
}
try {
}
// pass
catch(Exception::UpdateConflictNotRecovered) {}
```

BPCheckEmptyTableMethod

DESCRIPTION	THIS RULE CHECKS FOR TABLE METHODS THAT HAVE NO SOURCE CODE. EMPTY TABLE METHODS CAUSE RECORD-SET OPERATIONS ON THE TABLE TO FALL BACK TO A ROW-BY-ROW OPERATION.
Error message	%1 table has an empty %2 method
Issue type/severity	Code/Warning
How to fix it	Remove this method from your code.

BPCheckBatchJobsEnabled

DESCRIPTION	THIS RULE MAKES SURE THAT ALL CLASSES THAT EXTEND RUNBASEBATCH HAVE A CANGOBATCH METHOD THAT RETURNS TRUE.
Error message	Custom job is not batch-enabled in class %1
Issue type/severity	Code/Warning
How to fix it	The **canGoBatch** method must return **true** for all batch classes.

BPCheckDisplayMethodCached

Description	For each control that is bound to a data method, this rules fails if one of these conditions is met: • The **Cache Data Method** property is set to **Auto**, the corresponding table **display/edit** method doesn't have the **SysClientCacheDataMethodAttribute**, and the **init** method of the data source doesn't use **CacheAddMethod**. • The **Cache Data Method** property is set to **No**, and the **init** method of the data source doesn't use **CacheAddMethod**.
Error message	Display method %1 in form %2 not cached
Issue type/severity	Code/Warning
How to fix it	Use the note that follows this table.

You can fix this warning by using one of the following patterns:

- Set the **Cache Data Method** property to **Yes**.
- Set the **Cache Data Method** property to **Auto**, and mark the data method of the table with the **SysClientCacheDataMethodAttribute** attribute. Here is an example.

```
[SysClientCacheDataMethodAttribute(true)]
Display TransDate myDateMethod()
{
    //...
}
```

- Use **CacheAddMethod** in the **init** method of the form to mark the method as cached.

BPCheckSQLQueryInInit

DESCRIPTION	THIS RULE FAILS IF A DATA ACCESS QUERY THAT HAS A WHILE LOOP IS FOUND IN THE INIT METHOD OF A FORM. THIS PATTERN COULD CAUSE PERFORMANCE ISSUES WHEN THE FORM IS INITIALIZED.
Error message	SQL query with while loop was found in init method of form %1
Issue type/severity	Code/Warning
How to fix it	Refactor your code to avoid this pattern.

BPCheckNewQueryWithForm

DESCRIPTION	THIS RULE FAILS IF IT FINDS THE NEW QUERY() STATEMENT IN THE INIT OR EXECUTEQUERY METHOD OF A FORM.
Error message	Data source query overridden in form method %1
Issue type/severity	Code/Warning
How to fix it	Refactor your code to avoid this pattern.

DESCRIPTION	THIS RULE FAILS IF IT FINDS THE NEW QUERY() STATEMENT IN THE INIT OR EXECUTEQUERY METHOD OF A FORM.

BPCheckSelectForUpdateAbsent

DESCRIPTION	THIS RULE FAILS IF SELECT FORUPDATE IS USED TO SELECT RECORDS, BUT AN UPDATE ISN'T BEING PERFORMED. THIS RULES DOESN'T APPLY TO TABLES THAT ARE ENABLED FOR OPTIMISTIC CONCURRENCY CONTROL (OCC).
Error message	Select ForUpdate not implemented in method %1
Issue type/severity	Code/Warning
How to fix it	Use **Select** instead of **Select ForUpdate**, or set the **OCC Enabled** property to **Yes** on the table.

BPCheckTablePropertyMismatch

Description	This rule fails when the table belongs to a table group but doesn't have the appropriate **Cache Lookup** value. The rule fails if one of these conditions is met: • The **Table Group** property is set to **Main**, and the **Cache Lookup** property is set to **NotinTTS** or **EntireTable**. • The **Table Group** property is set to **Group** or **Parameter**, and the **Cache Lookup** property is set to **NotinTTS**. • The **Table Group** property is set to **WorksheetHeader**, **WorksheetLine**, or **Transaction**, and the **Cache Lookup** property is set to **Found**, **FoundAndEmpty**, or **EntireTable**.
Error message	%1 table has an invalid combination of table group and cache lookup
Issue type/severity	MetaData/Warning
How to fix it	Set an appropriate **Cache Lookup** value on the table.

BPCheckMissingDeleteActions

DESCRIPTION	THIS RULE VALIDATES THAT THE VALUE OF EITHER A DELETE ACTION OR THE ON DELETE PROPERTY OF A TABLE RELATION ISN'T EQUAL TO NONE. THE RULE ISN'T TRIGGERED WHEN THE RELATED OR CURRENT TABLE IS A TEMPDB, IN MEMORY TABLE, REFERENCE TABLE, STAGING TABLE, OR PARAMETER TABLE.
Error message	Delete actions missing in table %1 which is related to table %2 with relation name %3
Issue type/severity	MetaData/Warning
How to fix it	Set a **delete** action value that isn't equal to **None**.

BPCheckAddressModel

DESCRIPTION	THIS RULE FAILS IF A TABLE FIELD IS OF THE ADDRESSZIPCODEID OR ADDRESSSTATEID TYPE. THESE TYPES INDICATE THAT THE CODE DIDN'T UPTAKE THE NEWER ADDRESS FRAMEWORK.
Error message	Field %1 of table %2 is not part of address location model
Issue type/severity	MetaData/Warning
How to fix it	Replace these types with any other appropriate EDT type in the Directory model.

BPCheckDimensionModel

DESCRIPTION	THIS RULE FAILS IF A TABLE FIELD IS OF THE DIMENSION OR LEDGERACCOUNT TYPE. THESE TYPES INDICATE THAT THE CODE DIDN'T UPTAKE THE NEWER FINANCIAL DIMENSION FRAMEWORK.
Error message	Field %1 of table %2 is not part of financial dimension framework
Issue type/severity	MetaData/Warning
How to fix it	Replace these types with any other appropriate EDT type in the Dimensions model.

BPCheckNumberofNewFields

DESCRIPTION	THIS RULE VERIFIES THAT NO MORE THAN 10 FIELDS WERE ADDED TO A TABLE DURING THE PROCESS OF CUSTOMIZING OR EXTENDING THAT TABLE. THIS RULE DOESN'T APPLY TO STAGING TABLES.
Error message	Number of new fields in table %1 is greater than
Issue type/severity	Metadata/Warning
How to fix it	Refactor your schema and create related tables instead of adding too many fields to an existing table.

BPCheckEnumUpgradeIssue

DESCRIPTION	THIS RULE FAILS WHEN THE FOLLOWING CONDITION IS MET: WHEN YOU CUSTOMIZE AN ENUM (OVERLAYER), NEW ENUM VALUES ARE LESS THAN THE MAXIMUM EXISTING VALUE + 10. THIS RULES DOESN'T APPLY TO EXTENSIBLE ENUMS.
Error message	Enum %1 will have upgrade issues
Issue type/severity	MetaData/Warning
How to fix it	Use larger enum values, or extend the enum.

BPCheckPassiveJoinUse

Description	This rule validates that, when a form allows for pre-loading of data, the link type of tab page data sources is passive. The rule fails if all the following conditions are met: • A form has the **AllowPreLoading** property set to **Yes**. • A tab page on the form is bound to a top-level data source. • The data source's **Join Source** property is set. • The data source's **Link Type** property isn't set to **Passive**.
Error message	New message suggest: "Use passive joins on data sources %1 bound to a tab page control in form %2"
Issue type/severity	MetaData/Warning
How to fix it	Set the **AllowPreLoading** property to **No** on the form, or use passive joins on the data source. Passive joins require that you explicitly program when the query of a tab page is run.

BPCheckAlternateKeyAbsent

DESCRIPTION	THIS RULE VERIFIES THAT TABLES THAT HAVE A UNIQUE INDEX HAVE AT LEAST ONE ALTERNATE KEY.
Error message	Table %1 does not have an alternate key
Issue type/severity	MetaData/Warning
How to fix it	Set the **Alternate Key** property to **Yes** on a unique index of the table.

BPCheckBaseTableModified

DESCRIPTION	THIS RULE DISCOURAGES THE CUSTOMIZATION (OVERLAYERING) OF A LIST OF SPECIFIC BASE TABLES THAT ARE SHIPPED BY MICROSOFT. EXAMPLES ARE THE SOURCEDOCUMENTHEADER AND SOURCEDOCUMENTLINE TABLES.
Error message	%1 is a base table and must not be modified
Issue type/severity	MetaData/Warning
How to fix it	Don't customize the table.

Element designers

2/18/2021 • 3 minutes to read • Edit Online

This topic reviews the element designers and explains how to use them. The tools contain designers for each kind of element in the program. You use these designers when you create or modify elements.

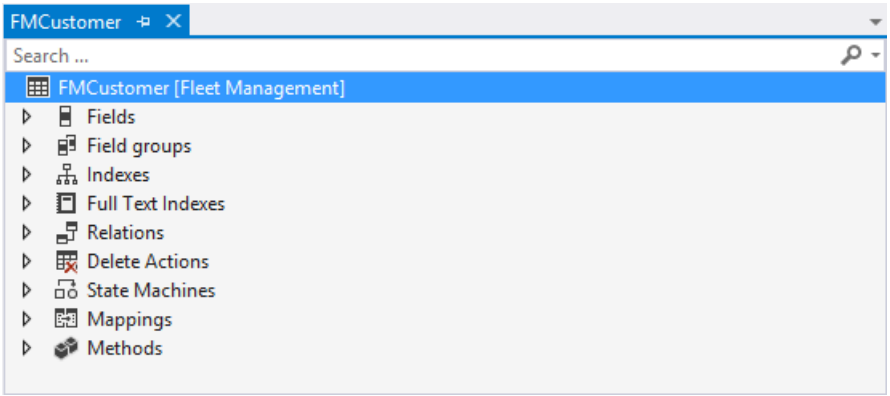
Open an element designer

To open an element designer, follow these steps.

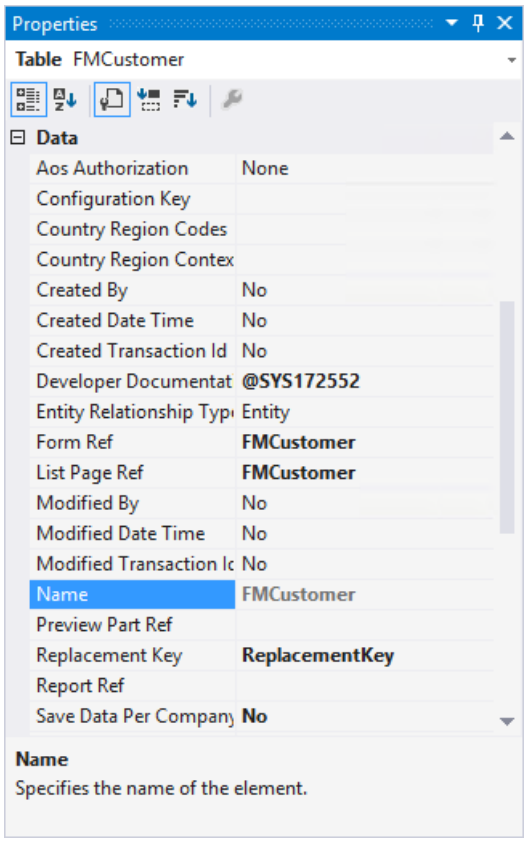
1. Find the element in the project or in Application Explorer.
2. Right-click the element. In Application Explorer, click **Open designer**. In the project, click **Open**.
3. Expand the nodes in the element designer to see the details about the element.

Node properties

When you select the individual nodes in the element designer, the **Properties** pane in Visual Studio shows the various properties for that node. Most of the characteristics of an element are controlled by these properties. For example, the following illustration shows the element designer for the FMCustomer table. Notice that the top-level node is selected.



The following illustration shows the set of properties for the table, which corresponds to the top-level node that is selected.

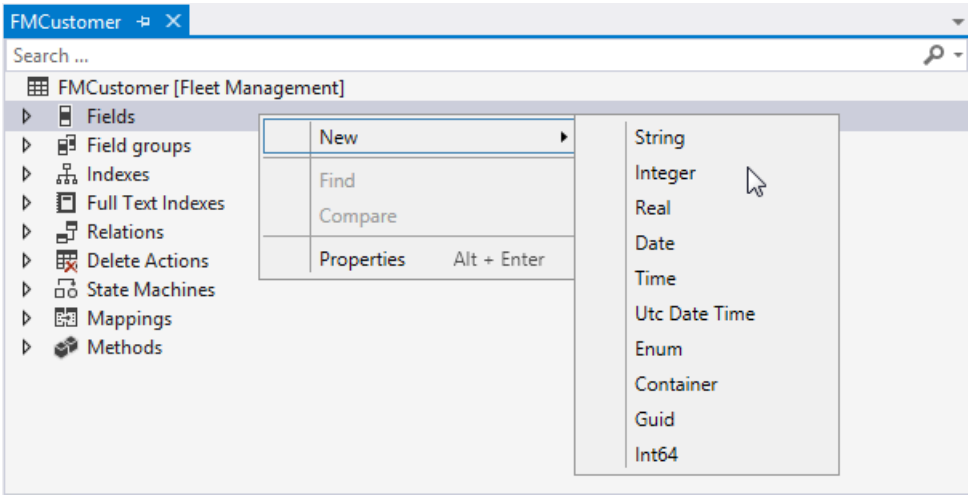


Each node for the element will have a set of properties that applies to it. To make it easier to find the properties that you want to work with, use the buttons at the top of the **Properties** pane to control how they are displayed. The properties can be arranged in the following ways.

ORGANIZATION	DESCRIPTION
Alphabetical	Arrange the properties in alphabetical order.
Categorized	Arrange the properties into standard categories for the node type.
Changed	Divide the properties into those that have been changed and those that use the default values.
Frequency	Divide the properties into categories, based on whether a property is often, occasionally, or rarely changed.

Working with nodes

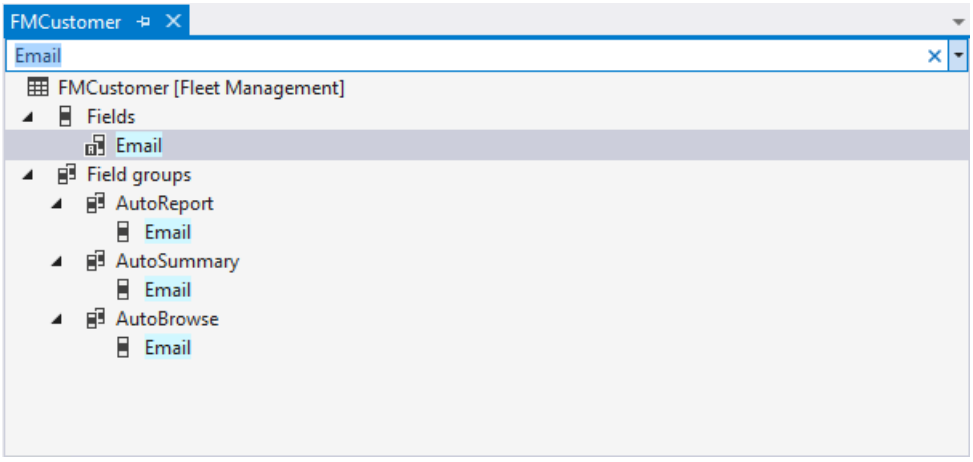
When you create or modify elements, you will often find that you must add or remove nodes for the element. For example, to add a field to a table, right-click the **Fields** node for the table element, point to **New**, and then click the type of field to add.



To remove a node, right-click the node, and then click **Delete**. You can also perform other actions for a node. You rename a node, duplicate a node, or move the node up or down in the node list.

Searching element nodes

Sometimes, the node list for an element can be long, so that it's difficult to find the specific node that you're looking for. Notice that there is a search bar at the top of each element designer. You can enter a string to search for, and the node list will be filtered to include only the nodes that match the search string. For example, the following illustration shows the element designer for the FMCustomer table after the “Email” search term was applied. Only nodes that have names that match that search term appear in the element designer.



If you're working with a customization element or an extension element, you can prefix your search string with **c:** (for "customization elements") or **e:** (for "extension elements") to return only customizations or extensions, respectively. **Examples**

- **e:** returns all extensions that belong to the current element.
- **c:** returns all customizations that belong to the current element.
- **e:Email** returns all extension nodes that have the string "Email" in their name.
- **c:Email** returns all customization nodes that have the string "Email" in their name.

Navigating to related elements

The value of a node in the element designer is often a reference to another element. For example, a field node in a table element is typically based on an extended data type (EDT) element. When you right-click a node in the element designer, you can click the **Go to <element>** command to navigate to that related element. For example, when you right-click the **FuelType** node in the list of fields for the FMVehicle table, you can click **Go to Base Enum FMFuelType** to show the base enumeration that is used to define the field.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Commands for determining how elements are used

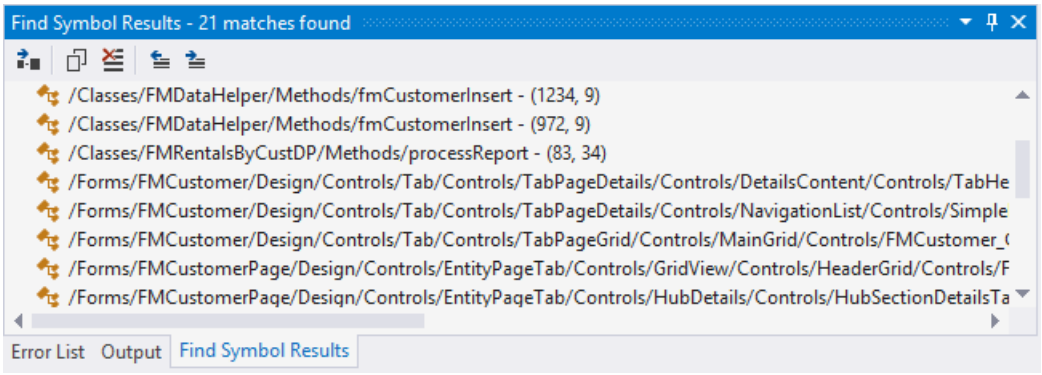
2/18/2021 • 2 minutes to read • Edit Online

This article reviews the commands that have been added to the Microsoft Visual studio Tools to help you determine how elements are used in an application.

Because of the large number of elements in a typical application, commands have been added to the Microsoft Visual Studio Tools to make it easier to determine how an element is used.

Finding where elements are used

During build operations, cross-reference information is generated that can be used to show how elements are used. You can right-click an element and then click **Find References** to display a list of the locations where that element is used. When you click one of the items in the list, the designer for the element opens.



Viewing a reference diagram

When you right-click some higher-level elements, such as tables, the **View Reference** command is available. This command produces a graphic that shows the elements that are related to the current element. You can right-click the items in the graphic and then click **Go To Definition** to navigate to those elements.

Export and import models

2/18/2021 • 2 minutes to read • Edit Online

Model files let you distribute models to customers and partners, and can be installed in development environments. They are key components of a Lifecycle Services (LCS) solution. Model files contain a model descriptor file, metadata, source code, and referenced .NET assemblies (when applicable). This article describes how to export a model into a model file, install a model file, and delete a model in a development environment.

Export a model into a model file for distribution

To export an existing model into a model file, use the ModelUtil.exe tool and the **-export** directive. This tool is located in the packages bin folder (typically, c:\packages\bin or i:\AosService\PackagesLocalDirectory\bin).

```
ModelUtil.exe -export -metadatastorepath=[path of the metadata store] -modelname=[name of the model to
export] -outputpath=[path of the folder where the model file should be saved]
```

Example

```
ModelUtil.exe -export -metadatastorepath=c:\packages -modelname="FleetManagement" -outputpath=c:\temp
```

The preceding example creates an .axmodel file under c:\temp. Typically, you then upload the model file to the Asset Library of the customer project or the Microsoft Dynamics Lifecycle Services (LCS) solution project.

Install a model in a development environment

To install a model file in a development environment, use the ModelUtil.exe tool and the **-import** directive.

```
ModelUtil.exe -import -metadatastorepath=[path of the metadata store where model should be imported] -file=
[full path of the file to import]
```

If the model already exists in your development environment, you must first delete it by using the **-delete** directive.

```
ModelUtil.exe -delete -metadatastorepath=[path of the metadata store] -modelname=[name of the model to
delete]
```

> **NOTE**
> If you're using an older version, you can use the -replace parameter to replace standard models (like Foundation) for overlayering.

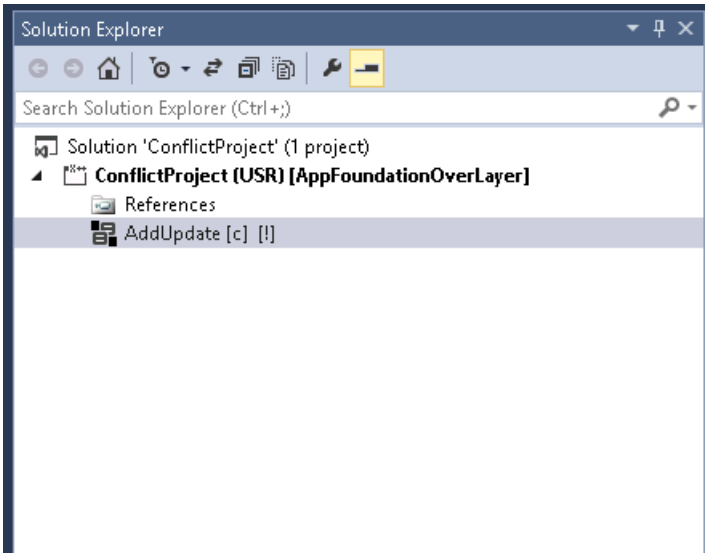
Resolve conflicts

If you install a model on a development environment that contains customizations to that model (in a higher-layer), you may have to resolve code or metadata conflicts. You can use the development tools to create a project that groups all items that have conflicts.

1. Under **Dynamics 365 > AddIns**, click **Create Project from Conflicts**.

2. In the dialog box, select the model to check for conflicts. This is the model that contains customizations to elements in the newly installed baseline model.

3. Click **Create project**. A project is generated that contains only the elements in that model that have conflicts.



4. Open the designer for the conflicting element to view and resolve conflicts by using the tools that are provided.

Metadata search in Visual Studio

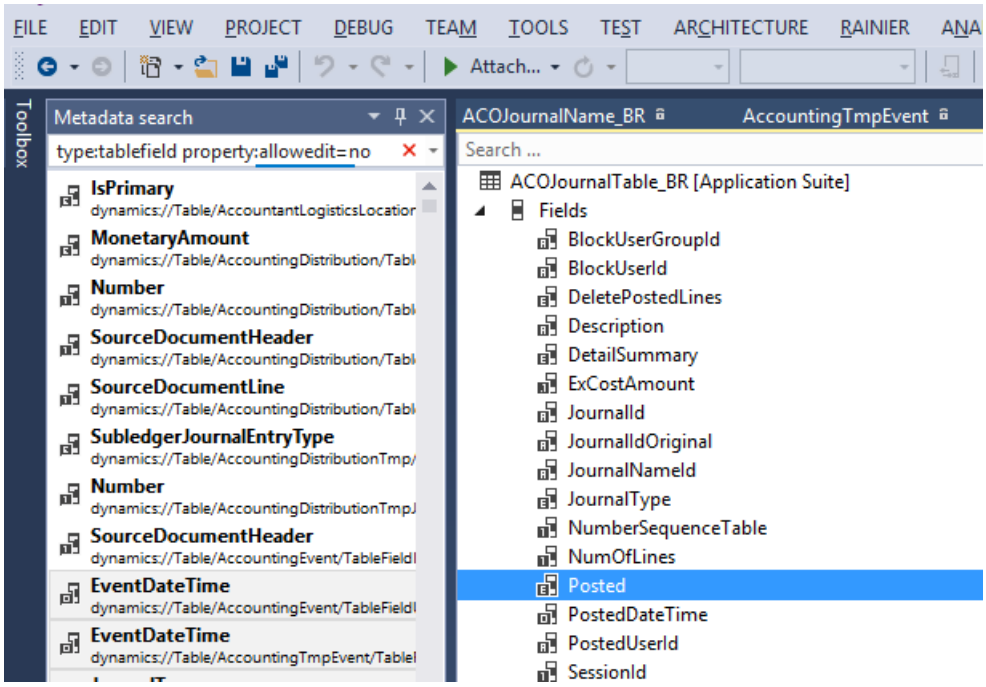
2/18/2021 • 3 minutes to read • Edit Online

This article describes how to use metadata search to search your code and metadata for arbitrary patterns and content.

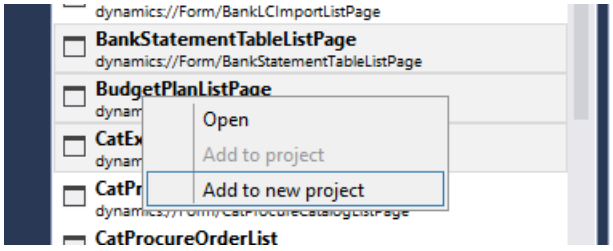
Given the large volume of the code base and metadata, it is often necessary to find things in the code that meet a certain criteria. For example, you might not know the name of the metadata element that contains the pattern or meets the criteria. Metadata search is exposed in Visual Studio through two user interfaces: the Metadata Search tool window and the Navigate To window.

Metadata search tool window

You can access the Metadata search tool window from the **Dynamics 365 > Metadata Search** menu command. Enter your search query to start the search. Results will start populating in the window asynchronously as you type. You can double-click any result line to navigate to the corresponding X++ code or metadata that matches your search query.



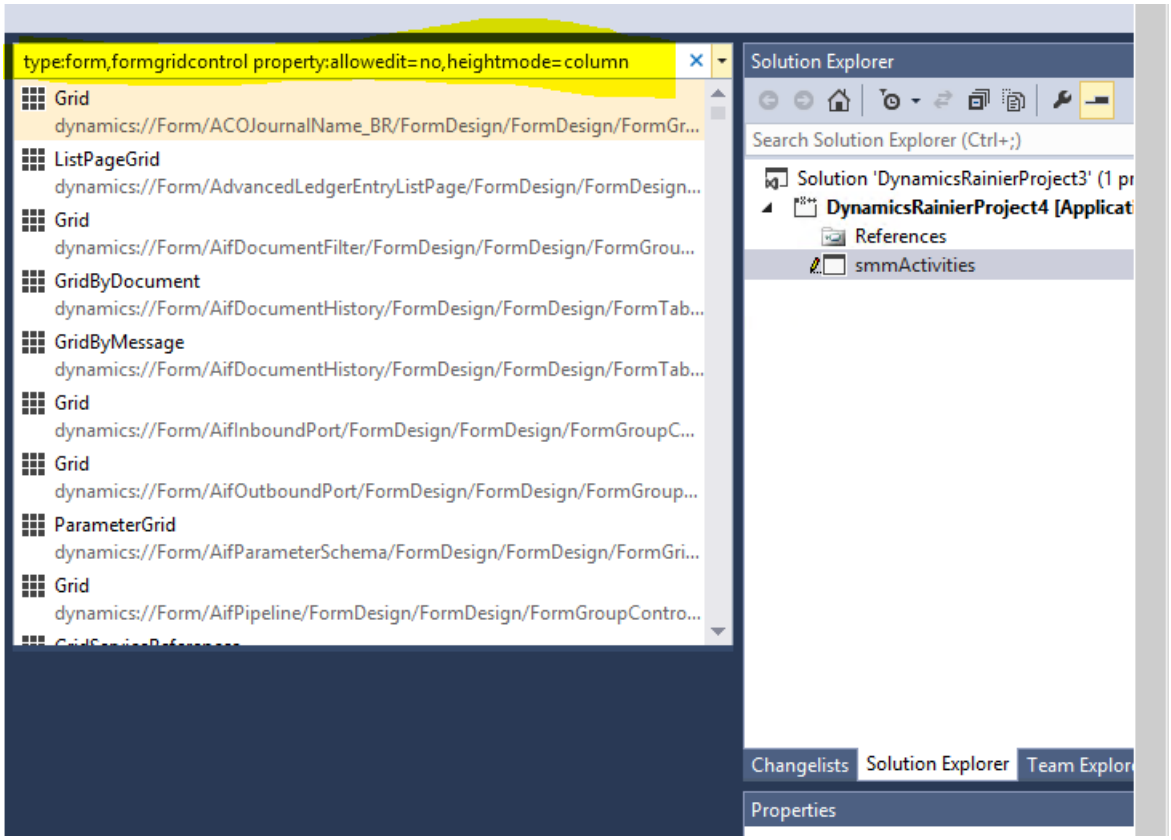
You can also select one or more results, right-click, and then add these elements to a project. You don't need to wait for the search to complete before you start interacting with the search results.



Navigate To window

The **Navigate To** window is invoked using the **Ctrl+',** (the comma character) shortcut keys. Pressing **Ctrl+',** displays the query entry box in top-right corner of the Visual Studio main document window. You can also

access the **Navigate To** window from the Visual Studio **Edit** menu. Enter you search query and see the results appear as you type. A progress indicator will stop when the search is complete. You don't need to wait for the search to complete to start interacting with the results.



Search query syntax

This section describes the search query syntax and provides example queries.

Syntax

The search query is a search string that consists of a set of filters in this general form:

```
<filter_1>:<filter_1_value> [<filter_2>:<filter_2_value> … [ <filter_N>:<filter_N\_value>]]
```

Where `<filter_i>` is one of the acceptable filter names, and < `filter_i_value>` are comma separated (and possibly quoted) filtering values.

Filter names

- **Name**: Filter by element name. This is the default filter, meaning if you just type a filter value, it is assumed to be an element name. Each comma-separated value is an acceptable element name.
- **Type**: Filter by element type. Each comma-separated value should be the name of an element or subelement type (root type or subtype) (that is, table, class, field). Logic of filtering is:

  `(roottype_1 OR roottype_2 OR … OR roottype_N) AND (subtype_1 OR subtype_2 OR … OR subtype_N)`
- **Model**: Filter by model name. Each comma-separated value should be the name of a model in your application.
- **Property**: Apply property filters. Each comma-separated value should be in the form `property_name=property_value`.
- **Code**: Filter using code snippets, use quotes around code snippets. The matching source code is the elements that contain the specified code snippet.

You can get help about using filter and filter syntax by opening the drop-down menu available in the search box.

[

]

Examples

QUERY STRING	WHAT IT DOES
`TrvExpTable`	If the token is by itself, it is assumed to be the name. So this will find everything in the application that has "TrvExpTable" in the name.
`type:form ccount`	Finds all forms that have "ccount" in their names.
`type:form property:formtemplate=listpage`	Finds all forms that contain the property "FormTemplate" equal to 'ListPage'.
`type:table,formDesign property:"WorkflowDataSource=TrvExpTable"`	Finds formDesign nodes under tables, nothing would be found.
`type:form,formmenufunctionbuttoncontrol property:Text=@SYS311998`	Finds all menu function button controls with the Text property equal to (a label) '@SYS311998'.
`type:table,method name:insert`	Finds tables with a method containing "insert" in the method name.
`type:table,tableindex name:Export`	Finds tables with an index name containing the word "Export".
`type:table,tableindexfield name:xpNum`	Finds table indexes with "xpNum" in the index field name.
`type:table,tablefieldgroup name:EPNew`	Finds FieldGroups (in tables) containing 'EPNew' in their names.
`type:form,formgridcontrol property:allowedit=no,heightmode=column`	Finds form grid controls, with properties **allowedit** equal to "no" and heightmode equal to "column".
`type:form,formtabcontrol property:arrangeMethod=Vertical,ViewEditMode=view,WidthMode=Auto`	Finds form tab controls, with properties arrangeMethod equal to "Vertical" and ViewEditMode equal to "view" and WidthMode equal to "Auto".
`type:form,formDesign property:"WorkflowDataSource=TrvExpTable"`	Finds all forms with the "WorkflowDataSource" property in the FormDesign node set to the value "TrvExpTable".
`model:"Application Suite" type:formdesign property:style=simplelistdetail`	Find all forms in Application Suite model that has the style property set to simpleListDetail in the FormDesign node.
`code:"return null"`	Finds all places in the source code that contains "return null".
`code:"element.lock()" type:form`	Finds all places in the forms source code that contain the snippet "element.lock()".

QUERY STRING	WHAT IT DOES
`code:"insert" type:table,form`	Finds all places in the source code of either forms or tables that contain "insert".
`code:"public display" type:form,method`	Finds all form methods that contain the code "public display".
`type:formbuttoncontrol property:text=`	Finds all form Button Controls that have **empty** text properties.

NOTE

The survey will take about seven minutes. No personal data is collected (privacy statement).

Models and packages

2/18/2021 • 4 minutes to read • Edit Online

This topic describes the concept of models and packages. It also explains how to use the development tools in Microsoft Visual Studio to create new models, how to update the parameters of existing models, and how to visualize dependencies between models.

To work with models in the model store, you use tools in Microsoft Visual Studio. You can create new models and change parameters for existing models.

Conceptual overview

A model is a group of elements, such as metadata and source files, that typically constitute a distributable software solution and includes customizations of an existing solution. A model is a design-time concept, for example a warehouse management model or a project accounting model. A model always belongs to a package. A package is a deployment and compilation unit of one or more models. It includes model metadata, binaries, and other associated resources. One or more packages can be packaged into a deployable package, which is the vehicle used for deployment on runtime environments.

Creating a new model

You use the **Create model** wizard to create new models. You can access this wizard from **Model Management** on the **Dynamics 365** menu. You can create two types of models:

- **A model that is deployed in its own package** – You can use this type of model to create new model elements, and extend the metadata and business logic of referenced models. The wizard lets you select the referenced models. This type of model is compiled into its own assembly and binaries, and will simplify and reduce the cost of upgrades, deployment, and application lifecycle management in general.
- **A model that is a part of an existing package** – You can use this type of model to perform advanced customizations, such as overlayering source code and metadata.

In the **Create model** wizard, select **usr** for the layer. This layer will store user customizations. If needed, you can patch your customizations using the **usp** layer. If there are multiple versions of the same object in different layers, then the top layer will take precedence and will be used.

When the **Create model** wizard is completed, if you chose to create a new project, you will be prompted to specify a name and location for it.

Updating model parameters

If you must change the parameters for a model, you can use the **Update model parameters** dialog box.

1. On the **Dynamics 365** menu, point to **Model Management**, and then click **Update model parameters**.
2. In the **Model name** field, select the model to update parameters for.
3. Update the parameters as you require.
4. Click **Next**.
5. Update the dependency information for the current model, if changes are required.
6. Click **Next**. The summary information for the model is displayed.
7. Click **Finish**.

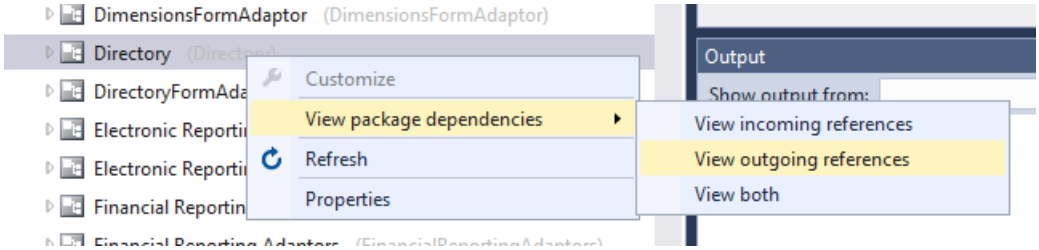
The updated model parameters become effective only after you restart Visual Studio.

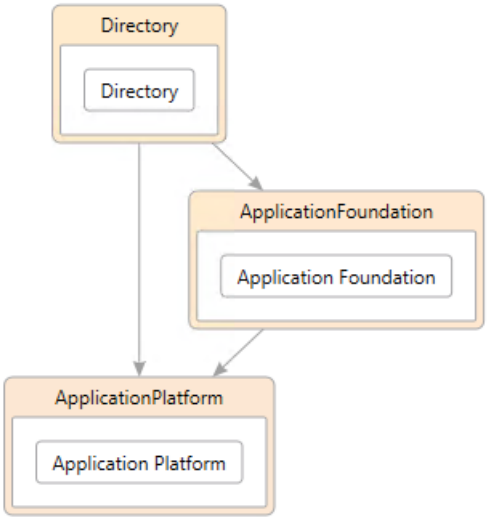
Viewing package dependencies

You can create a graphical representation that shows which packages and their models have dependencies on other packages. On the **Dynamics 365** menu, point to **Model Management**, and then click **View package dependencies**. A Directed Graph Markup Language (DGML) diagram will be generated for the current packages and their models. This diagram is a collection of interdependent nodes, each of which represents a package. Each node lists all the models that belong to that package. Additional tools let you enhance or simplify the diagram. For example, you can add comments, move nodes around, or remove nodes. You can also view package dependencies of a single model by following these steps:

1. Make sure the Application Explorer is in Model view: Right-click the AOT node and select **Model view**.
2. Right-click on any model and select **View package dependencies** > **View outgoing references.**

This will generate a graph of all packages that the selected model depends on.





Deleting a model

In a development or test environment, follow these steps to delete a model.

The following steps assume the local model store folder is C:\AOSService\PackagesLocalDirectory and your model is named MyModel1.

If your model belongs to its own package. For example an extension package with no other models in the package.

1. Stop the following services: AOS web service and Batch Management service.
2. Delete the package folder C:\AOSService\PackagesLocalDirectory\MyModel1.
3. Restart the services that were stopped in step 1.
4. If Visual Studio is running, refresh your models (**Visual Studio > Dynamics 365 > Model management > Refresh models**)
5. In Visual Studio, perform a full database synchronization (**Visual Studio > Dynamics 365 > Synchronize**

database).

If your model belongs to a package with multiple models. For example, the MyModel1 overlays Application Suite.

1. Stop the following services: AOS web service and Batch Management service.
2. Delete the model folder C:\AOSService\PackagesLocalDirectory<PackageName>\MyModel1. In this example. PackageName=ApplicationSuite.
3. Restart the services that were stopped in step 1.
4. In Visual Studio, refresh your models (**Visual Studio > Dynamics 365 > Model management > Refresh models**).
5. In Visual Studio, build the package that the deleted models belonged to (**Visual Studio > Dynamics 365 > Build models**).
6. In Visual Studio, perform a full database synchronization (**Visual Studio > Dynamics 365 > Synchronize database**).

Export and import models

Finance and Operations project type in Visual Studio

2/18/2021 • 5 minutes to read • Edit Online

The Finance and Operations project type is part of the development tools. This project type resembles other projects in Visual Studio. It helps you organize and manage the elements that you're working with for a model. For example, the project can have folders that help you group the elements. A Visual Studio solution can contain multiple projects. There is one important constraint for a project: it can contain elements from only one model. If you must work with elements from different models, you must use multiple projects in your Visual Studio solution.

Create a new project

To create a new, empty project, follow these steps.

1. On the **File** menu, point to **New**, and then click **Project**.
2. In the list of template types, expand the **Installed** node.
3. Expand the **Templates** node.
4. Select the **Finance and Operations** category.
5. Select the **Operations Project** template.
6. Enter the name and location for the new project.
7. Specify whether you want to create a new solution or add the project to the current solution.
8. Click **OK**.

Every project has several important properties. To set the properties for a project, right-click the project in Solution Explorer, and then click **Properties**. The following table describes these properties.

PROPERTY	DESCRIPTION
Startup Object type	The type of object that will be used as the Startup Object when the project is run. The following types are available: Form Class Output menu item
Startup Object	The object that will be invoked when the project is run.
Company	The default company that will be used when the project is run.
Partition	The partition that will be used when the project is run.
Project File	The name of the file that contains information about the project.
Project Folder	The location of the project.
Model	The model that the project is associated with. All elements in the project must be in the selected model.

PROPERTY	DESCRIPTION
Model Publisher	A read-only value that indicates the publisher of the model.
Layer	A read-only value that indicates the application layer that the model is located in.
Synchronize database on build	A value that indicates whether the synchronize operation for tables will be performed when the build action is performed for the project.

Of these properties, the **Model** property is particularly important. You must specify which model the project is associated with. All the elements that you create or add to the project must be part of this model. The **Startup Object type** and **Startup Object** properties are useful when you test and debug your application. When you start your project (by pressing F5 for debugging or Ctrl+F5 for no debugging), the specified form will be loaded, or the **main()** method from the specified class will be run. The method must have the following signature:
public static void main(Args _args)

Add elements to a project

There are several ways to add existing elements to a project. Here are the most typical:

- After you select the project in Solution Explorer, you can find the element in Application Explorer, right-click it, and then click **Add to Project**. This is the simplest method.
- You can use drag-and-drop operations to add an element from Application Explorer to a project.
- If you're limiting your search results to a single model, you can add the results of a filter in Application Explorer to a project.

After you've added the elements, you might want to use Solution Explorer to group them into folders, so that they are easier to find. The location of the project file and the folders that you create in the project don't affect the location of the XML files that represent the model elements. The model elements are always stored in the appropriate folder in the model store. To organize elements into folders, select the **Organize projects by element type** option. On the **Dynamics 365** menu, click **Options**. Select the **Projects** category to see this option. When this option is selected, elements that are added to a new or existing project (such as when search results in Application Explorer are added to a project) are grouped into folders, based on the element type name. To create a new element for a project, follow these steps.

1. In Solution Explorer, right-click the project, point to **Add**, and then click **New Item**.
2. In the **Operations Artifacts** list, select the category of element to create.
3. Select the specific element type.
4. Enter a name for the element.
5. Click **Add**. The element will be added to the project. It will also be added to the model in the model store that the project is associated with.

After you've added the new element, you might want to use Solution Explorer to move it into a folder in the project, so that it's easier to find.

Export a projects as an .axpp file

To transfer elements to a different installation, you can use a project package file. Project package files have the .axpp file name extension. A project package contains all the elements from the project. To export a project, follow these steps.

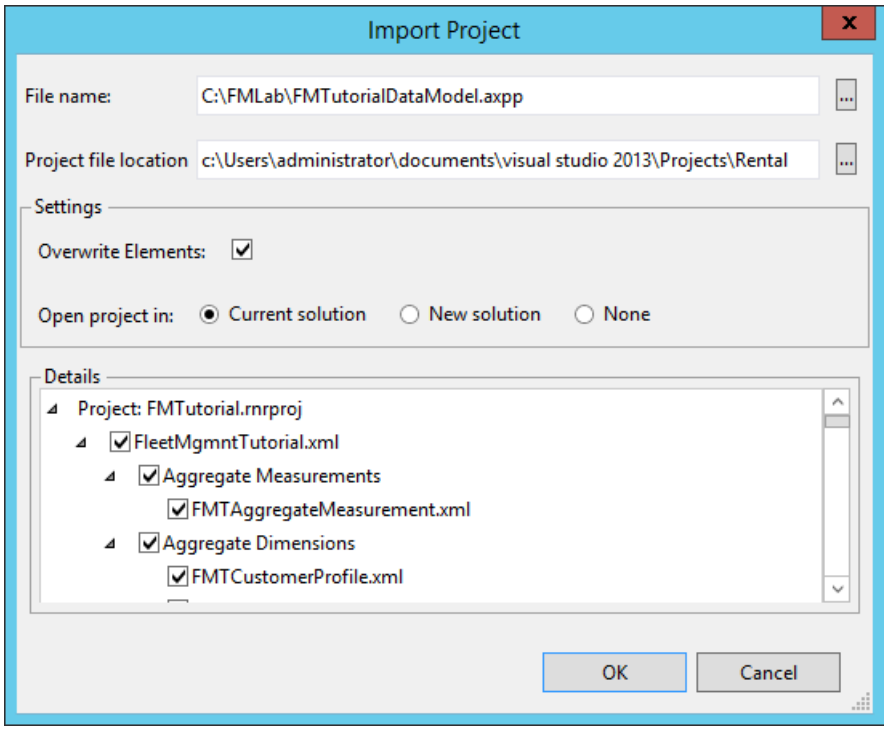
1. In Solution Explorer, select the project to export.

2. On the **Project** menu, click **Export Project**. (The command on the menu will contain the name of the selected project.)
3. Enter a name for the project package file, and select a location.
4. Click **Save**.

Import an .axpp file

To use the contents of a project package file, you must import the .axpp file into an installation. The elements from the project package file will be imported into the same model that they were exported from. If that model doesn't exist in the installation, it will be created during the import process. To import a project package file, follow these steps.

1. On the **Dynamics 365** menu, click **Import Project**.
2. In the **Import Project** dialog box, specify the location of the project package (.axpp) file to import.
3. If you want elements from the project package file to overwrite any existing elements, select **Overwrite Elements**.
4. Specify whether you want to open the project in the current selection, in a new solution, or not at all.
5. In the **Details** field, review the elements that will be imported. You can clear the check box next to any elements that you don't want to import.



6. Click **OK** to complete the import process.

Tools add-ins for Visual Studio

2/18/2021 • 2 minutes to read • Edit Online

This topic reviews the Add-ins infrastructure that has been added to Microsoft Visual Studio, so that developers can more easily add tools for development.

A lot of great tools have been added to Microsoft Visual Studio to support development. However, there will always be additional tools to meet specific requirements. To make it easier to add these additional tools, an **Add-ins** infrastructure has been provided for developers. The additional tools are available in two places:

- The **Add-ins** submenu on the **Dynamics 365** menu
- The **Add-ins** submenu on the shortcut menu in the element designer

To make it easier to create your own add-ins, you can select the **Dynamics Developer Tools Add-in** project type when you create a new project in Visual Studio. This project type has the infrastructure that is required to implement an add-in.

For more information on add-ins, see:

- Visual Studio add-ins that support form patterns

Update the Visual Studio development tools

2/18/2021 • 2 minutes to read • Edit Online

This topic explains how to update the development tools.

Use this tutorial to update your Visual Studio development tools with a new version. It explains how to uninstall your existing Visual Studio development tools and install the new extension. The new extension is in the form of an installable VSIX file. This file is a part of the binary hotfix available on the Dynamics Lifecycle Services (LCS) site. The VSIX file is located in the **DevToolsService\Scripts** folder of the binary hotfix package.

> **NOTE**
> You do not need to follow the instructions in this article if you are upgrading your Finance and Operations platform to Platform update 4 or newer. It is an automatic step that is part of the platform upgrade process.

Uninstall the existing Visual Studio extension

In order to install a new version of the development tools, you'll need to uninstall the existing version first. Verify the version of the development tools that you have installed. If you don't have it installed, you can skip this section.

Verify your current version of the Visual Studio extension

1. Open the Visual Studio **Help > About Microsoft Visual Studio** dialog and find **Finance and Operations Developer Tools**.
2. Select it and click **OK**.

Uninstall the extension

1. Open the Visual Studio **Tools > Extensions and Updates** dialog.
2. Select **Finance and Operations Visual Studio Tools** and click **Uninstall**.
3. When the extension is uninstalled, exit Visual Studio.

Install a new version of the extension

1. Make sure Visual Studio is not running.
2. Double-click (or right-click and **Open**) the VSIX file of the new version.
3. Follow the installation instructions.
4. When installation is complete, you can start Visual Studio and start developing your application.

> **NOTE**
> Can you tell us about your documentation language preferences? Take a short survey.
>
> The survey will take about seven minutes. No personal data is collected (privacy statement).

X++ and debugger features

2/18/2021 • 28 minutes to read • Edit Online

This tutorial is for developers to use advanced constructs of the X++ language and take advantage of productive debugger features. This is a walkthrough of the new features with exercises included to practice using these features.

In previous versions, the X++ code was compiled into pseudo-code, or p-code, that was interpreted on the server or on the client application. This code was then subject to further compilation into CIL. Today the story is much simpler--only CIL is supported, and this code is generated from a new compiler. In this tutorial, we'll be discussing some of the new features that have been added to the X++ language. As we run through the scenarios, you'll also see some of the new features in the debugger.

Declare anywhere

Previously, all local variables had to be placed at the start of the method in which they're used. Now, you have fine-grained control over the scope of your variables. With this new feature, it's possible to provide smaller scopes for variables, outside of which the variables can't be referenced. The lifetime of the variable is the scope in which it's declared. Scopes can be started at the block level (inside compound statements), in for statements, and in using statements as we will see below. There are several advantages to making scopes small.

- Readability is enhanced.
- You can reduce the risk of reusing a variable inappropriately during long-term maintenance of the code.
- Refactoring becomes much easier. You can copy code in without having to worry about variables being reused in contexts they shouldn't.

Example - declare a loop counter

In this example, we declare the loop counter inside the 'for' statement in which it's used.

```
void MyMethod()
{
    for (int i = 0; i < 10; i++)
    {
        info(strfmt("i is %1", i));
    }
}
```

The scope of the variable is the for statement itself, including the condition expression and the loop update parts. The value can't be used outside this scope. If you attempt to do that, you will get the following.

```
void MyMethod()
{
    for (int i = 0; i < 10; i++)
    {
        if (i == 7)
        {
            break;
        }
    }
    info(strfmt("Found: %1", i));
}
```

The compiler will issue an error message in the info call: 'i' is not declared.

Example - declare in a using statement

There's another place where scopes can be established: the `using` statement, which is another newcomer to the X++ language.

```
static void AnotherMethod()
{
    str textFromFile;

    using (System.IO.StreamReader sr = new System.IO.StreamReader("c:\\test.txt"))
    {
        textFromFile = sr.ReadToEnd();
    }
}
```

As a rule, when you use an **IDisposable** object, you should declare and instantiate it in a using statement. The using statement calls the **Dispose** method on the object in the correct way, even if an exception occurs while you are calling methods on the object. You can achieve the same result by putting the object inside a try block, and then explicitly calling Dispose in a finally block; in fact, this is how the using statement is translated by the compiler. Declarations can now be provided anywhere statements can be provided-- a declaration is syntactically a statement, a declaration statement. You can, therefore, provide declarations immediately prior to the usage. You don't have to declare the variables all in one place.

Example with new features

The following sample shows some of the features described above.

```
// loop variable declared within the loop: It will
// not be misused outside the loop
for(int i = 1; i < 10; i++)
{
    // Because this value is not used from outside the loop,
    // its declaration belongs in this smaller scope.
    str s = int2str(i);
    info(s);
}
```

To avoid confusion, the X++ compiler will issue an error if you attempt to introduce a variable that would hide another variable in an enclosing scope or even in the same scope. For instance, the following code will cause the compiler to issue the following diagnostic message: A local variable named 'i' cannot be declared in this scope because it would give a different meaning to 'i', which is already used in a parent or current scope to denote something else.

```
{
    int i;
    {
        int i;
    }
}
```

This aligns well with the rules that are known from C#, but is different from the rule in C++ where shadowing is not diagnosed.

Adapt code to use a smaller scope

Adapt the code in **FMVehicleInventoryServiceClass** to use smaller scopes.

Static constructors and static fields

Static constructors and static fields are new features in the X++ language. Static constructors are guaranteed to run before any static or instance calls are made to the class. In C#, the concept of static relates to the whole executing application domain. The execution of the static constructor is relative to the user's session. The static constructor has the following profile.

```
static void TypeNew()
```

You'll never call the static constructor explicitly; the compiler will generate code to ensure that the constructor is called exactly once prior to any other method on the class. A static constructor is used to initialize any static data, or to perform a particular action that needs to be performed only once. No parameters can be provided for the static constructor, and it must be marked as static. Static fields are fields that are declared using the static keyword. Conceptually they apply to the class, not instances of the class.

Implement a singleton

We'll show how a singleton, called instance in the example below, can be created by using the static constructor.

```
public class Singleton
{
    private static Singleton instance;

    private void new()
    {
    }

    static void TypeNew()
    {
        instance = new Singleton();
    }

    public static Singleton instance()
    {
        return Singleton::instance;
    }
}
```

The singleton will guarantee that only one instance of the class will ever be called, which is consumed by the following.

```
{
    // Your code here.
    Singleton i = Singleton::instance();
}
```

Assignment of field members inline

It's now possible to assign a value to a field inline, i.e. along with the declaration of the field itself. This applies to both static and instance fields. In the following code, the values of field1 and field2 are defined in this fashion.

```
public class MyClass2
{
    int field1 = 1;
    str field2 = "Banana";

    void new()
    {
        // Your code here.
    }
}
```

The code above has the same semantic meaning as:

```
public class MyClass2
{
    int field1;
    str field2;

    void new()
    {
        this.field1 = 1;
        this.field2 = "Banana";
        // Your code here.
    }
}
```

The inline assignments work for both static and instance members.

Consts and Readonly

The concept of macros continues to be fully supported in X++. However, using constants instead of #defines has a number of benefits.

- You can add a documentation comment to the const, not to the value of the macro. Ultimately, the language service will pick this up and provide good information to the user.
- The const is known by IntelliSense.
- The const is cross referenced, so you can find all references of a particular constant. This is not the case for a macro.
- The const is subject to access modifiers, either private, protected, or public. The accessibility of macros is not well understood or even rigorously defined.
- Consts have scope, while macros do not.
- You can see the value of consts and readonly variables in the debugger.

Macros that are defined in class scopes (in class declarations) are effectively available in all methods of all derived classes. This was originally a bug in the legacy compiler macro implementation, but this loophole is now massively exploited by application programmers. The new X++ compiler still honors this, but no new code that uses this should be written. This particular feature also considerably impacts compiler performance. Constants can be declared at the class level as suggested below.

```
private const str MyConstant = 'SomeValue';
```

The constants can then be referenced by using the double-colon syntax.

```
str value = MyClass::MyConstant;
```

If you're in the scope of the class where the const is defined, you can omit the type name prefix (MyClass in the example above). You can easily implement the concept of a macro library this way. The list of macro symbols becomes a class with public const definitions.

Example - macro definitions

The fleet application contains the **FMDataHelper** class that contains the following macro definitions.

```
public class FMDataHelper
{
    #define.FMSvcTechUserId('FMSvcTec')
    #define.FMClerkUserId('FMClerk')
    #define.FMManagerUserId('FMMgr')
    #define.FMSvcTechUserGrpId('FMSvcTech')
    #define.FMClerkUserGrpId('FMClerk')
    #define.FMManagerUserGrpId('FMManager')
}
```

Change these to const definitions and update the places where the macros are used accordingly.

You can also define consts solely as variables. The compiler will maintain the invariant that the value can't be modified.

```
{
    const int Blue = 0x0000FF;
    const int Green = 0x00FF00;
    const int Red = 0xFF0000;
}
```

Read-only fields can only be assigned a value once, and that value never changes; the field can be assigned its value either inline, at the place where the field is declared, or in the constructor. Currently, that's the only difference between const and read-only.

Var

You can now declare a variable without explicitly providing the type of the variable, if the compiler can determine the type from the initialization expression. Note that the variable is still strongly-typed into one, unambiguous type. It's only possible to use var on declarations where initialization expressions are provided (from which the compiler will infer the type). There are situations where this can make code easier to read, but this feature shouldn't be misused. You should consider the following rules:

- Use var to declare local variables when the type of the variable is obvious from the right side of the assignment, or when the precise type is not important.

  ```
  // When the type of a variable is clear from the context, use var
  // in the declaration.
  var var1 = "This is clearly a string.";
  var var2 = 27; // This is an integer (not a real).
  var i = System.Convert::ToInt32(3.4);
  ```

- Don't use var when the type isn't apparent from the initialization expression.

  ```
  // When the type of a variable is not clear from the context, use an
  // explicit type.
  int var4 = myObject.ResultSoFar();
  ```

- Use var for the declarations of for loop counters.

- Use var for disposable objects inside using statements.

Private and protected member variables

Previously, all member variables defined in a class were invariably protected. It's now possible to make the visibility of member variables explicit by adding the private, protected, and public keywords. The interpretation of these modifiers is obvious and aligns with the semantics for methods:

- A private member can only be used within the class where it's defined.
- A protected member can be used in the class where it's defined, and all subclasses thereof.
- A public member can be used anywhere: it's visible outside the confines of the class hierarchy in which it's defined.

The default for member variables that aren't adorned with an explicit modifier is still protected. You should make it a habit of explicitly specifying the visibility. As described, when a member variable is defined as public, it may be consumed outside of the class in which it's defined. In this case, a qualifier designating the object hosting the variable has to be specified, using the dot notation (as is the case for method calls). Reusing the code from above:

```
public class MyClass2
{
    int field1;
    str field2;

    void new()
    {
        this.field1 = 1;   // Explicit object designated
        field2 = "Banana";  // 'this' assumed, as usual
    }
}
```

In this case, field1 is accessed using the explicit 'this.' qualifier.

> **NOTE**
> Making a member variable public may not be a good idea since it exposes the internal workings of the class to its consumers, creating a strong dependency between the class implementation and its consumers. You should always strive to only depend on a contract, not an implementation.

Finally in try/catch statements

Try/catch statements can now include an optional finally clause. The semantics are the same as they are in C# and other managed languages. The statements in the finally clause are executed when control leaves the try block, either normally or through an exception.

```
try
{
    // ...
}
catch
{
    // Executes when any exception is thrown in the dynamic
    // scope in the try block.
}
finally
{
    // Executed irrespective of how the try block exits.
}
```

Event handlers and Pre/Post methods

In legacy X++, it was possible to prescribe in metadata that certain methods were to be executed prior to and after the execution of a method. The information about what subscribes call was recorded on the publisher, which isn't useful in the environment. It's now possible to provide Pre and Post handlers through code, by providing the SubscribesTo attribute on the subscribers.

Example of pre and post methods

```
[PreHandlerFor(classStr(MyClass2), methodstr(MyClass2, publisher))]
public static void PreHandler(XppPrePostArgs arguments)
{
    int arg = arguments.getArg("i");
}

[PostHandlerFor(classStr(MyClass2), methodstr(MyClass2, publisher))]
public static void PostHandler(XppPrePostArgs arguments)
{
    int arg = arguments.getArg("i");
    int retvalFromMethod = arguments.getReturnValue();
}

public int Publisher(int i)
{
    return 1;
}
```

This example shows a publishing method called Publisher. Two subscribers are enlisted with the PreHandlerFor and PostHandlerFor. The code shows how to access the variables, and the return values.

This feature is provided for backward compatibility and, because the application code doesn't have many delegates, to publish important application events. Pre and Post handlers can easily break as the result of added or removed parameters, changed parameter types, or because methods are no longer called, or called under different circumstances. Attributes are also used for binding event handlers to delegates:

```
[SubscribesTo(
    classstr(FMRentalCheckoutProcessor),
    delegatestr(FMRentalCheckoutProcessor, RentalTransactionAboutTobeFinalizedEvent))]
public static void RentalFinalizedEventHandler(
    FMRental rentalrecord, Struct rentalConfirmation)
{
}

    delegate void RentalTransactionAboutTobeFinalizedEvent(
        FMRental fmrentalrecord, struct RentalConfirmation)
{
}
```

In this case, the SubscribesTo attribute specifies that the method RentalFinalizedEventHandler should be called when the FmRentalCheckoutProcessor.RentalTransactionAboutToBeFinalizedEvent delegate is called. Since the binding between the publisher and subscribers is done through attributes, there's no way of specifying the sequence in which subscribers are called.

Extension methods

The extension method feature lets you add extension methods to a target class by writing the methods in a separate extension class. The following rules apply:

- The extension class must be static.
- The name of the extension class must end with the ten-character suffix _Extension. However, there's no restriction on the part of the name that precedes the suffix.
- Every extension method in the extension class must be declared as public static.
- The first parameter in every extension method is the type that the extension method extends. However, when the extension method is called, the caller must not pass in anything for the first parameter. Instead, the system automatically passes in the required object for the first parameter.

It's perfectly valid to have private or protected static methods in an extension class. These are typically used for implementation details and are not exposed as extensions. The example below illustrates an extension class holding a few extension methods:

```
public static class AtlInventLocation_Extension
{
    public static InventLocation refillEnabled(
        InventLocation _warehouse,
        boolean _isRefillEnabled = true)
    {
        _warehouse.ReqRefill = _isRefillEnabled;
        return _warehouse;
    }

    public static InventLocation save(InventLocation _warehouse)
    {
        _warehouse.write();
        return _warehouse;
    }
}
```

Reasons to use extension methods

The extension method technique doesn't affect the source code of the class it extends. Therefore, the addition to the class can be done without over-layering. Upgrades to the target class are never affected by any existing extension methods. However, if an upgrade to the target class adds a method that has the same name as your extension method, your extension method becomes unreachable through objects of the target class. Extension

methods are easy to use. The extension method technique uses the same dot-delimited syntax that you routinely use the call regular instance methods. Extension methods can access all public artifacts of the target class, but they can't access things that are protected or private. In this way, extension methods can be seen as a kind of syntactic sugar.

Where can extension methods be applied

The target of an extension method must be one of the following application object types:

- Class
- Table
- View
- Map

Regardless of the target type, an extension *class* is used to add extension methods to the type. For example, an extension table is *not* used to add methods to a table, and there's no such thing as an extension table.

Using clauses

Previously, all references to managed artifacts that weren't authored in X++ was done using fully qualified names, including the namespace for each type. This is still possible, but you can now provide using clauses to make the use of such artifacts less onerous. As opposed to a using statement, each using clause precedes the class in which the clause is applied. It's also possible to provide aliases that introduce a short name for a fully qualified name. Aliases can denote namespaces and classes as shown below.

Example of using clause

Consider the following code:

```
using System;
using IONS=System.IO; // Namespace alias
using Alist=System.Collections.ArrayList; // Class alias

public class MyClass2
{
    public static void Main(Args a)
    {
        Int32 I; // Alternative to System.Int32
        Alist al; // Using a class alias

        al = new Alist();
        str s;

        al.Add(1);

        s = IONS.Path::ChangeExtension(@"c:\tmp\test.xml", ".txt");
    }
}
```

Differences between legacy X++ and new X++

In this section, we'll see some of the differences between legacy X++ and the new X++.

Reals are Decimals

The type used to represent real values has changed from interpreted X++. This won't require you to rewrite any code, because the new type can express all of the values that the old one could. We provide this material in the interest of full disclosure only. All instances of the real type are now implemented as instances of the .NET decimal type (System.Decimal). Just as the real type in previous versions, the decimal type in a binary coded decimal type that, unlike floating point type, is resilient to rounding errors. The range and resolution of the

decimal type are different from the original types. The original X++ real type supported 16 digits and an exponent that defined where the decimal point is placed. The new X++ real type can represent decimal numbers ranging from positive 79,228,162,514,264,337,593,543,950,335 (2^{96}-1) to negative 79,228,162,514,264,337,593,543,950,335 (-(2^{96}-1)). The new real type doesn't eliminate the need for rounding. For example, the following code produces a result of 0.9999999999999999999999999999 instead of 1. This is readily seen when using the debugger to show the value of the variables below.

```
public class MyClass2
{
    public static void Main(Args a)
    {
        real dividend = 1.0;
        real divisor = 3.0;
        str stringvalue;
        System.Decimal valueAsDecimal;

        real value = dividend/divisor * divisor;

        valueAsDecimal = value;
        info(valueAsDecimal.ToString("G28"));
    }
}
```

No number of decimals will suffice to represent the value of 1/3 accurately. The discrepancy obtained here is due to the fact that only a finite number of decimals are provided. You should use the Round function to round to the number of decimals required.

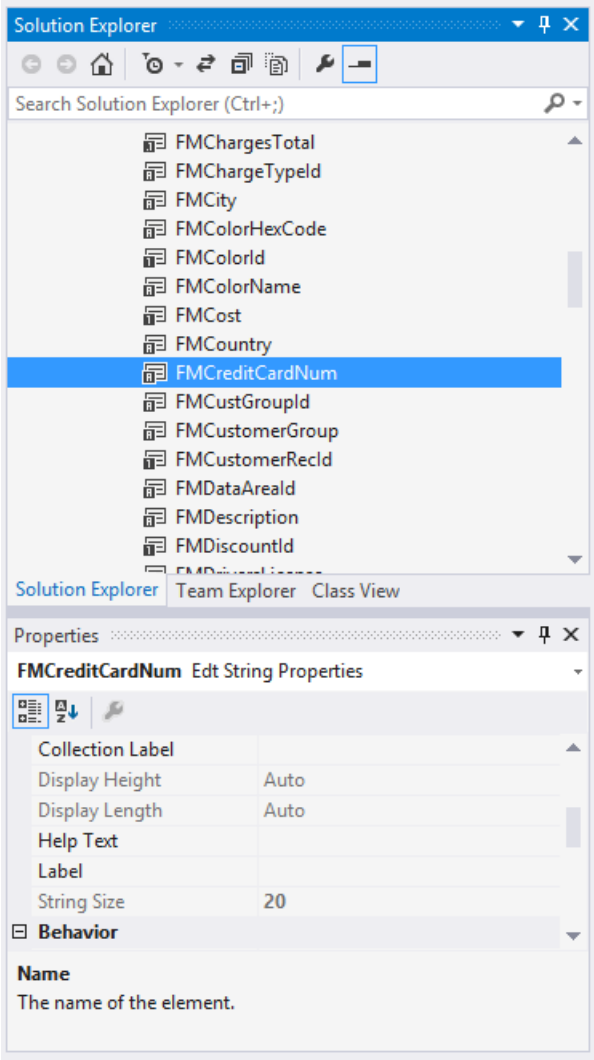
```
value = round(value, 2);
```

Internal representation

A decimal number is a floating-point value that consists of a sign, a numeric value where each digit in the value ranges from 0 to 9, and a scaling factor that indicates the position of a floating decimal point that separates the integral and fractional parts of the numeric value. The binary representation of a real value consists of a 1-bit sign, a 96-bit integer number, and a scaling factor used to divide the 96-bit integer and specify what portion of it is a decimal fraction. The scaling factor is implicitly the number 10, raised to an exponent ranging from 0 to 28. Therefore, the binary representation of a decimal value represents ((-2^{96} to 2^{96})/10(0\ to\ 28)), where -(2^{96}-1) is equal to the minimum value and 2^{96}-1 is equal to the maximum value that can be expressed.

String truncation

String truncation is not a new feature. However, when code is executed in IL in previous versions, the automatic string truncation described here doesn’t take place. String values can be declared in X++ to contain a maximum number of characters. Typically, this is achieved by encoding this information in an extended data type, as shown below: Credit card numbers cannot exceed 20 characters.



It's also possible to specify length constraints directly in the X++ syntax:

```
str 20 creditCardNumber;
```

All assignments to these values are implicitly truncated to this maximum length.

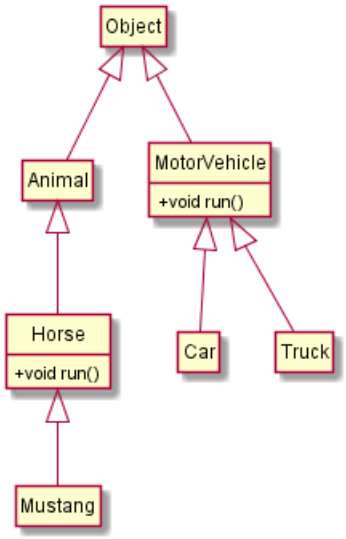
Exercise

Run the following code in the debugger by including it in a static main method:

```
creditCardNumber = "12345678901234567890Excess string";
```

Casting

The previous version of X++ was very permissive in its treatment of type casting. Both up-casting and down-casting were allowed without intervention from the programmer. Some of the casting permitted in legacy X++ can't be implemented in the confines of the .NET runtime environment. In object oriented programming languages, including X++, casting refers to assignments between variables whose declared types are both in the same inheritance chain. A cast is either a down-cast or an up-cast. To set the stage for this discussion, we introduce a few self-explanatory class hierarchies:



As you can see, the MotorVehicle class isn't related to the Animal class. An **up-cast** happens when assigning an expression of a derived type to a base type:

```
Animal a = new Horse();
```

A **down-cast** happens when assigning an expression of a base type to a derived variable.

```
Horse h = new Animal();
```

Both up-casts and down-casts are supported in X++. However, down-casts are dangerous and should be avoided whenever possible. The example above will fail with an InvalidCastException at runtime, since the assignment doesn't make sense. X++ supports late binding on a few types, like object and formrun. This means that the compiler won't diagnose any errors at compile-time when it sees a method being called on those types, if that method isn't declared explicitly on the type. It's assumed that the developer knows what they're doing. For instance, the following code may be found in a form.

```
Object o = element.args().caller();
    o.MyMethod(3.14, “Banana”);
```

The compiler can't check the parameters, return values, etc. for the MyMethod method, since this method isn't declared on the object class. At runtime, the call will be made using reflection, which is orders of magnitude slower than normal calls. Note that calls to methods that are actually defined on the late binding types will be naturally checked. For example, the call to ToString():

```
o.ToString(45);
```

will cause a compilation error:

```
'Object.toString' expects 0 argument(s), but 1 specified.
```

because the ToString method is defined on the object class. There's one difference from the implementation of previous version of X++, related to the fact that methods could be called on unrelated objects, as long as the name of the method was correct, even if the parameter profiles weren't entirely correct. This isn't supported in CIL.

Example - casting

```
public class MyClass2
{
    public static void Main(Args a)
    {
        Object obj = new Car();
        Horse horse = obj; // exception now thrown
        horse.run();    // Used to call car.run()!
    }
}
```

You should use the IS and AS operators liberally in your code. The IS operator can be used if the expression provided is of a particular type (including derived types); the AS operator will perform casting into the given type and return null if a cast isn't possible.

Compiler diagnoses attempts to store objects in containers

In previous incarnations of the X++ compiler, it was possible to store object references into containers, even though this would fail at runtime. This is no longer possible. When the compiler sees an attempt to store an object reference into a container:

```
container c = [new Query()];
```

It will issue the error message:

```
Instances of type 'Query' cannot be added to a container.
```

If the type of the element that is added to the container is any type that the compiler can't make the determination of whether the value is a reference type. The compiler will allow this under the assumption that the user knows what they're doing. The compiler won't diagnose the following code as erroneous but an error will be thrown at runtime.:

```
anytype a = new Query();
    container c = [a];
```

Cross company clause can contain arbitrary expressions

The cross company clause can be used on select statements to indicate the companies that the search statement should take into account. The syntax has been enhanced to allow arbitrary expressions (of type container) instead of a single identifier, which is a variable of type container.

```
private void SampleMethod()
{
    MyTable t;
    container mycompanies = ['dat', 'dmo'];
    select crosscompany: mycompanies t;
}
```

Now, it's possible to provide the expression without having to use a variable for this purpose.

```
private void SampleMethod()
{
    MyTable t;
    container mycompanies = ['dat', 'dmo'];
    select crosscompany: (['dat'] + ['dmo']) t;
}
```

mkDate predefined function no longer accepts shorthand values

In legacy systems, it was possible to use "shorthand" values for the year argument of the mkDate function. The effect can be seen in the following code sample.

```
static void Job16(Args _args)
{
    int y;
    date d;

    for (y = 0; y < 150; y++)
    {
        d = mkDate(1,1,y);
        info(strFmt("%1 - %2", y, year(d)));
    }
}
```

Running this code in the legacy system will produce the following values: 0 – 2000 1 – 2001 2 – 2002 ... 27 – 2027 28 – 2028 29 – 2029 **30 – 2030 31 – 1931** 32 – 1932 33 – 1933 ... 97 – 1997 98 – 1998 **99 – 1999 100 – 1900** We no longer support these values. Attempts to use such values will cause the mkDate function to return the null date (1/1/1900).

Obsolete statement types

The following statements are no longer supported.

Pause and Window statements

The X++ pause statement is no longer supported because the pop-up **Print Window** that it affected has been removed. The pause and window statements were mainly used for debugging within the MorphX development environment, which was the same as the execution environment. Since the two are now separated, with Visual Studio taking the place of the MorphX environment, these statements are no longer relevant.

Print statement

The X++ print statement is another statement that existed only for debugging purposes. It still exists, and its basic idea is unchanged. But print now outputs through System.Diagnostics.WriteLine. The product configuration determines the detail of the written information is sent. You may find that using the Infolog is more compelling, since its output appears in the debugger and the running form.

The Ignore list

Since the legacy environment was all interpreted, it was possible to have some parts not compile, and use the rest. As long as you only called methods that compiled correctly, you were fine; however, you would run into trouble if you tried to call methods that weren't successfully compiled. This way of working doesn't work in CIL. Assemblies are generated from successful compilations and the runtime system can't load incomplete assemblies. However, there are legitimate scenarios when porting legacy applications into the new environment where it's beneficial to get things running in a staged fashion and where parts of the application need to be tested before everything is ported. While this is useful for this very limited scenario, it shouldn't be used once the application is ready for production, since you would be hiding problems that will occur at runtime, after the

system has been deployed. This is how it currently works: You can specify a method in an XML by selecting, "Edit Best Practice Suppressions," from the context menu on the project. This will open an XML document where the exclusions are maintained.

New Debugger features

This section provides information about the new features that we've added to the debugging experience in Visual Studio.

Adding ToString methods to your classes

It's often a benefit to add ToString() methods to your classes. The effort spent doing this comes back many times and it's easy to do. This advice also holds true for legacy X++.

> **NOTE**
> Since ToString methods can be called at unpredictable times, it isn't a good idea to change the state of the object here.

Identifying unselected fields

It's a common source of bugs to use fields from a table when these fields don't appear in the field list in a select statement. Such fields will have a default value according to their type. It's now possible in the debugger to see if a value has been selected or not.

Using breakpoints

Consider the following code:

```
class MyClass
{
    public static void Main(Args a)
    {
        FMRental rental;

        select EndMileage, RentalId from rental;

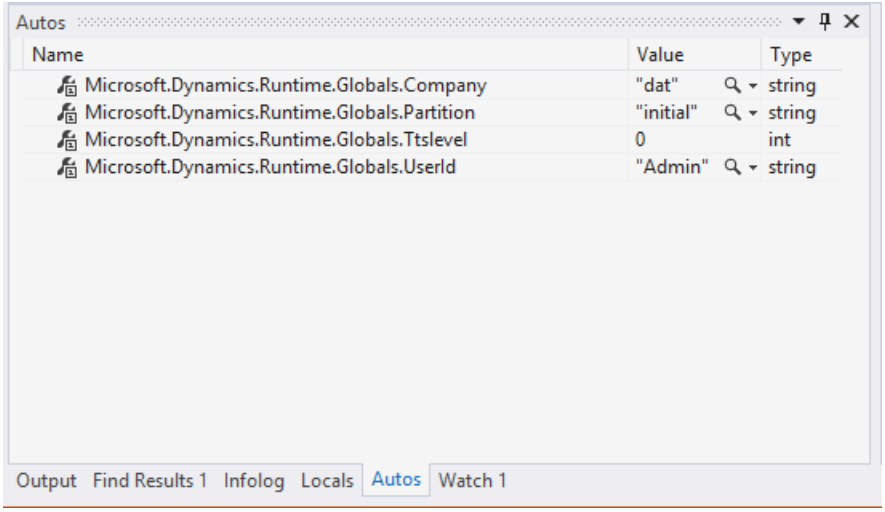
        rental.Comments = "Something";
    }
}
```

Set a breakpoint on the assignment statement. Make your class the startup object in your project, and start by pressing F5. When the breakpoint is encountered, view the rental variable by expanding it in the locals window. You can see that the fields that have been selected (EndMileage and RentalId) appear with their selected values, while the unselected fields appear as null. This signifies their value wasn't fetched from the database. Obviously, this is a debugging artifact. The values of the unselected fields will be the default value for the type of the field. Step over this and notice how the debugger changes the rendering to the actual value.

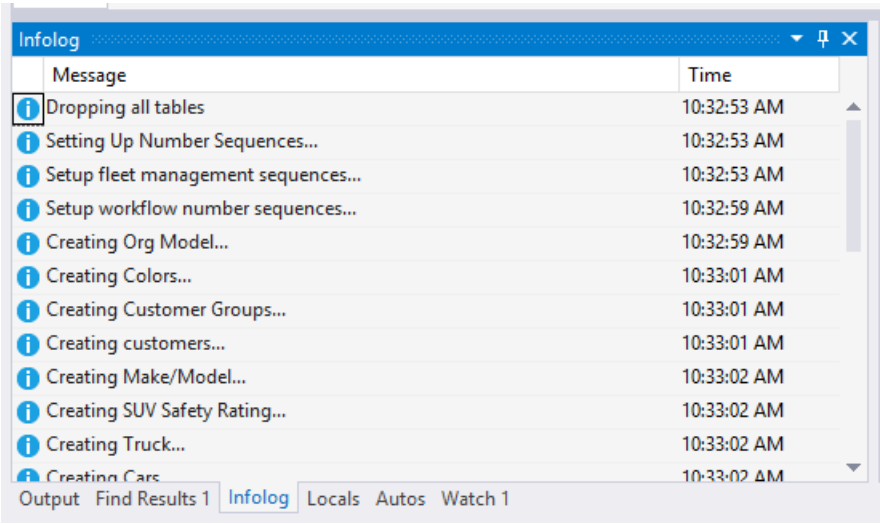
> **NOTE**
> If the table is set to Cache, the system will always fetch all fields from the entire table, irrespective of the field list provided in the code.

The Auto and Infolog Windows

The debugger will allow you to easily access certain parts of the state of the application. This information is available in the autos window, where the current company, the partition, the transaction level, and the current user ID are listed.



There is also a window showing the data that is written to the Infolog.



New breakpoint features

The Visual Studio debugger supports conditional breakpoints and breakpoints that are triggered by hit count. You can also have the system perform specific actions for you as you hit the breakpoint. None of these features were available in the legacy debugger. These are explained below:

- Hit count enables you to determine how many times the breakpoint is hit before the debugger breaks execution. By default, the debugger breaks execution every time that the breakpoint is hit. You can set a hit count to tell the debugger to break every 2 times the breakpoint is hit, or every 10 times, or every 512 times, or any other number you choose. Hit counts can be useful because some bugs don't appear the first time your program executes a loop, calls a function, or accesses a variable. Sometimes, the bug might not appear until the 100th or the 1000th iteration. To debug such a problem, you can set a breakpoint with a hit count of 100 or 1000.
- Condition is an expression that determines whether the breakpoint is hit or skipped. When the debugger reaches the breakpoint, it'll evaluate the condition. The breakpoint will be hit only if the condition is satisfied. You can use a condition with a location breakpoint to stop at a specified location only when a certain condition is true. For example, suppose you're debugging a banking program where the account balance is never allowed to go below zero. You might set breakpoints at certain locations in the code and attach a condition such as balance < 0 to each one. When you run the program, execution will break at those locations only when the balance is less than zero. You can examine variables and program state at the first breakpoint location, and then continue execution to the second breakpoint location, and so on.
- Action specifies something that should occur when the breakpoint is hit. By default, the debugger breaks execution, but you can choose to print a message or run a Visual Studio macro instead. If you decide to print a message instead of breaking, the breakpoint has an effect very similar to a Trace statement. This method of

using breakpoints is called trace points.

Using breakpoints with conditions

Consider the following code:

```
class PVsClass
{
    public static void Main(Args a)
    {
        int i;
        for (i = 0; i < 10; i++)
        {
            print i;
        }
    }
}
```

Put a breakpoint on the print statements by pressing F9 while that statement is selected. This will create a normal, unconditional breakpoint. Now, use the mouse to open the context menu for the breakpoint and select **Condition**. Put in a condition that indicates that the breakpoint should happen when the value of the 'i' variable exceeds 5. Set the class as a startup project, and the class containing the code as the startup item in the project. Run the code. Feel free to modify the value of 'i' using the debugger. Now, remove this breakpoint, and use the Hit count feature to accomplish the same thing.

> **NOTE**
>
> A breakpoint can have several conditions. It's often helpful to hover the cursor over the breakpoint, causing an informative tooltip to appear. Trace points are often useful tot race execution. Insert a trace point on the line in question and log the value of the variable. The trace output will appear in the output window in the debugger.

The immediate window

The immediate window is a useful feature in the VS debugger that allows the user to enter expression and statements to evaluate at any given time. This feature isn't currently implemented in the X++ stack, as is the case for many other languages, notably F#. However, that doesn't mean that the savvy user can't benefit from the immediate window. It just means that snippets must be expressed in C#, not in X++. There's a separate document that describes the details of how this can be done to great effect.

Debug X++ code by using the debugger in Visual Studio

2/18/2021 • 2 minutes to read • Edit Online

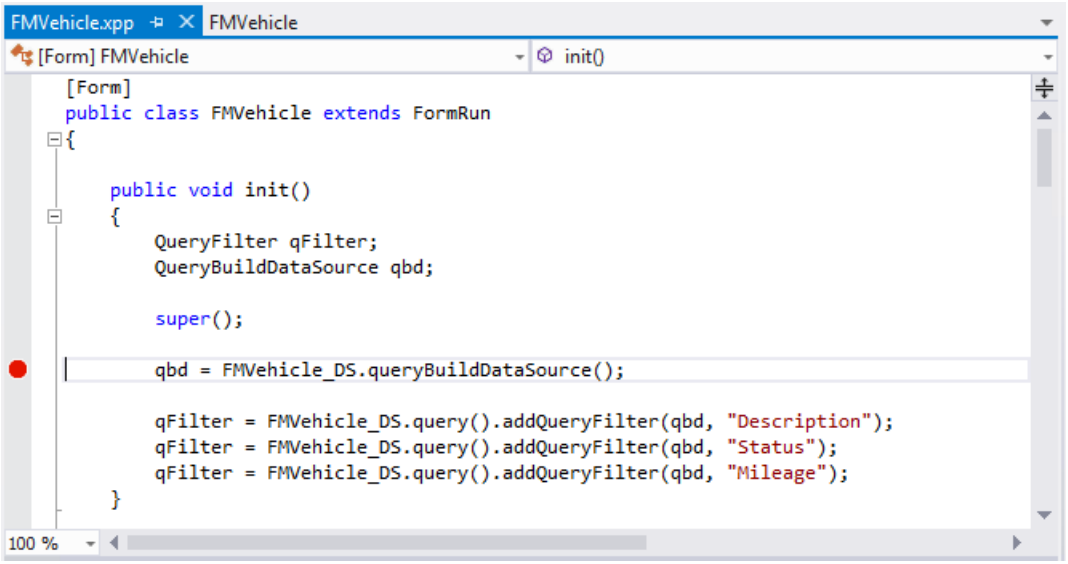
This topic reviews how you can debug X++ code by using the debugging feature in Microsoft Visual Studio.

To debug X++ code, you use the debugger in Microsoft Visual Studio. The process is similar to the process that is used for any other application that is created in Visual Studio. For example, the standard tools for examining the application are available when your code is stopped at a breakpoint.

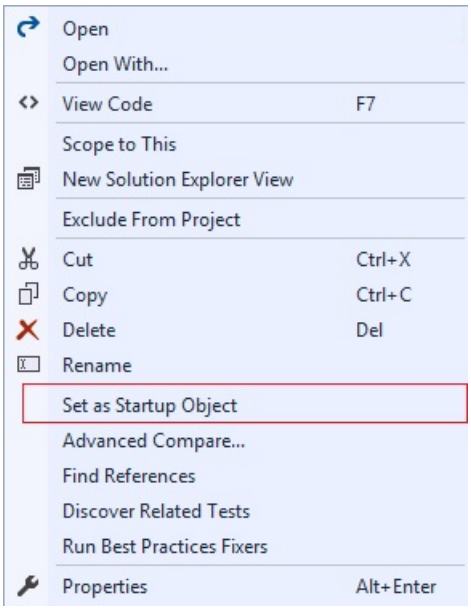
Debug your code

To debug X++ code, follow these steps.

1. In Visual Studio, open the X++ code to debug.
2. Find the line or lines where you want execution to stop, and set breakpoints in those lines. To set a breakpoint in a line, click in the left column of the code editor or press F9 while the cursor is on that line. A red dot indicates that a breakpoint has been set.

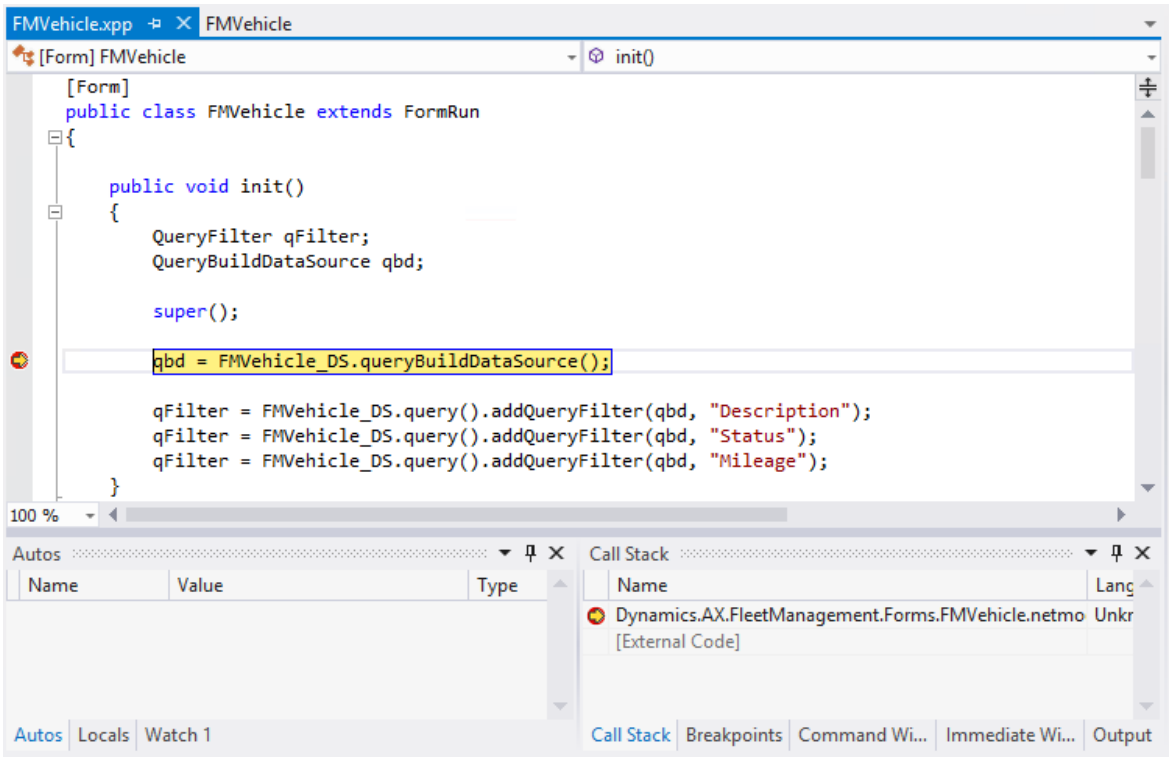


3. Set a startup project and a startup object. Startup objects can be any form, any class that has the **main** method, or any menu item. You can set the startup object in the **Properties** pane for the project. Alternatively, right-click the element in Solution Explorer, and then click **Set as Startup Object**.

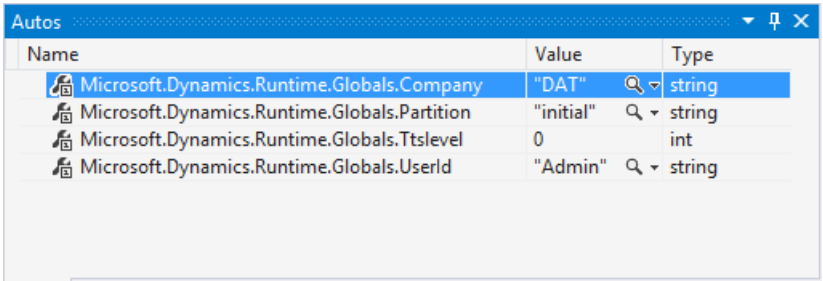


4. On the **Debug** menu, click **Start Debugging**.

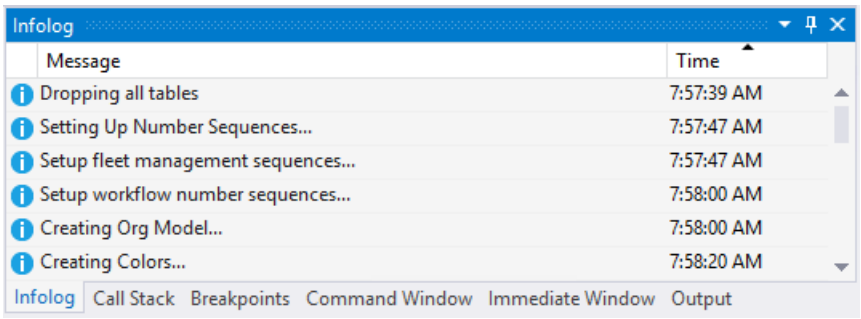
5. In the application, perform the action that causes the code that you're interested in to run. Typical actions include opening a form. Processing stops at the breakpoints that you set.



6. Use the tools in Visual Studio to examine the application. For example, you can hover over variables in the X++ code to see their values. You can also use commands on the **Debug** menu to step through the code. Additionally, tools such as the **Autos** pane in Visual Studio will show important information about the state of the application.



Another tool that is specific to Finance and Operations applications is the Infolog. Often, **info()** statements are added to code to log status messages while the application is running. You can view these Infolog messages directly in Visual Studio. On the **View** menu, click **Infolog**.



7. After you've finished debugging the application, exit the application. Visual Studio will exit debugging mode.

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

EventHandlerResult classes in request or response scenarios

2/18/2021 • 3 minutes to read • Edit Online

Delegate methods and delegate handler methods can be declared to support a request/response scenario, where the delegate calling logic requests the subscribers to provide a response. To support this scenario the **EventHandlerResult** class is most often passed as a parameter, and the delegate handler methods provide their result using one of the result methods on the class. However, the **EventHandlerResult** class can only contain a single result, so if multiple subscribers provide their individual result, the last respondent wins, and the results from the previous subscribers are overwritten.

Before the functionality described in this topic was introduced (platform update 5), there was no mechanism to ensure that, at most, a single subscriber provided a result, and that no results were lost if there were multiple subscribers.

Ensuring, at most, one response

In platform update 5, the **EventHandlerResult** class has an additional static constructor which ensures that the logic fails if more than one subscriber provides a result. The new constructor is named **newSingleResponse**. When instantiating an **EventHandlerResult** object using this method, the framework will throw an exception as soon as a second delegate handler method attempts to provide a result.

```
EventHandlerResult result = EventHandlerResult::newSingleResponse();
this.validateWarehouseTypeDelegate(this.WarehouseType, result);
```

IEventHandlerResultValidator interface

The validation in the **EventHandlerResult** class is handled by injecting an object of a type that implements the **IEventHandlerResultValidator** interface. When instantiating the **EventHandlerResult** object using the **newSingleResponse** static constructor, an **EventHandlerSingleResponseValidator** object is instantiated and injected into the **EventHandlerResult** object, and the injected object becomes responsible for validating any result provided to the **EventhandlerResult** object. Other validation classes can be implemented by having the class implement the **IEventHandlerResultValidator** interface, and injecting it into the **EventHandlerResult** class by instantiating the **EventHandlerResult** object using another new static constructor named **newWithResultValidator**. The constructor takes an argument of type **IEventHandlerResultValidator**, which makes it possible to inject any validator object as long as it implements the **IEventHandlerResultValidator** interface.

For example, the **newSingleResponse** static constructor simply delegates the instantiation to the **newWithResultValidator** static constructor like this.

```
return EventHandlerResult::newWithResultValidator(EventHandlerSingleResponseValidator::construct());
```

Accept and reject request/response scenarios

In certain request/response scenarios, the subscriber is only expected to provide their acceptance or rejection. Using the **EventHandlerResult** class to request acceptance/rejection can be confusing, if the subscriber is only

expected to respond with a Boolean value. In a validation scenario, for example, should the subscriber only respond with Boolean false, when validation fails, or should the subscriber also respond with Boolean true, if validation succeeds? If the response is gathered using an **EventHandlerResult** object, then the second subscriber that validates and replies with Boolean true, might overwrite the Boolean false from the first subscriber.

To mitigate this confusion, two new result type classes have been introduced in Platform update 5: **EventHandlerAcceptResult** and **EventHandlerRejectResult**.

When using the **EventHandlerAcceptResult** class, the delegate handler method can only respond by calling the **accept** method. When using the **EventHandlerRejectResult** class, only the **reject** method can be called.

```
[SubscribesTo(tableStr(InventWarehouseEntity), delegateStr(InventWarehouseEntity,
validateWarehouseTypeDelegate))]
public static void validateWarehouseTypeIsSupportedStandardDelegateHandler(
    InventLocationType _inventLocationType,
    EventHandlerAcceptResult _result)
{
    switch (_inventLocationType)
    {
        case InventLocationType::Standard:
        case InventLocationType::Quarantine:
        case InventLocationType::Transit:
            _result.accept();
            break;
    }
}
```

The two new classes also contain a **newSingleResponse** static constructor for use in scenarios where, at most, one subscriber is allowed to respond with their rejection or acceptance. Whether any subscriber has responded can still be answered by querying the **hasResult** method, and the acceptance/rejection is queried by calling either the **isAccepted** or **isRejected** methods for the **EventHandlerAcceptResult** and **EventHandlerRejectResult** classes, respectively.

```
boolean ret = false;
EventHandlerAcceptResult result = EventHandlerAcceptResult::newSingleResponse();
this.validateWarehouseTypeDelegate(this.WarehouseType, result);
if (result.hasResult())
{
    ret = result.isAccepted();
}
```

Write business logic by using C# and X++ source code

2/18/2021 • 11 minutes to read • Edit Online

The primary goal of this tutorial is to illustrate the interoperability between C# and X++. In this tutorial, you'll write business logic in C# source code and in X++ source code.

In this tutorial, you'll write business logic in C# source code and in X++ source code. You'll get experience with the following:

- New tools in Visual Studio.
- The handling of events in C#.
- The use of Language Integrated Query (LINQ) in C# to fetch data.

Prerequisite

This tutorial requires that you access the environment using Remote Desktop, and be provisioned as an administrator on the instance.

> **NOTE**
> Debugging support for the C# project does not work if the **Load symbols only for items in the solution** check box is selected. Since this option is selected by default, it must be changed prior to running the lab. In Visual Studio, click **Dynamics 365** > **Options**, and clear the **Load symbols only for items in the solution** check box.

Scenario

Too many cars have been rented to drivers who have a history of unsafe driving habits. The Fleet Management rental company needs to check driving records from external sources. Upper management has decided to subscribe to a service that is hosted by the Department of Transportation (DOT), which is the legal entity that manages drivers' licenses and associated information. This service retrieves the number of citations for the given unique license number. It's not easy to call external services directly from X++ source code. Visual Studio has tools for generating the "code-behind" (in C#) that calls the services, and these tools make the development effort easy. The obvious choice would be to leverage Visual Studio to write the code. However, in this tutorial your code won't actually call an external service, because the logistics are beyond the scope of the simple lab environment. Instead, we provide a mock implementation of a service call. The goal of this tutorial is to teach an understanding of the current state of C# and of interoperability with X++.

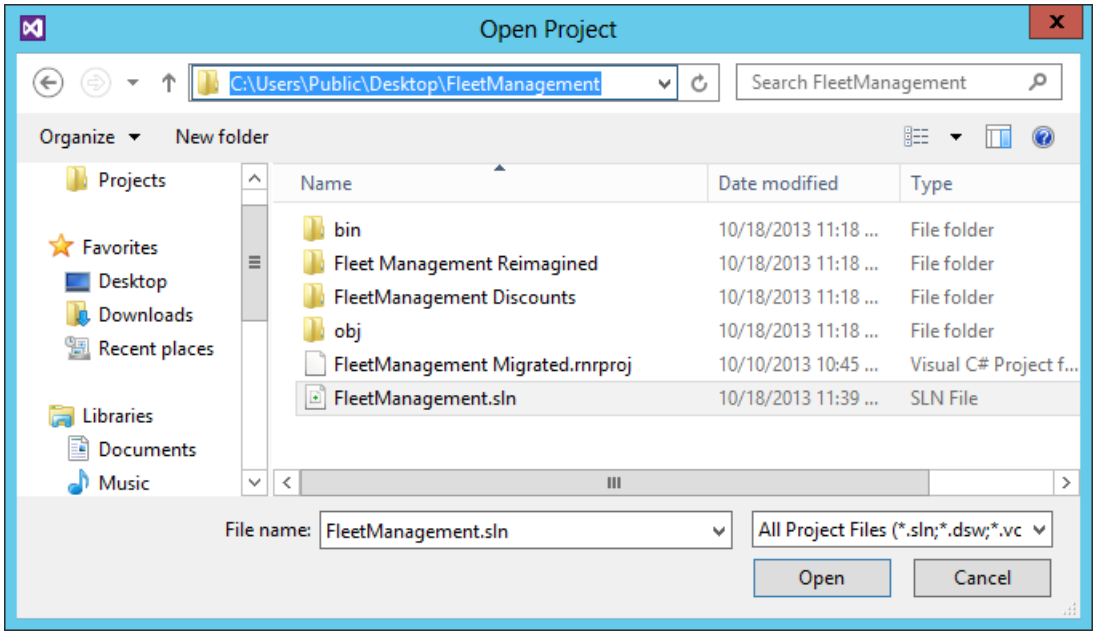
Create a C# class library

You can create a reference from a project to the C# class library, or to any other type of C# project that generates an assembly. Such references affect the build order. The C# project is built before the project that references and depends on it. The infrastructure understands the references, and will make sure that the C# assemblies are deployed correctly to the cloud before execution. Follow these steps to create a C# class library in the Fleet Management solution:

1. In Visual Studio, click **File** > **Open project/solution**.
2. In the **Open Project** dialog box, in the **File name** text box, type the following path, and then press

Enter: *C:\users\public\desktop\FleetManagement*.

3. Select the file named FleetManagement.sln, and then click **Open**. If the solution file is not on your computer, the steps to create it are listed in Tutorial: Create a Fleet Management solution file out of the Fleet Management models in the AOT.



4. Right-click the **FleetManagement** solution, and then click **Add** > **New Project**. The **Add New Project** dialog is displayed.

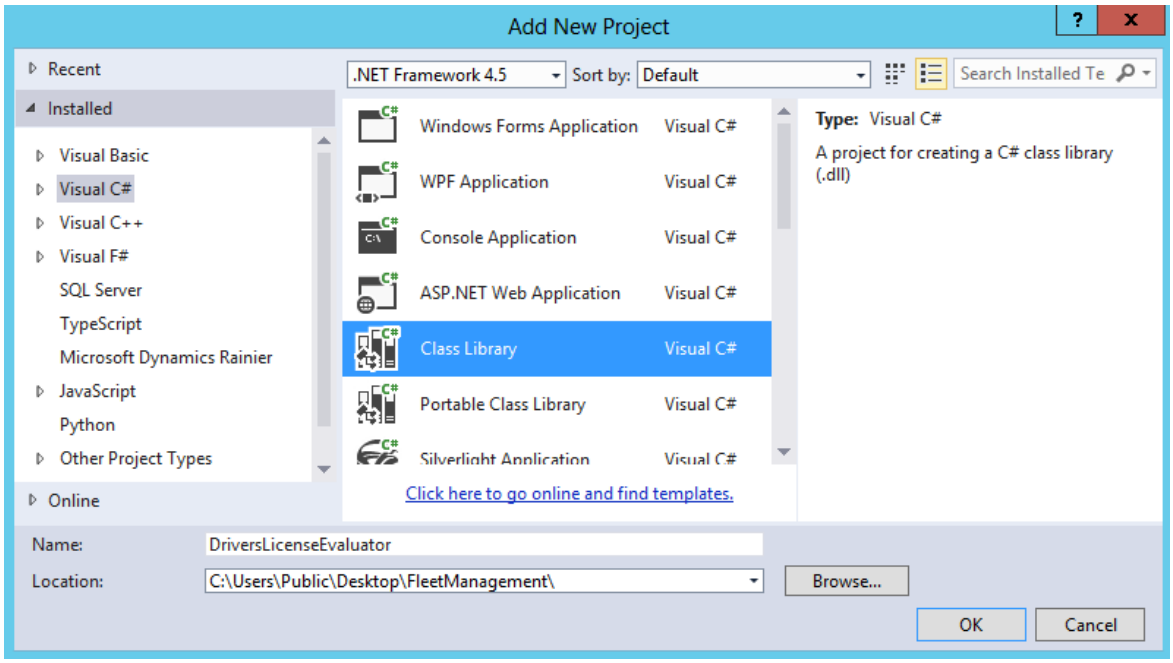
5. In the left pane, click **Visual C#**, and then in the middle pane, click **Class Library**.

6. At the bottom in the **Name** text box, type the name **DriversLicenseEvaluator**.

7. In the **Location** text box, type the following directory path: *C:\users\public\desktop\FleetManagement*.

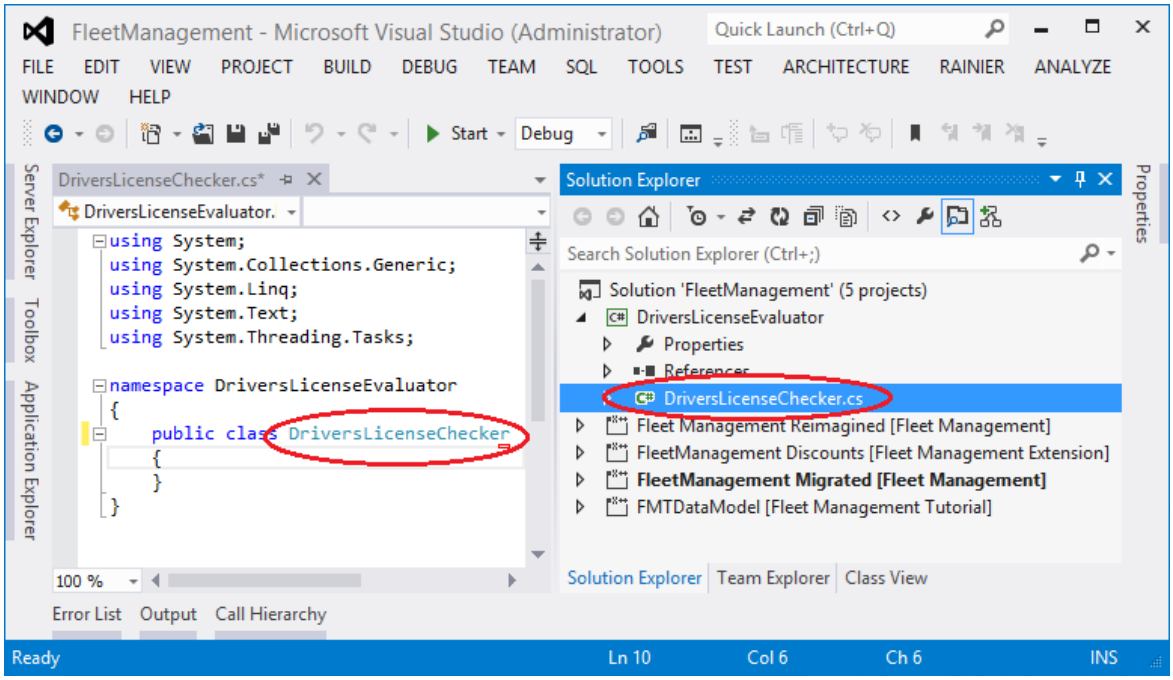
8. Verify that your project is set to ".NET Framework 4.5" in the drop-down list at the top.

9. Click **OK** to create the project.



10. In **Solution Explorer**, under the DriversLicenseEvaluator project, right-click the file name Class1.cs and rename it DriversLicenseChecker.cs.

11. Click **Yes**, when prompted to rename all references to the class.



Write a C# method named CheckDriversLicense

In this section, you add C# code for a method named CheckDriversLicense. The method must validate the driver's license. To do this, the method must retrieve the driver's license number, which is stored in the customer table. The method is given the RecId value for the customer record that contains the information required by the method. Your C# code uses the LINQ provider to read from the customer table. For LINQ to work, you must first add references pointing to the LINQ assemblies. You add these references to the C# project named DriversLicenseEvaluator.

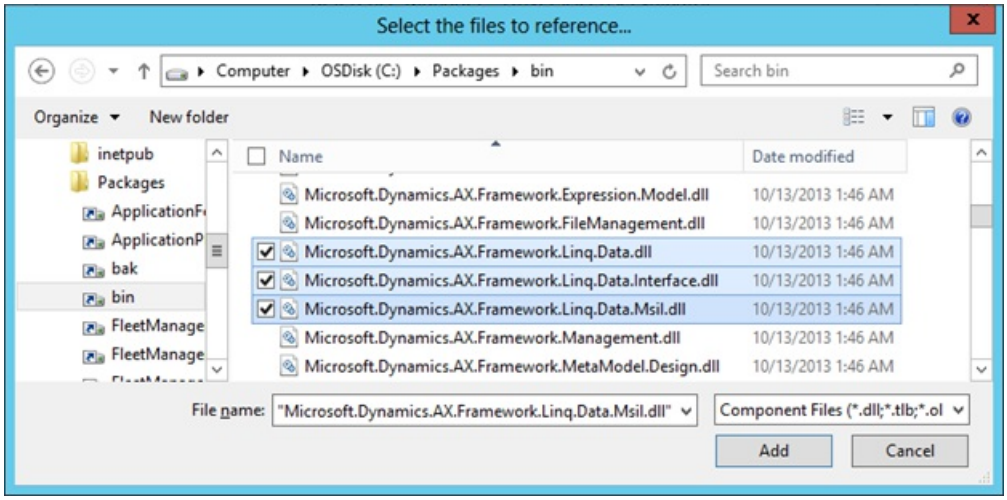
1. In **Solution Explorer**, expand the DriversLicenseEvaluator project node, right-click **References**, and then click **Add Reference**.

2. Click **Browse** and then enter the following path: C:\Packages\bin

   Note that in some environments, the location of the packages folder is not on the c: drive.

3. In the **File name** field, type the pattern *LINQ*.dll and then press **Enter**. You'll see a list of assemblies with the name LINQ in them. From that list, select the following files, and then click **Add**:

   - Microsoft.Dynamics.AX.Framework.Linq.Data.dll
   - Microsoft.Dynamics.AX.Framework.Linq.Data.Interface.dll
   - Microsoft.Dynamics.AX.Framework.Linq.Data.Msil.dll



4. You must also add the support assemblies that contain the Common type that you'll use in the code below. Click **Browse** again, and then type the following file name into the field:

   - Microsoft.Dynamics.AX.Xpp.Support.dll
   - Microsoft.Dynamics.AX.Data.Core.dll

5. Click **Add**, and then click **OK**. The assemblies now appear under the references node in the project.

6. Repeat the **Add Reference** process, except this time, add the following DLL file from the indicated path:

   - Dynamics.Ax.FleetManagement.dll, in C:\Packages\FleetManagement\bin

7. In **Solution Explorer**, select the reference Dynamics.Ax.FleetManagement.dll reference and set the property **Copy Local = False**.

8. In **Solution Explorer**, right-click **DriversLicenseChecker.cs**, and then click **View Code**.

9. Add the following three using statements to the **DriversLicenseEvaluator** namespace, to reduce the verbosity of code that references external classes. using Dynamics.AX.Application; using Microsoft.Dynamics.AX.Framework.Linq.Data; using Microsoft.Dynamics.AX.Xpp; Your C# code should now look something like the following example.

```
using System;
using System.Collections.Generic;
using System.Linq;
using System.Text;
using System.Threading.Tasks;

namespace DriversLicenseEvaluator
{
    using Dynamics.AX.Application;
    using Microsoft.Dynamics.AX.Framework.Linq.Data;
    using Microsoft.Dynamics.Ax.Xpp;

    public class DriversLicenseChecker
    {
    }
}
```

10. Replace the class CheckDriversLicense with the following code.

> **TIP**
> If you prefer, you can paste in the code from the DriversLicenseChecker.cs file in the C:\FMLab directory.

```
public class DriversLicenseChecker
{
    public static bool CheckDriversLicense(long customerId)
    {
        // Use LINQ to get back to the information about the license number
        FMCustomer customer;
        QueryProvider provider = new AXQueryProvider(null);
        var customers = new QueryCollection<FMCustomer>(provider);

        // Build the query (but do not execute it)
        var query = from c in customers
            where c.RecId == customerId
            select c;

        // Execute the query:
        customer = query.FirstOrDefault();
        if (customer == null)
        {
            throw new ArgumentException
                ("The customerId does not designate a customer");
        }

        if (string.IsNullOrEmpty(customer.DriverLicense))
        {
            // No driver's license was recorded. Veto the rental.
            return false;
        }

        // Call the DOT web service to validate the license number.
        // This is not practical for this lab, because all the service providers
        // charge for this service. Instead, just assume that any license number
        // that contains the sequence "89" is valid.
        // In the demo data, this is true for Adrian Lannin,
        // but not for Phil Spencer.
        return customer.DriverLicense.Contains("89");
    }
}
```

Understand the LINQ code

Before proceeding with more C# code, verify that you understand the LINQ code you just added. More details about LINQ are provided in the Technical Concepts Guide, so only the basics are described below.

- First, a *provider* is created. It provides access to all the tables.
- Next, a *collection* of all customers is created. The customer of interest is retrieved from this collection.
- Then, a *query* is created with a where clause that designates the requested customer by **RecId**.
- The call to the FirstOrDefault method forces execution of the query.
- The method assigns the single matching customer to the customer variable. (Null is assigned if the RecId value matches no customer.)
- Finally, the customer data is tested to see if the associated driver's license is valid. (Does the license contain "89"?)

Handle the event when a record is added

The following subsections provide the following:

- Explain the upcoming code items and their inter-relationships.
- Show the code for an event handler.
- Associate the handler with the event occurrences.

Preparatory overview

When an attempt is made to add a record to a table, the OnValidateWrite event is raised before the record is written to the database. You want your CheckDriversLicense method to be called each time on the OnValidateWrite event is raised for the FMRental table. To do this, you now need to write a C# method that is invoked by the event, and which calls your checkDriversLicense method. In other words, you need to write an event handler that calls your CheckDriversLicense method. The event handler method receives a parameter of the type, DataEventArgs. The event handler can set a value in the DataEventArgs structure to accept or reject the record. After you write your event handler method, you connect it to the event by assigning, or adding it to the OnValidatedWrite delegate that is a member of the FMRental table. You write this assignment in the init method of the data source of the FMRental form. This assignment to a delegate might seem odd. After all, we're modifying existing code (FMRental) to add handlers, which contradicts the main value proposition of loose coupling that eventing is supposed to offer. This assignment step is temporary. We'll eventually have the same story in C# as we do in X++, where an attribute is applied to the C# event handler as the mechanism that ties the delegate to the handler.

> **NOTE**
>
> The data source init method is called when the form is opened. Technically, the init method is inherited from the FormDataSource class.

Write an event handler method

In C#, write the following event handler method and add it to the DriversLicenseChecker class.

```
public static void OnValidatedWriteHandler(Common table, DataEventArgs args)
{
    var validateEventArgs = args as ValidateEventArgs;

    // Do not check if already rejected.
    if (validateEventArgs.parmValidateResult())
    {
        var rentalTable = table as FMRental;
        if (rentalTable == null)
        {
            throw new ArgumentNullException("table");
        }

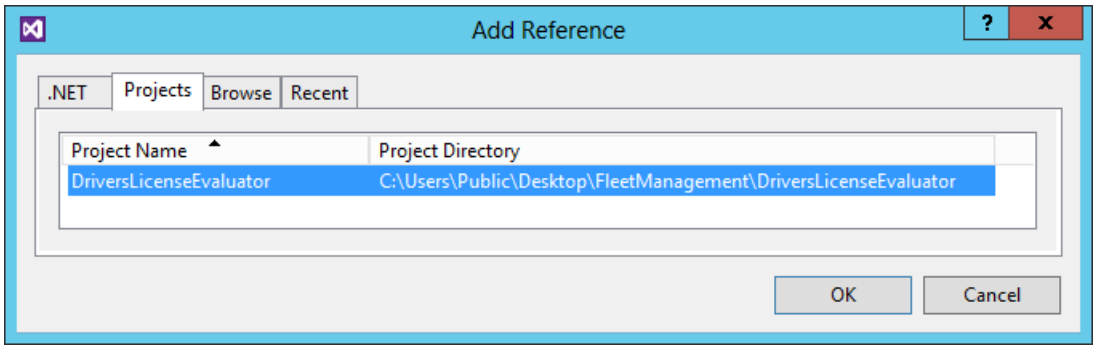
        var result = CheckDriversLicense(rentalTable.Customer);
        validateEventArgs.parmValidateResult(result);
    }
}
```

Build the DriversLicenseEvaluator project by right-clicking the project node and then clicking **Build**.

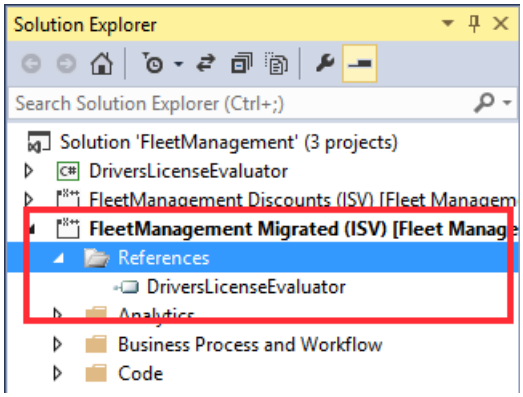
Add a reference pointing to the DriversLIcenseEvaluator project

Create a reference from the X++ project named **FleetManagement Migrated** to the C# project named **DriversLicenseEvaluator**, by completing the following steps.

1. Right-click the FleetManagement Migrated project, click **Add**, and then click **Reference**. Select the row for the DriversLicenseEvaluator project in the **Projects** references tab, and then click **OK**.

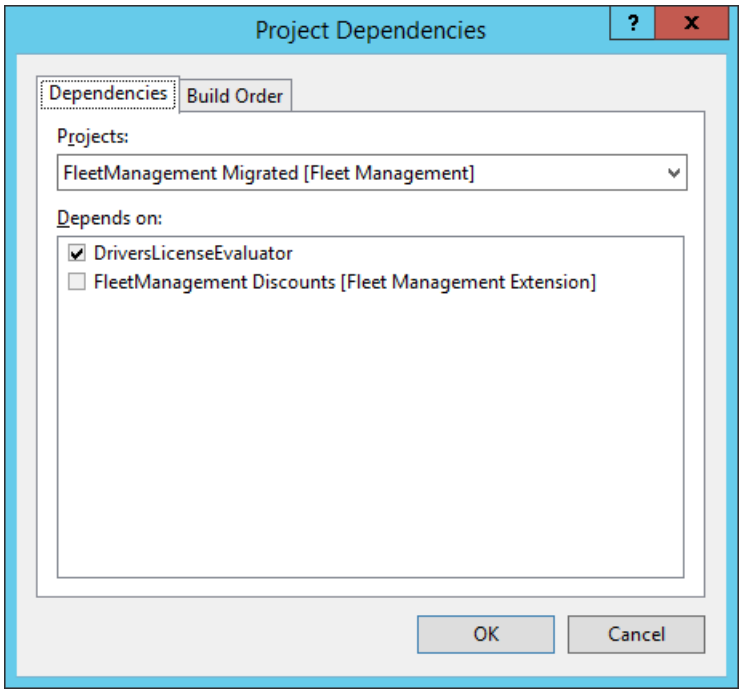


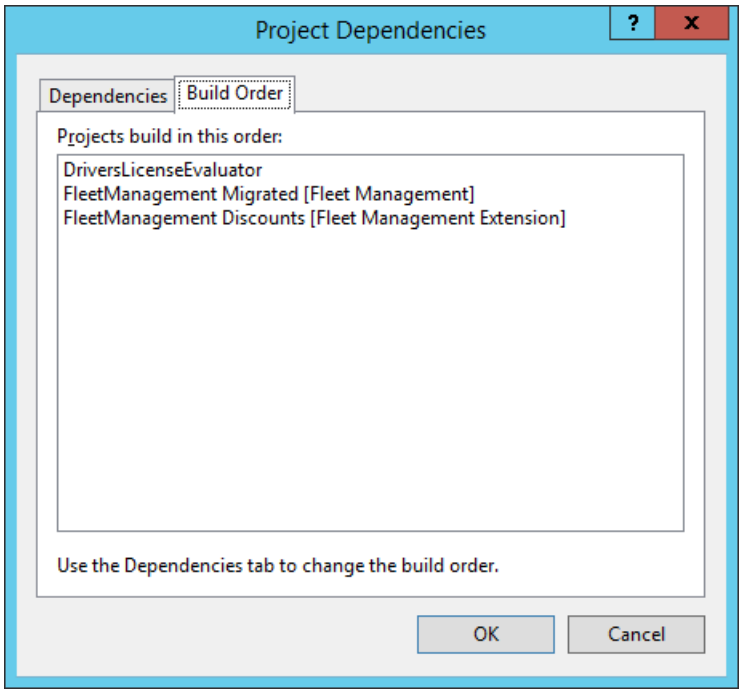
2. Under the FleetManagement Migrated project, expand the **References** node, and there you see new reference to the **DriversLicenseEvaluator** project.



Build sequence

Your C# DriversLicenseEvaluator project will be built before the FleetManagement Migrated project is built. This is because the added reference makes the Fleet project dependent on your project. The build sequence is easy to see if you right-click the FleetManagement solution, click **Project Build Order**, and then click **Dependencies**.





Add your event handler to a delegate

1. In **Solution Explorer**, navigate to **FleetManagement Migrated > User Interface > Forms > FMRental**.
2. Double-click the **FMRental** form. The Visual Studio designer opens to the form.
3. Expand the **Data Sources** node to show the data sources used in the form.
4. Expand the **FMRental** data source, and then the **Methods** node to list the methods defined on the data source.
5. Right-click **Methods**, and then click **Override > init**. The list displays all of the methods on the data source that haven't yet been overridden. When you select **init**, this opens the file **FMRental.xpp** in the X++ code editor with the cursor near the template for the init method.
6. At the end of the **init** method body, use the += operator to add one assignment to a delegate.

```
FMRental.onValidatedWrite += eventhandler
    (DriversLicenseEvaluator.DriversLicenseChecker::OnValidatedWriteHandler);
```

7. Click to save, and then build the entire solution.

Final test

In this section, you set breakpoints and run the Fleet application under the Visual Studio debugger. This enables you to prove the following:

- Your LINQ query runs when the OnValidateWrite event is raised.
- Your LINQ query successfully retrieves the data for one customer.

Prepare the test

1. In **Solution Explorer**, navigate to **FleetManagement Migrated > User Interface > Forms.**
2. Right-click **FMRental**, and then click **Set as Startup Object**.
3. In the code editor for DriversLicenseChecker.cs, find the OnValidateWriteHandler method. Find the following line of code.

```
var result = CheckDriversLicense(rentalTable.Customer);
```

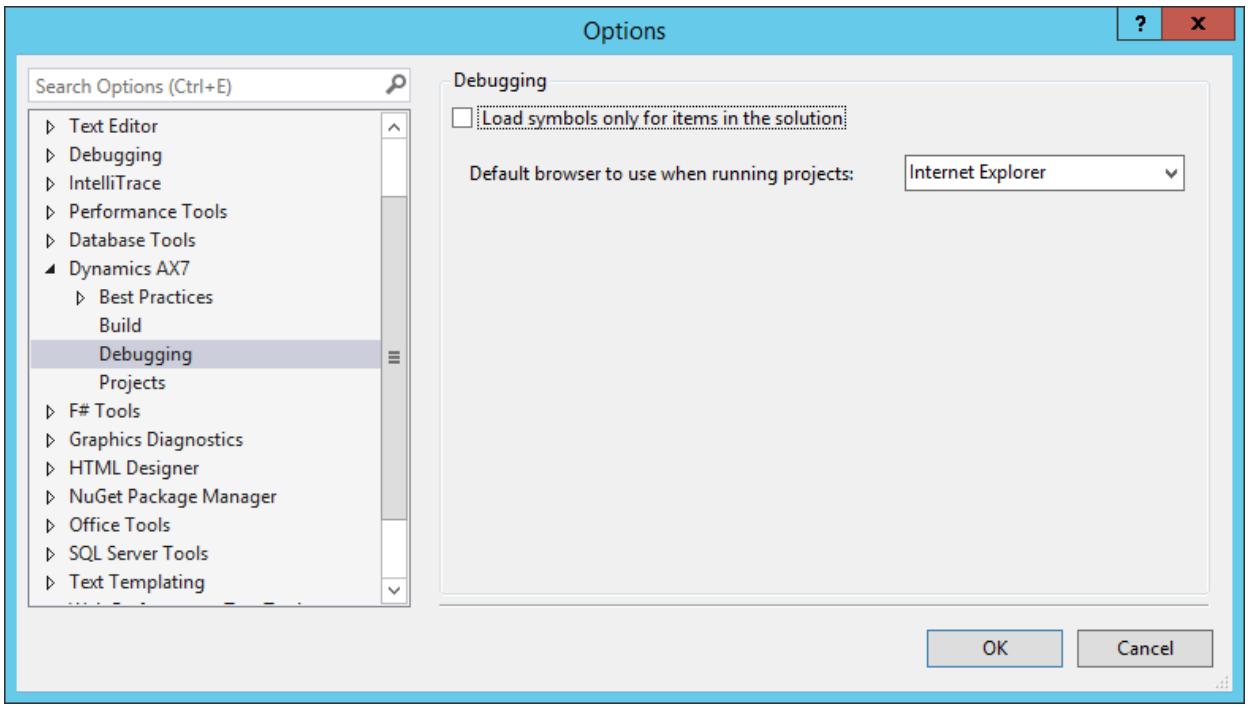
4. Set a breakpoint on that line of code. You do this by clicking in the left margin at that line. A red dot displays when the breakpoint is set.

5. In the CheckDriversLicense method, set another breakpoint at the following line.

```
if (string.IsNullOrEmpty(customer.DriverLicense))
```

Run the test

For this test, we'll be debugging the C# code that we've written. To do this, we need to inform Visual Studio to load the symbols for the assembly that contains the C# code. Go to **Dynamics 365 > Options > Debugging** and verify that the **Load symbols only for items in the solution** check box is not selected.



> **TIP**
> If you're unable to get to the breakpoint in the C# code, you may want to open the **Modules** window (**Debug > Windows > Modules**), find the C# module and load it explicitly.

1. Click **Debug > Start Debugging**. This starts the Fleet application, and a browser window with the **FMRental** form is displayed.

2. Click on any **Vehicle rental ID** to view details.

3. Click the **Edit** icon near the top left of the form. The icon looks like a pencil.

4. In the **To** field of the **Rental** section, increase the date by one day.

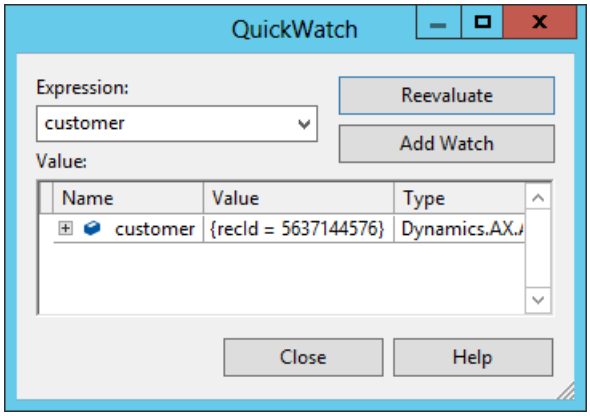
5. Click the **Save** button. This causes the focus to shift to Visual Studio at your highlighted breakpoint. This line shows that the OnValidatedWrite event was raised, and that your handler method was called.

6. Press **F5** to continue the run. Instantly, your other breakpoint becomes highlighted.

7. Find the variable customer a few lines above your breakpoint.

8. Right-click the customer variable, and then click **QuickWatch**. Any long integer value proves that your

LINQ query worked.



9. Press **F5** to complete the **Save** operation.

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Changes in X++ and the X++ compiler

2/18/2021 • 6 minutes to read • Edit Online

This topic reviews the changes made to the compiler for Finance and Operations applications. The X++ compiler has been rewritten. No backward-incompatible changes have been introduced to X++ except where required by structural changes to the product. A few language enhancements have been added. A new X++ best practice tool has also been implemented, which allows the addition of user-defined custom rules.

No more p-code, everything is in .NET Framework CIL

Through Microsoft Dynamics AX 2012, X++ source code was compiled into p-code, which was understood by the interpreter at run time. Optionally, you could then compile the p-code into Microsoft .NET CIL (Common Intermediate Language). CIL is what the .NET compilers for C# and Visual Basic generate. However, X++ CIL code was usable only in limited cases, mainly for code executed in services and batch jobs. The new X++ compiler generates CIL only. There is no more p-code. The following tools that worked with p-code are now obsolete and have been removed from Dynamics AX and replaced by .NET tools:

- The X++ compiler that generated p-code.
- The special compiler that input p-code and generated .NET CIL.
- The run time interpreter of p-code including its deterministic garbage collector.
- The Dynamics AX Debugger.
- The Dynamics AX Code Profiler, which helped find performance bottlenecks.
- The AX .NET Business Connector for external applications that interoperated with Dynamics AX.

There are important benefits to X++ code running exclusively as .NET CIL, including:

- CIL runs much faster in most scenarios. In cases where there are many method calls, and a lot of algorithmic content (as opposed to database access), you can expect significant performance improvements.
  - It's easier to write application logic in other managed languages.
  - There's no longer any need for the AX .NET Business Connector or managed proxies, because the assemblies can be consumed directly.
  - The preferred way of consuming business logic externally is by using services.
- CIL can efficiently reference classes that are available in other .NET assembly DLL files, without the run time reflection-based overhead that burdened the p-code interpreter.
- CIL can be operated on by the many .NET tools.

Unit of compilation

Previous versions of Microsoft Dynamics AX could compile X++ at the level of an individual method. Thus if a compilation of a class found an error in one method of the class, the methods that did compile correctly were still runnable. In the standard compilation unit now is the same as for other .NET languages such as C#. If any method in a model element (class, form, query etc.) fails to compile, the whole compilation fails.

Enhancements to X++

X++ is now a first-class citizen in the .NET world. Therefore we are adding to X++ several constructs that are available in C# and other mainstream .NET languages. The changes are generally non-intrusive. In fact, very few changes have been made to the syntax and semantics of existing X++ code. Most of these additions are in the following list:

- The `finally` keyword is now available to follow the `try` and `catch` keywords. The semantics are identical to the semantics in C#. The statements provided in the finally clause are executed irrespective of whether the try block threw any exceptions.
- The `using` keyword has been added as shorthand for referencing .NET namespaces. The following code example illustrates two ways of utilizing the using keyword to reference namespaces:

```
using SysColl = System.Collections;  // SysColl is an alias for the whole namespace.
using           System.CodeDom;      // Contains the class named CodeComment.

public class MyClass2
{
    static SysColl.ArrayList arrayList = new SysColl.ArrayList(); // Initialized on declaration.
    CodeComment codeComment          = new CodeComment("I am a comment.");

    // More X++ code here.
}
```

- You can now initialize a class's field in the field's declaration statement. This is illustrated twice in the previous code example.
- You can declare variables in smaller scopes, not just at the start of methods.
- The `var` keyword is available as a shortcut that allows the compiler to infer the type of the declared variable.
- A class's fields can now be static. In previous versions, only instance fields were allowed.
- A class can now have one static constructor. In previous versions, only instance constructors were available. The following X++ code example shows the syntax for a static constructor, through the new keyword typenew.

```
public class MyClass4
{
    static utcdatetime utcInitialized3;  // Static variable member.
    static void typenew()                // Static constructor member. 'typenew' is a new keyword.
    {
        utcInitialized3 = DateTimeUtil::utcNow(); // Static variable referenced without class name.
    }
}
```

- An attribute decoration, such as on a class or a method, can now omit the suffix of the attribute name if the suffix is `Attribute`. So the X++ joins the C# in allowing `[MyFavorite]` instead of requiring `[MyFavoriteAttribute]`.
- A delegate can now be defined in a table, form, or query, and not just in a class.
- Attributes are now applied to the handlers of delegates and methods, to map the handlers to those targets.
- Classes can now be nested in X++ source code. Nested classes are available only inside forms (such as a class that extends FormRun) to represent controls, data sources, or data fields.

Backward-incompatible changes to X++

There are a few changes to X++ that require corresponding changes in legacy custom X++ source code. Most of these changes are in the following list:

- The following keywords are no longer part of the X++ language, and their use causes compilation errors:

    - `changeSite`
    - `pause`
    - `window`
- In legacy X++, it was possible to designate a method to run either on the client or the server. This is no longer possible. All compiled X++ code is executed as .NET CIL on the server. There is no longer any X++ code that is evaluated at the client site or in the browser, therefore, the two keywords, *client* and *server*, are now ignored. Their use doesn't cause a compile error, but they should not be used in any new X++ code.
- In Microsoft Dynamics AX 2012, there were a few areas where X++ behaved differently when compiled to p-code versus CIL. In Finance and Operations applications, all these areas behave as they did in CIL in Microsoft Dynamics AX 2012. The significant behavioral differences between X++ p-code versus X++ as CIL were as follows:
    - In CIL, the `real` data type is represented as `System.Decimal`. This means the range and precision for each `real` is different than it was under p-code. This change was already in effect in Microsoft Dynamics AX 2012 when .NET CIL was run.
    - An assignment of one entire array to another was performed in value in p-code mode, but it's performed by reference in CIL mode.
    - CIL helper methods such as `Global::runClassMethodIL` have been removed, since they're no longer relevant.
- There is no concept of a job, in the sense of **AOT** > **Jobs** > **MyJob**. To quickly and easily run an X++ method, you can still add in a `static Main` method to a class, and then set the class as the startup object form for the project in Microsoft Visual Studio. When the project is run, the `Main` method will be run.

Language Integrated Query (LINQ) provider for C#

2/18/2021 • 6 minutes to read • Edit Online

This topic discusses the LINQ provider.

LINQ (Language Integrated Query) is a set of classes and methods that enable you to access data that is stored in a variety of places and formats. The LINQ framework is the standard for accessing data in managed languages. LINQ presents to programmers a unified and consistent API for data access from heterogeneous data sources, such as:

- In-memory object graphs
- Active Directory entries
- Flickr pictures and XML
- SQL Server

The LINQ provider allows the user to access business data by using .NET managed languages.

Two syntactical mechanisms for accessing LINQ

There are two syntactical approaches for using LINQ, as described in the following table.

APPROACH	X++	C# AND VISUAL BASIC
LINQ by standard method call syntax.	Impractical. Language support for generics is vital for LINQ and is not supported in X++.	Available, requires lambda syntax.
LINQ by specialized syntax that is understood by the compiler.	Not available.	Available, easier to use.

There are two syntactic mechanisms for accessing the LINQ provider in C# (or in Visual Basic):

- By standard, or fluent, method call syntax.
- By specialized syntax that the C# compiler has been enhanced to understand as equivalent to the LINQ method calls. (Such syntax is sometimes called "syntactic sugar".)

This topic is going to review each syntactic mechanism for LINQ, starting with the easier specialized syntax.

LINQ by specialized syntax in C#

Some .NET languages understand specialized syntax for LINQ as an alternative that is easier for us to write. C# is one such language.

To use LINQ in C#, you must understand the C# keyword **var**, which is used to declare variables. The var keyword tells the compiler to figure out the data type of the variable by what is assigned to the variable. This feature is now also available in X++. The type is implicit in the source code, and the type is settled and unvarying after the compilation completes.

Comparing X++ to C# LINQ

The X++ language supports the useful and easy to use `while select` statement. This lest you compare the X++ `while select` syntax to the specialized C# LINQ syntax. First, here is the X++ sample.

```
CustTable ct;     // X++, traditional while select.
CustTrans trans;

while select * from ct
    where ct.AccountNum >= '4000'
    join RecId from trans
    where trans.RecId == ct.RecId
    order by ct.AccountNum desc
{
    print ct.AccountNum;
}
```

Next is an equivalent query in C# with the specialized LINQ syntax.

```
// C#, with specialized LINQ syntax.
// Get access to the data provider:
var provider = new QueryProvider(null);

var customers = new QueryCollection(provider);
var customerTransactions = new QueryCollection(provider);

var query = from ct in customers
            from trans in customerTransactions
            where ct.AccountNum >= "4000"
            where trans.AccountNum == ct.AccountNum
            orderby ct.AccountNum descending
            select ct;

foreach (var ct in query)
{
    System.Console.WriteLine(ct.AccountNum);
}
```

LINQ query in C# by method syntax, using the lambda operator >

Next is another use of LINQ in C#, except this time the more standard syntax is used to call the LINQ API. The approach also involves use of the lambda operator `>`. The following C# query is functionally equivalent to the preceding C# query.

```
var query = customers
    .Where(c => string.Compare(c.AccountNum, "4000") >= 0)
    .Join(customers,
        primary => primary.AccountNum,
        foreign => foreign.AccountNum,
        (primary, foreign) => new { P = primary, F = foreign })
    .OrderBy(primaryAndForeign => primaryAndForeign.P.AccountNum)
    .Select(primaryAndForeign => primaryAndForeign.P);
```

There's a good match between the `while select` syntax used in X++ and the specialized LINQ syntax in C# (Visual Basic has particularly good LINQ syntax). It's evident that the specialized LINQ syntax is actually very useful in expressing joins, but the specialized syntax built into the C# compiler doesn't handle the extensions provided by the Finance and Operations applications.

Limitation of the specialized LINQ syntax

A limitation of the specialized LINQ syntax is that it can't be augmented with extensions to the LINQ provider. In contrast, standard syntax of method calls plus the lambda operator can be extended as needed. For instance, the LINQ framework provides a method for cross-company hints that can't be expressed in the special syntax for LINQ in C#. Fortunately, due to the ability to compose queries, this limitation need not be a major problem. Calls

to esoteric LINQ methods can be appended to the specialized LINQ syntax. The following C# code shows this being done for the **crosscompany** method.

```
// C#, mixing LINQ syntax mechanisms.
var query = (from ct in customers
             from trans in customerTransactions
             where ct.AccountNum >= “4000”
             where trans.AccountNum == ct.AccountNum
             orderby ct.AccountNum descending
             select ct).crosscompany();
```

LINQ query execution

The code generated for a LINQ query builds a tree at run time. When the results of the query are required, this tree is passed to the backend that will interpret it, and will provide the data as expressed in the query. The X++ compiler also builds a tree to express the query, but the X++ compiler has intimate knowledge about the capabilities of the database backend. This has several important implications as described in the following subsections.

Inability to diagnose problems at LINQ compile-time

The C# compiler is largely unable to foresee and diagnose errors that will occur at run time due to the inability of the backend to process an incompatible LINQ query. For instance, in the following C# code block, the specialized LINQ syntax is valid according to the C# compiler. Yet at run time, an error would occur.

```
var customerQuery = from c in db.Customers
                    where (from o in db.Orders
                    where o.ShipCountry == “Germany”
                    select o.CustomerID).Contains(c.CustomerID);
```

This query can't be handled by the current data layer, and while no errors are diagnosed at compile time, an error would occur at run time.

Performance penalty with LINQ

There is an overhead penalty paid at run time, when analysis of the tree occurs, and a suitable access language is generated. As we might expect, the performance penalty is incurred when analyzing the LINQ expression tree. The time required at run time to actually fetch the data doesn't vary much between C# and LINQ versus X++ with `while select`. Our preliminary numbers show that the beginning-to-end performance of the query is about three times longer with C# LINQ, compared to X++ `while select`, when very few records are fetched. But when many records are fetched, the total times are about the same between C# and X++. The conclusion is that it takes much longer to fetch a lot of records than it takes to analyze the language tree.

Composing queries with LINQ

The model that's provided by LINQ allows queries to be composed of subqueries. The X++ language can't cleanly provide this feature. To understand this, consider the following C# LINQ code. A flag is passed to a method to control the ordering of data results.

```
private IEnumerable RichCustomers(bool orderByName)
{
    // Create a query for the rich customers. Note carefully
    // that no data is fetched when this is executed.
    var q = from c in customers where c.AmountMst > 1000000.0m select c;

    if (orderByName)
    {
        // Add the order by clause to the existing query.
        // Still no data is yet fetched.
        return q.OrderBy(c => c.AccountNum);
    }
    else
    {
        return q;
    }
}
```

Set based operations with LINQ

LINQ queries can be applied for CRUD operations. But the model for updating, deleting, and inserting records isn't useful for the expression of set based operations. We're now working on extensions to add to the LINQ model that will translate into set based operations.

Write best practice rules

2/18/2021 • 17 minutes to read • Edit Online

This topic describes how you can author best practice rules in C#, for both metadata and X++ code. Best practice checks are run by the compiler. You can run them in daily builds to catch objectionable practices that are unacceptable in shipping code. The features can also be used to author simple one-of tools to gather information about the application.

You can also use best practice rules to author simple tools that gather information about your application. The framework is built on top of a managed framework called XLNT (shorthand for X++ LaNguage Toolkit). You can use the framework to build custom tools that extract information from, and modify, X++ code. There are two types of best practice rules: rules that deal with metadata and rules that deal with source code.

Code Best Practice framework

The Code Best Practice Framework (CBPF) enables you to write your own tools for analyzing X++ source code. These rules diagnose things that you consider to be problems with X++ source code. This section describes the foundation of the Best Practice functionality. This information is helpful for understanding the later sections that describe creating your own rules in greater detail. It is also helpful to developers who want to code rules that are more complex than those demonstrated in this document. The CBPF API lets you focus on the rule you are expressing, without having to deal with infrastructure issues. You don't need to read tokens and piece them together to create something intelligible from them. Instead, the CBPF provides the following parts:

- A parser that builds an Abstract Syntax Tree (AST) from X++ source code.
- A pipeline that runs a sequence of passes over the X++ code.
- A number of prebuilt passes. The first pass is the parsing of the source code.
- Infrastructure to read metadata.

Because rules are based on ASTs, it is important to understand that concept before starting to write rules.

The parser and ASTs

The parser reads X++ code and produces an AST from it if it does not contain egregious syntax errors. The parser has a built-in error recovery scheme, so it can recover from most syntax errors reasonably well. When a syntax error happens, the parser will read symbols until it encounters a semicolon, and then try to building the AST by unstacking its state until it reaches a state where a semicolon is a correct symbol. In addition, the parser is able to suggest the correct set of symbols when a syntax error occurs. The parser is not intended to be directly interacted with by consumers of the API, but should be considered a black box that works without user intervention. As the parser recognizes the language constructs in the source code, it builds an AST. The AST consists of nodes that are abstractions of the X++ artifact they represent. We will illustrate the concept by showing a few AST nodes below:

```
public abstract class Statement : Ast
{
    /// <summary>
    /// Gets or sets the comments in the statement
    /// </summary>
    public string Comments { get; set; }

    public abstract string ToString(int indent);
}
```

The **Statement** class is abstract, because it doesn't make sense to instantiate a "statement". Only concrete derived classes, like **if** and **while** statements, can be instantiated. Since the Comments property is placed on this base class, it applies to all derived classes. In other words, all statements can have comments preceding the statement. The comments are accessible through the given property. There are many different kinds of statement in X++ and each one is described by a class derived in one or more steps from the abstract **Statement** class shown above. The following example shows the definition of a **while** statement.

```
public class WhileStatement : Statement
{
    /// <summary>
    /// Gets or sets the while condition.
    /// </summary>
    public Expression Condition { get; set; }

    /// <summary>
    /// Gets or sets the constituent while statement.
    /// </summary>
    public Statement Statement { get; set; }
}
```

The **while** statement consists of the condition (an expression) and the constituent statement, that is executed as long as the condition evaluates to true. The parser will maintain the source code positions where the represented artifact starts and ends (that is, its extent). As the ASTs are traversed, it may be useful to add information to the individual nodes. For example, every expression has a type. As the tree is traversed to diagnose type compatibility problems it becomes useful to be able to place that information on the individual node. Rather than having to modify the AST nodes for each requirement, there is a property collection that can be used to provide name/value pairs to each node. Each AST node has a **ToString** method that will return a high fidelity string representation of the node, which is useful in debugging scenarios.

The AstSweeper class

The AstSweeper applies a visitor pattern to the AST instance that it is given. The visitor pattern allows the programmer to separate the underlying data structure (that is, the AST) from the operations that the user wants to perform on the nodes (that is, the logic reasoning about the code). The **AstSweeper** class has a virtual method for each of the AST node types, and it will call them as directed by the structure of the AST. The following examples show how the sweeper works. Some details have been omitted for clarity.

```
/// <summary>The AST sweeper visits each node in the AST</summary>
/// <typeparm name="TReturn">The type returned by each of the sweeper methods</typeparm>
/// <typeparm name="TPayload">
/// The type of the payload passed to each of the sweeper methods
/// </typeparm>
public class AstSweeper<TReturn, TPayload> where TReturn : class
{
    protected virtual TReturn VisitStatement(TPayload o, Statement statement)
    {
        var compoundStatement = statement as CompoundStatement;
        if (compoundStatement != null)
        {
            return this.VisitCompoundStatement(o, compoundStatement);
        }

        var whileStatement = statement as WhileStatement;
        if (whileStatement != null)
        {
            return this.VisitWhileStatement(o, whileStatement);
        }
    }

    protected virtual TReturn VisitWhileStatement(TPayload o, WhileStatement statement)
    {
        this.VisitExpression(statement.Condition);
        this.VisitStatement(statement.Statement);

        return null;
    }
}
```

The name of the virtual method handling a particular AST node is the name of the AST class prepended with Visit. The parameters are the node to visit and a payload that may be passed to all the visitors as they are called. In this way, the sweeper will call the virtual method once for each and every one of the nodes in the AST that is passed to it in a depth-first traversal. The payload parameter can be used to pass information (for example, a symbol table) to each node as required. Developers will build classes derived from the AstSweeper class, overriding the methods of particular interest to them.

Example

Suppose you need to determine the percentage of parameter names starting with an underscore character, thus conforming to the X++ coding guidelines. You would then write a class deriving from the **AstSweeper** class with logic that calculated the number of parameters and the number of parameters starting with underscore. The following example shows this code.

```
public class ParameterCounter : AstSweeper<object, object>
{
    /// <summary>
    /// The parameter count maintained as the methods are encountered.
    /// </summary>
    public int ParameterCount { get; set; }

    /// <summary>
    /// The number of parameters that start with an underscore character.
    /// </summary>
    public int UnderscoredParameters { get; set; }

    /// <summary>
    /// Visits the method parameters.
    /// </summary>
    /// <param name="o">The payload. Not used in this scenario.</param>
    /// <param name="parameters">The list of parameters to visit.</param>
    /// <returns>The method parameters.</returns>
    protected override object VisitMethodParameters(object o,
        IEnumerable<ParameterDeclaration> parameters)
    {
        this.ParameterCount += parameters.Count();
        this.UnderscoredParameters += parameters
            .Where(p => p.Name.StartsWith("_")).Count();

        return null;
    }
}
```

In this case, the tally is maintained in the **ParametersCount** and **UnderscoredParameters** properties that are defined in the class scope. Another equally valid approach would be to pass this information into the payload that is passed to all the **Visit** methods. In most cases, the user should unconditionally call **super()** from the overridden method to make sure that the **Visit** methods are called for all nodes below the one being visited. In the case above, it does not make a difference so we opt to improve performance by pruning the AST tree traversal.

Writing code for Best Practice rules

To author a business rule:

1. Define the situation you want to diagnose in terms of properties of the AST. You will write **Visit*** methods that can do the analysis.
2. When the error condition has been found, a diagnostic message must be generated. There is an API that is used for this purpose; basically you need to write some boilerplate code for each diagnostic message.
3. You need to hook your new best practice rule into the rest of the framework, so the user can decide whether or not to include your rule and to run it if so directed.

Create a best practice rules project in Visual Studio

In this walkthrough, we imagine the following scenario:

- Some methods are adorned with an Author attribute that provides the name of the individual who wrote the code. The attribute is useful when finding who to point the finger at when stack traces containing that method appear.
- Since we have a significant turnaround of developers, the names of the developers listed cannot be static. We want to find the names that are used in the Author attributes, and match them against a list of names of current developers.

The author attribute class is defined as:

```
class AuthorAttribute extends SysAttribute
{
    private str theAuthor;

    public void new(str _author)
    {
        this.theAuthor = _author;
    }
}
```

In production code, we would put in documentation comments and assertions to validate key assumptions about parameter values etc. For the sake of clarity, we omit these steps in this walkthrough, where the code is written for clarity. Now that we have set the stage for what we want to achieve, we can start up Visual Studio and create a best practice rules project. Provide a meaningful name that properly conveys what the rules are intended to do: Visual Studio creates a project with some source code snippets and project references set up. You can save considerable time by using this source code as a starting point for your own code. The pre-canned example contains rules that prohibit the word “Microsoft” in any method names (presumably for copyright reasons) and a metadata-based rule prohibiting certain characters in names. Since we are not concerned with the metadata checks for now, you can delete the InvalidCharactersDiagnosticItem.cs and DemoMetadataCheck.cs files from the project. Also, since we are not interested in the Microsoft name check, go ahead and delete the content of the VisitMethod method in the DemoAST class. The first thing we need to do is to find out if there are one or more Author attributes for a particular method. You will notice that the Method type (that is passed as a parameter to the VisitMethod method) has an Attributes property of type AttributeList. Let's use it to see if any Author attributes are defined on this method:

```
protected override object VisitMethod(BestPracticeCheckerPayload payload, Method method)
{
    var names = new List<string>();
    foreach (var attribute in method.Attributes.Attributes)
    {
        if (string.Compare(attribute.Name, "Author",
            ignoreCase: true, culture: CultureInfo.InvariantCulture) == 0)
        {
            var authorNameLiteral = attribute.Parameters.First().Literal as StringAttributeLiteral;
            // The name contains quotes (either single or double). Get rid of those
            var authorName = authorNameLiteral.Value.Trim('\'', '"');
            names.Add(authorName);
        }
    }

    // More to come...
    return null;
}
```

At this point we have looped through any attributes, and collected a list of author names, that is names that are provided as the first parameters to the Author attributes. Now we need to compare the list against a list of acceptable authors, that we maintain in a static list. Whenever an author is provided that is not mentioned in the list we need to issue an appropriate diagnostic message. At this time, we have something like:

```
public class AuthorListRule : BestPracticeAstChecker<BestPracticeCheckerPayload>
{
    private static HashSet<string> authorlist = new HashSet<string>()
    {
        "Alan Kay", "John von Neuman", "C.A.R. Hoare"
    };

    public AuthorListRule() : base()
    {
    }

    protected override object VisitMethod(BestPracticeCheckerPayload payload, Method method)
    {
        var names = new List<string>();
        foreach (var attribute in method.Attributes.Attributes)
        {
            if (string.Compare(attribute.Name, "Author",
                ignoreCase: true, culture: CultureInfo.InvariantCulture) == 0)
            {
                var authorNameLiteral = attribute.Parameters.First().Literal as StringAttributeLiteral;
                // The name contains quotes (either single or double). Get rid of those
                var authorName = authorNameLiteral.Value.Trim('\'', '"');
                names.Add(authorName);
            }
        }

        foreach (var name in names)
        {
            if (!authorlist.Contains(name))
            {
                // TODO: Add a diagnostic message
            }
        }
        return null;
    }
}
```

In other words, we need to create a diagnostic message to let the user know about the transgression of the rule. As noted before, it is important to call the base implementation of your visitor, which will then call visitor methods for all the nodes that are contained in the method. However, in this case, we do not want to do any further processing once we have determined if the author attribute is on the list.

Add a class for the diagnostic message

The project already includes boilerplate code for an error message, so we will use that as our starting point to create the diagnostic message that will be returned if the rule is violated. Each message is implemented as a class of its own. Each error message may have any amount of contextual information encoded into it. In this case, the contextual information is the name of the author that is not found in the list. We will start by adding the message to the messages resource file: Open that file in the project and add a string to it. We will use the name (also known as the error moniker) AuthorNotCurrent. The '{0}' string is a placeholder for the contextual information, in this case the name of the author who is not in the list. In addition to the actual text that will appear in the error message, there is also a string containing a description of the rule. This information is shown in the best practice dialog within Visual Studio and is designed to help the user decide which rules to enable on the system. Create a class for the diagnostic message, and call it **AuthorNotCurrentDiagnosticItem.cs**. Add the following code inspired from the **NotAllowedWordDiagnosticItem** class.

```
namespace CompareAuthorsToList
{
    using System;
    using System.Collections.Generic;
    using System.Runtime.Serialization;
    using System.Xml.Linq;
    using Microsoft.Dynamics.AX.Metadata.XppCompiler;

    [DataContract]
    public class AuthorNotCurrentDiagnosticItem : CustomDiagnosticItem
    {
        private const string AuthorNotCurrentKey = "Author";
        public const string DiagnosticMoniker = "AuthorNotCurrent";

        public AuthorNotCurrentDiagnosticItem(string path, string elementType, TextPosition textPosition,
string author)
            : base(path, elementType, textPosition, DiagnosticType.BestPractices, Severity.Warning,
DiagnosticMoniker, Messages.AuthorNotCurrent, author)
        {
            this.AuthorNotCurrent = author;
        }

        public AuthorNotCurrentDiagnosticItem(Stack<Ast> context, TextPosition textPosition, string author)
            : base(context, textPosition, DiagnosticType.BestPractices, Severity.Warning, DiagnosticMoniker,
Messages.AuthorNotCurrent, author)
        {
            this.AuthorNotCurrent = author;
        }

        // Serialization support
        public AuthorNotCurrentDiagnosticItem(XElement element)
            : base(element)
        {
        }

        [DataMember]
        public string AuthorNotCurrent { get; private set; }

        /// <summary>
        /// Hydrate the diagnostic item from the given XML element.
        /// </summary>
        /// <param name="itemSpecificNode">The XML element containing the diagnostic.</param>
        protected override void ReadItemSpecificFields(System.Xml.Linq.XElement itemSpecificNode)
        {
            this.AuthorNotCurrent = base.ReadCustomField(itemSpecificNode, AuthorNotCurrentKey);
        }

        /// <summary>
        /// Write the state into the given XML element.
        /// </summary>
        /// <param name="itemSpecificNode">The element into which the state is persisted.</param>
        protected override void WriteItemSpecificFields(System.Xml.Linq.XElement itemSpecificNode)
        {
            this.WriteCustomField(itemSpecificNode, AuthorNotCurrentKey, this.AuthorNotCurrent);
        }
    }
}
```

The diagnostic message is ready for consumption. There is just one piece of bookkeeping that needs to be done; the rule needs to publish declaratively which diagnostics it potentially issues. Go back to your rule and modify the BestPracticeRule attribute to reflect the new diagnostic message:

```
[BestPracticeRule(
    AuthorNotCurrentDiagnosticItem.DiagnosticMoniker,
    typeof(Messages),
    AuthorNotCurrentDiagnosticItem.DiagnosticMoniker + "Description",
    BestPracticeCheckerTargets.Class)]
public class AuthorListRule : BestPracticeAstChecker<BestPracticeCheckerPayload>
{ // ... }
```

As you can see, there are four parameters specified for the **BestPracticeRule** attribute:

1. The rule moniker.
2. The type of the resource file holding the rule description. In this example, we are using the default resource file named. Messages, which created a class called Messages. We want the type of this class as the second argument.
3. The name of the string resource that contains the description of the rule. This name is the string called **AuthorNotCurrentDescription** that we added to the resource file above; it contains a human legible string to describe the rule. This string is used to describe the rule to the user in a best practice dialog within Visual Studio. In Visual Studio, select **Dynamics 365 > Best Practices Configuration** to view the dialog.
4. A description of the artifacts to check. In this case, the value specifies that the rule should only be applied to classes. Modify the description as needed by using one of the other literals in the **BestPracticeCheckerTargets** enumeration.

Instantiate the class that describes the diagnostic message and add it to the set of diagnostics:

```
foreach (var name in names)
{
    if (!authorlist.Contains(name))
    {
        // Create the custom error message, including
        // the contextual name information...
        var warning = new AuthorNotCurrentDiagnosticItem(
            this.Context, method.Position, name);

        // and add it to the set of reported messages.
        this.ExtensionContext.AddErrorMessage(warning);
    }
}
```

At this point, you have a complete best practice rule, ready to provide value in your organization. Build it and fix any errors.

Metadata based Best Practice rules

Until now we have been describing how to write rules that deal with code. In this section we show how to author rules that apply to metadata, not code. Classes that deal with metadata rules are derived from **BestPracticeMetadataChecker**. The derived instance receives an instance of the metadata describing the artifact that must be checked. You then use the APIs in the **Microsoft.Dynamics.AX.Metadata.Metamodel** to fetch further metadata as needed, and use LINQ queries over the metadata graphs. The template for best practice checks contains a class performing metadata checks as well as a code based one we discussed in the previous section. The mechanics involved in issuing diagnostic messages is the same as we covered above.

Install, run, and test your rule

When your code compiles cleanly, a DLL will be created. In order for the tooling to be able to pick up the new rule, this DLL must be installed before running it. Installing the DLL can be done in two ways:

- By using the button on the Best Practice configuration dialog. Click the **Install extension** button. You will be asked to point to the assembly file that contains your rule (that is, the DLL generated when you build the rule). Press OK, and the system will copy the DLL where it needs to be (see below).
- By manually installing the DLL into the C:\Packages\bin\BPExtensions folder.

If you want to debug your rule, you will find it useful to copy the .pdb file to the same directory as the assembly. After the DLL has been deployed to the target directory, Visual Studio needs to be restarted. After that, the rule is available for use. You may have to debug your rule to iron out any remaining kinks. In fact, stepping through your rule and inspecting the ASTs is valuable when you are getting started. To debug a rule, you need to know that the best practice rule is run by the **xppAgent** process; it is therefore not run within the context of VS itself. Make sure you have selected **Run best practice checks** in the Visual Studio Options dialog, in the **Finance and Operations** page. Otherwise, your check will not run. Set a breakpoint in the **VisitMethod** method, and then do a build of a model that has the new rule switched on as shown above for the Fleet management model. Attach your VS instance to the **xppcAgent** process. When you do a build your breakpoint will be hit, and you can start drilling into your code. You can see all the properties, the list of declarations and statements, and find out all the details about them.

Running rules in XppBp.exe

As described above the best practice rules are often run as part of the build of a project from Visual Studio, but there is also a dedicated command-line tool to run them. This tools is the **xppbp.exe** tool, and it is intended mainly for nightly build scenarios. Invoking it from the command line yields a useful overview of the command-line switches and arguments. Here are some useful examples:

- Run BP on all forms in a module: `xppbp -module:FleetManagement form:*`
- Run BP on specific elements: `xppbp -module:FleetManagement class:MyClass form:MyForm`
- Run BP on all items in the model (and only for this one model in the module): `xppbp -module:FleetManagement -model:FleetManagement –all`
- Run BP on all items in all models in the module: `xppbp -module:FleetManagement –all`
- Write the output to log files: `xppbp -module:FleetManagement -all -xmllog=Log.xml -log=Log.txt`

Application Explorer properties

2/18/2021 • 114 minutes to read • Edit Online

This topic describes the properties that appear in the Properties window of Microsoft Visual Studio for items in Application Explorer.

Many nodes in Application Explorer represent elements that have properties associated with them. You can read or modify these properties in the **Properties** window of Microsoft Visual Studio.

System and common properties

Most application objects in Application Explorer have a standard set of system properties. These system properties are read-only. You can use the **Properties** window to view the properties for any item in Application Explorer. To open the **Properties** window, right-click a node in Application Explorer, and then click **Properties**. On the **Categories** tab of the **Properties** window, many system properties are listed under the **Statistics** node. This article lists additional common properties that are repeated on many, but not all, Application Explorer nodes. The following table shows the system properties that are found on almost all Application Explorer nodes. All these system properties are read-only.

PROPERTY	DESCRIPTION
ChangedBy	The user who last changed the object (often the release version).
ChangedDate	The date when the object was last changed.
ChangedTime	The time when the object was last changed.
CreatedBy	The user who created the object.
CreationDate	The date when the object was created.
CreationTime	The time when the object was created.

The following table shows other common properties that are found on many, but not all, Application Explorer nodes.

PROPERTY	DESCRIPTION
ConfigurationKey	Specify the configuration key that controls access to or display of an element. If a user doesn't have access to the configuration key, the element isn't visible. Elements include pages, controls on pages, tables, and other elements.
LegacyID	An identifier element from an earlier version. During upgrade from a previous version, the old identifier is assigned to **LegacyID**. An installation-specific identifier isn't assigned, and business logic remains intact. This property isn't used for new elements.

PROPERTY	DESCRIPTION
NeededAccessLevel	The minimum access level that a user requires. This property is read-only.
Origin	The globally unique identifier (GUID) of an Application Explorer element. This property is used to identify elements during synchronization and in upgrade scenarios. It's a read-only property, and the value never changes after the system assigns it. No origin GUID value is duplicated anywhere in the system.
SecurityKey	This property is obsolete but is retained for reference in systems that were upgraded from an earlier version.

Base enum properties

The following table describes the properties that are available for enumerations.

PROPERTY	DESCRIPTION
AnalysisUsage	Specify the role of the enumeration in a cube. This setting is automatically propagated to all table fields that reference the enumeration. However, you can override the setting on a table field. The following options are available: • **Attribute** – A field that references the enumeration is a dimension attribute. • **None** – A field that references the enumeration isn't a dimension attribute.
ConfigurationKey	Specify the configuration key.
CountryRegionCodes	Specify the codes for the countries/regions where the view is applicable or valid. This property is implemented as a comma-separated list of International Organization for Standardization (ISO) country/region codes in a single string. The values must match data in the global address book. The client framework and application might use this property to enable or disable country/region-specific features.
DisplayLength	Specify the number of characters that are shown. The default value is **Auto**.
Help	Create a Help string for the field. The Help string is shown when the field is used on a page.
Label	Specify the label that is shown on pages and reports.
Model	Specify the model that the table is in. A model is a logical grouping of elements in a layer. Examples of elements include a table and a class. An element can exist in exactly one model in a layer. The same element can exist in a customized version in a model that is in a higher layer.

PROPERTY	DESCRIPTION
Name	Specify the enumeration name. An enumeration name must indicate either the possible enumeration values or the type of the enumeration value. Examples of enumerations that are named according to the possible values are **InclExcl** and **NextPrevious**. Examples of enumerations that are named according to the type of the enumeration value are **ArrivalPostingType** and **ListStatus**.
Style	Change the default appearance of the enumeration. The following options are available: • Combo box • Radio button
UseEnumValue	A value of **Yes** indicates that default values of the **EnumValue** property were modified. A value of **No** resets the **EnumValue** property to the default values.

Extended data type properties

Extended data type (EDT) properties are divided into the following groups, based on whether they are common to all EDTs or available only for certain base data types.

Properties that are common to all EDTs

PROPERTY	DESCRIPTION
Alignment	Change the alignment of the text. The available options are **Left**, **Right**, and **Center**.
AnalysisDefaultSort	Specify the default sort order for a field in a report model that has this EDT.
AnalysisDefaultTotal	Specify the aggregate function for a measure. Use this property when the **AnalysisUsage** property is set to **Measure**. The following options are available: • **Sum** – Return the sum of all the values in a set. • **Count** – Return the number of non-null items in a set. • **CountDistinct** – Return the number of distinct non-null items in a set. • **Min** – Return the minimum value in a set. • **Max** – Return the maximum value in a set. • **None** – No aggregate function is applied. • **Auto** – This option applies to derived EDTs. The value of the **AnalysisUsage** property for the parent EDT is used. You can override the aggregate function at the field level. In other words, you can change the aggregate function for the field by using the **AnalysisDefaultTotal** property for that field.

PROPERTY	DESCRIPTION
AnalysisGrouping	Specify whether a field that has this EDT is grouped by default when the field is added to a report by using Report Builder for Microsoft SQL Server Reporting Services (SSRS). This property is automatically set to **Discouraged** for currency amounts. For other fields that are unique, you should set this property to **Discouraged**.
AnalysisUsage	Specify the role of the EDT in a cube. This setting is automatically propagated to all table fields that reference the EDT. However, you can override the setting on a table field. The following options are available: • **Attribute** – A field that references the EDT is a dimension attribute. • **Measure** – A field that references the EDT is a measure. • **Both** – A field that references the EDT is both a dimension attribute and a measure. • **None** – A field that references the EDT is neither a dimension attribute nor a measure. • **Auto** – This option applies to derived EDTs. The value of the **AnalysisUsage** property for the parent EDT is used. **Note:** Data types that are based on enumerations can't be measures.
ArrayLength	This property is a read-only. The default value is **1**. To add array elements to the EDT, right-click the **Array Element** node, and then click **New Array Element**. The value of the **ArrayLength** property is increased to reflect this change.
ButtonImage	Specify the image that is shown when the EDT is used for a lookup button on a page. The following options are available: • **Arrow** • **Mail** – You can select this option for the **e-mail** type, for example. • **URL** – You can select this option for the **URL** type, for example. • **ThreeDots** (...) • **OpenFile** – You can select this option for the **FilenameOpen** and **FilenameSave** types, for example. • **Calendar** – You can select this option for date types, for example. The default value is **Arrow**.
CollectionLabel	Specify the label that is used to show the plural name of a field that has this EDT.
ConfigurationKey	Specify the configuration key for the EDT.

PROPERTY	DESCRIPTION
CountryRegionCodes	Specify the codes for the countries/regions where the menu is applicable or valid. This property is implemented as a comma-separated list of ISO country codes in a single string. The values must match data in the global address book. The client uses this property to enable or disable country/region-specific features.
DisplayLength	Specify the maximum number of characters that are shown on a page or report.
EnumType	Specify an enumerated data type. This property must be set for EDTs of the **enum** type.
Extends	Use this property to base the EDT on another EDT.
FormHelp	Specify the page to use when you perform a lookup from a field on a page.
HelpText	Create a Help string for the EDT. The Help string is shown when the type is used on a page.
ID	This property is read-only.
Label	Specify the label that is used for the type when the type is used on a page or report.
Model	Specify the model that the table is in. A model is a logical grouping of elements in a layer. Examples of elements include a table and a class. An element can exist in exactly one model in a layer. The same element can exist in a customized version in a model that is in a higher layer.
Name	Specify the name of the type. The name is used to refer to the type from X++.
PresenceClass	Specify the X++ class that is used together with the **PresenceMethod** property to return an instance of the **PresenceInfo** object.
PresenceIndicatorAllowed	Specify whether the control that references the EDT should use presence. The default value is **Yes**.
PresenceMethod	For the X++ class that is specified in the **PresenceClass** property, specify the X++ static class method that should be called by using a controls data value. This method returns an instance of the **PresenceInfo** object that contains the data that the Presence indicator requires.
ReferenceTable	Specify the table that is referenced by this EDT, and that has the primary key. In other words, this property indicates the primary key table that this EDT references.

PROPERTY	DESCRIPTION
Style	Change the default appearance of the EDT. The following options are available: • Auto • Combo box • Radio button

Properties that are available for only some base data types

Unless the following table specifies otherwise, you should leave all these properties set to **Auto**.

PROPERTY	TYPE THAT THE PROPERTY EXISTS FOR	DESCRIPTION
Adjustment	String	For strings of fixed length, specify whether the characters that are entered should be stored on the left side or the right side of the padding spaces. The available options are **Left** and **Right**. The default value is **Left**.
AllowNegative	IntegerInt64Real	Specify whether the field can accept negative values.
AutoInsSeparator	Real	Specify whether the system should automatically insert a decimal separator. For example, if you enter **2222**, the system automatically shows **2222.00**.
ChangeCase	String	Specify how text that is entered in a string control should be formatted. For example, the text can be formatted as all uppercase letters, or it can use title capitalization. **Note:** This property isn't supported for Enterprise Portal.
DateDay	DateUtcDateTime	Specify how the day should be shown.
DateFormat	DateUtcDateTime	Specify the layout of a date.
DateMonth	DateUtcDateTime	Specify how the month should be shown.
DateSeparator	DateUtcDateTime	Specify the separators between year, month, and day.
DateYear	DateUtcDateTime	Specify how the year should be shown.
DecimalSeparator	Real	Specify the decimal separator. When the default setting (**Auto**) is used, the decimal separator that is specified in the system setup is used.
DisplaceNegative	IntegerInt64Real	Specify whether to align negative numbers to the left.

PROPERTY	TYPE THAT THE PROPERTY EXISTS FOR	DESCRIPTION
DisplayHeight	String	Specify the number of lines to show at the same time when the EDT is shown on a page.
EnumType	Enum	Specify the base enum that is used to create the EDT.
FormatMST	Real	Specify master currency values should be formatted. The following options are available: • Auto • Yes • No The default value is **Auto**.
NoOfDecimals	Real	Specify the number of decimal places when a value is shown on a page or a report.
RotateSign	IntegerInt64Real	Select this option to reverse the sign for the number. In other words, change a minus sign (–) to a plus sign (+) or a plus sign to a minus sign.
ShowZero	IntegerInt64Real	Specify whether to show a field that has a value of 0 (zero) as an empty field. If a value of 0 in fields of this type means null/nothing, set this property to **No**.
SignDisplay	IntegerInt64Real	Specify whether to show the sign of a negative number, and also whether the sign should appear before or after the number. Typically, you should set this property to **Auto**. However, you can set it to **None** if the **DisplaceNegative** property is used.
StringSize	String	Specify the maximum size of the string.
ThousandSeparator	Real	Specify the symbol that is used to separate thousands.
TimeFormat	TimeUtcDateTime	Specify how times should be formatted.
TimeHours	TimeUtcDateTime	Specify whether to include hours.
TimeMinute	TimeUtcDateTime	Specify whether to include minutes.
TimeSeconds	TimeUtcDateTime	Specify whether to include seconds.
TimeSeparator	TimeUtcDateTime	Specify the separator that is used for times.

PROPERTY	TYPE THAT THE PROPERTY EXISTS FOR	DESCRIPTION
TimezonePreference	UtcDateTime	Specify the time zone to convert the value to from Coordinated Universal Time (UTC).

Perspective properties

In Application Explorer, under the **Data Dictionary** node, there is a **Perspectives** node. A perspective is a collection of tables and views that contain the measures and dimensions for a cube. The following table describes the properties that can be set for each perspective. For information about the system properties that are available for a perspective, see the "System and common properties" section. For information about the properties for tables that are associated with a perspective, see the "Table properties" and "Table field properties" sections.

PROPERTY	DESCRIPTION
ConfigurationKey	Specify the configuration key that is assigned to the perspective. The configuration key determines which configurations of a perspective are included for in report models that are generated.
HelpText	Create a string to use as a description for the perspective in a report model.
ID	Specify the identifier of the perspective.
Label	Specify the name that is shown for the perspective in a report model.
Model	Specify the model that the perspective is in. A model is a logical grouping of elements in a layer. An element can exist in exactly one model in a layer. The same element can exist in a customized version in a model that is in a higher layer.
SharedDimensionContainer	Specify whether to share items in the perspective. When this property is set to **Yes**, the items in the perspective are added to all other perspectives that are in the project, and no cube is created for the perspective. The default value is **No**.
Usage	Specify the materialization options for a perspective. The following options are available: • **AdHocReporting** – The perspective will be used to generate a transactional Semantic Model Definition Language (SMDL) model. • **OLAP** – The perspective will be used to generate a cube in a Microsoft SQL Server Analysis Services (SSAS) Business Intelligence project. • **Both** – The perspective will be used to generate both a transactional SDML model and a cube in an SSAS Business Intelligence project. • **None** – The perspective won't be materialized. The default value is **None**.

Table properties

This section describes the properties that appear in the **Properties** window for table elements in Application Explorer. Table elements are located under **Data Dictionary** > **Tables**.

Table properties

The following table describes the properties of table elements in Application Explorer.

PROPERTY	DESCRIPTION
Abstract	Specify whether the table supports inheritance. The default value is **No**. If the value is set to **Yes**, the table can't be a direct target of X++ SQL statements such as **update_recordset** and **select**. **Note:** This property is unavailable when the **SupportInheritance** property is set to **No**.
AnalysisDimensionType	Specify the type of dimension that is created, based on the setting of the **IsLookup** property. If the **IsLookup** property is set to **Yes**, the following options are available: • **Auto** – The table can contain both factual and dimensional data. The BI Wizard will extract dimensional data, and create dimensions and attributes. Factual data will be extracted to create measures. One child dimension is created that has attributes from the parent table. • **MasterInner** – An inner (full) join is used to create relationships with this table to the child table. Each record combination for this table and the child table are generated in the dimension. One child dimension is created that has attributes from the parent table. • **MasterLeftOuter** – A left outer join is used to create relationships with this table to the child table. Dimensions will have additional attributes, based on values in this table that can also be empty. One child dimension is created that has attributes from the parent table. • **Transaction** – The table should be used to generate only factual data (measures). You should use this option when a table contains only transactional data. One child dimension is created that contains only enumeration fields from the table. If the **IsLookup** property is set to **No**, the following options are available: • **Auto** – Table can contain both factual and dimensional data. The BI Wizard will extract dimensional data, and create dimensions and attributes, Factual data will be extracted to create measures. One parent and child dimension are created. • **MasterInner** – Not applicable. This option is the same as **Auto**. • **MasterLeftOuter** – Not applicable. This option is the same as **Auto**. • **Transaction** – The table should be used to generate only factual data (measures). You should use this option when a table contains only transactional data. One child dimension is created that contains only enumeration values from the table.

PROPERTY	DESCRIPTION
AnalysisIdentifier	Specify the field to use as the identifier for the dimension in an SSAS cube.
AOSAuthorization	Specify the type of operation that a user can perform on a table, depending on the user's permissions. When this property is set to **None**, no authorization check is performed.
CacheLookup	Specify how to cache the records that are retrieved during a lookup operation. This property exists only on tables that don't inherit from another table. On an inheritance root table, you can' set this property to **EntireTable** by using the Application Explorer **Properties** window. You must not use other techniques to assign this value to inheritance root tables. For example, don't use the **AOTsetProperty** method of the **TreeNode** class to assign this value.
ClusterIndex	Specify the cluster index. This property is used only for SQL optimization.
ConfigurationKey	Specify the configuration key for the table. Configuration keys let a system administrator enable and disable specific parts of an application.
CountryRegionCodes	Specify the codes for the countries/regions where the table is applicable or valid. This property is implemented as a comma-separated list of ISO country codes in a single string. The values must match data in the global address book. The client framework uses this property to enable or disable country/region-specific features.
CountryRegionContextField	Specify the field that is used to identify the country/region context. This property is related to the **CountryRegionCodes** property.
CreatedBy	Specify whether the system maintains the **CreatedBy** field for the records in a table. This field contains information about the person who created a record.
CreatedDateTime	Specify whether the system maintains the **CreationDate** and **CreationTime** fields for the records in a table. This field contains the date when a record was created.
CreatedTransactionId	Specify whether the system maintains the **CreatedTransactionId** field for the records in a table. This field contains information about the transaction that created a record.
CreateRecIdIndex	Specify whether an index on the **Record ID** field is created.
DeveloperDocumentation	Describe the purpose of a table, and explain how it's used in the program. Typically, a description contains no more than five sentences and is written as a single paragraph.

PROPERTY	DESCRIPTION
EntityRelationshipType	Classify a table according to common entity relationship (ER) data model notation. A table is classified as either an entity or a relationship. An entity represents an object, whereas a relationship represents an association between two objects.
Extends	Derive the table from the specified table. The value of this property is **null** when the **SupportInheritance** property is set to **Yes**.
FormRef	Specify the display menu item that is activated when a table is referenced. A display menu item is associated with a page. When you use a primary index field on a report, this page is available as a link in the report. You specify a primary index by using the **PrimaryIndex** property. If you leave this property blank, the system tries to display a page that has the same name as the table.
ID	The system-generated table ID.
IsLookup	For report models, use this property to specify whether the table information is incorporated into other tables that reference it when a report model is generated. For online analytical processing (OLAP) cubes, use this property to specify whether to generate a consolidated dimension or a distinct dimension. The following options are available: • **Yes** – Attributes from the table should be consolidated into the parent dimension (star schema). • **No** – A separate dimension should be generated for the table (snowflake schema).
Label	Specify the label for a table.
ListPageRef	Specify a display menu item that points to a page that can show a list of this record type.
Model	Specify the model that the table is in. A model is a logical grouping of elements in a layer. Examples of elements include a table and a class. An element can exist in exactly one model in a layer. The same element can exist in a customized version in a model that is in a higher layer.
ModifiedBy	Specify whether the system maintains the **ModifiedBy** field for the records in a table. This field contains information about the person who last modified a record.
ModifiedDateTime	Specify whether the system maintains the **ModifiedDate** field for the records in a table. This field contains the date when a record was last modified.
ModifiedTime	Specify whether the system maintains the **ModifiedDateTime** field for the records in a table. This field contains the date and time when a record was last modified.
Name	Specify the table name.

PROPERTY	DESCRIPTION
OccEnabled	Specify whether the optimistic concurrency mode is enabled for a table. When this mode is enabled, data isn't locked from future modification when it's fetched from the database. Data is locked only when the actual update is performed.
PreviewPartRef	Specify the info part or form part to use in the enhanced preview. An info part shows a collection of data fields from a specified query. It uses metadata to describe how the data appears. A form part represents a pointer to a page.
PrimaryIndex	Specify the primary index. Only a unique index can be selected. This property is used for database optimization and to indicate which unique index should be used as the caching key. If you don't specify a primary index, the unique index that has the lowest ID is used as the caching key.
ReplacementKey	Specify the fields to display as the identifier for data in some page controls.
ReportRef	Specify the output menu item that is activated when a table is referenced. An output menu item is associated with a report. When you use a primary index field on a report, this report is available as a link in the report. You specify a primary index by using the **PrimaryIndex** property.
SaveDataPerCompany	Specify whether the data for the current company is saved. If you set the property to **No**, data is saved without a company identifier (DataAreaId). **Note:** If the **SaveDataPerCompany** property on a table is set to **Yes**, the **SetCompany** property on a page design that uses the table as a data source must also be set to **Yes**. **Tip:** The status line shows the acronym for the company. Double-click the acronym to open a dialog box where you can change the company.
SaveDataPerPartition	A value that indicates whether the table has a system field that is named **Partition**. This property is intended to be read-only. If the table has a **Partition** field, each record is assigned to one partition. Each record is hidden from data access operations that are run under the context of other partitions.
SearchLinkRefName	Specify the name of the menu item that links to information on a website about a table record that is listed in the Enterprise Portal search results. If the **SearchLinkRefType** property is set to **URL**, select a menu item that links to a Web Part page that shows the table data. Forms and reports on Web Part pages can display data.
SearchLinkRefType	Specify the type of the menu item that links to information on a website about a table record that is listed in the Enterprise Portal search results.
SingularLabel	Specify the label that is used in a report model or a cube to show the singular name of items that are stored in the table.

PROPERTY	DESCRIPTION
SupportInheritance	When you set this property to **Yes**, you can set a value for other inheritance-related properties, such as **Extends** and **Abstract**. **Caution:** If you set this property to **Yes**, any fields on the table are dropped and must be created again.
SystemTable	Indicate whether a table appears as a system table. A table that appears as a system table can be filtered during export and import. System tables are always synchronized when you sign in. Therefore, this property might be useful for tables that you use as soon as you sign in.
TableContents	Specify how setup/parameter data can be reused from one customer to another. The following options are available: • **Not specified** – Use this option for most tables. • **Default Data** – Use this option for customer-independent data, such as postal codes, units, and time intervals. • **Base Data** – Use this option for customer-dependent data, such as calendars, groups, and parameters. • **Default+Base data** – Use this option for data where the local perception varies. For example, Chart of Accounts is customer-independent in Germany but is customer dependent in most other places.
TableGroup	Specify the group that the table belongs to. Table groups provide a method for categorizing tables according to the type of data that they contain. You can use table groups to define whether the system should prompt users when they update or delete data from the table on pages by using the table as the data source. When you export data, you can use table groups to filter records.
TableType	This property replaces the **Temporary** property that is found in Microsoft Dynamics AX 2009.
TitleField1, TitleField2	You can use this property in the following ways: • Add table field data to a form caption. • Show additional fields on a lookup page. The **TitleField1** property is also used when you activate the lookup list in a field on a page. The fields that you specify for the **TitleField1** and **TitleField2** properties can be merged with the key value. • Show field information in a tooltip.
TypicalRowCount	Specify the number of records that typically appear in a table. If the **AnalysisSelection** property isn't set, this property determines how records are selected by using Report Builder for SSRS. The setting of this property affects whether a drop-down list, a list box, or a filtered list box is used to select table records.
ValidTimeStateFieldType	Specify the type of date-time field that the system uses when it tracks data within time spans.

PROPERTY	DESCRIPTION
Visible	Specify the access rights when the table is used as a data source on a page or a report. If the table is used as a data source on a page, the access rights on the page can't exceed the access rights that are defined for the table.

Tables and report models

The following properties are related to report models that are used to add information to a report:

- AnalysisSelection
- AnalysisVisibility
- IsLookup
- SingularLabel
- TypicalRowCount

Table field properties

The following properties are related to report models that are used to add information to a report:

- AnalysisDefaultTotal
- AnalysisLabel
- AnalysisTotaling
- AnalysisUsage
- AnalysisVisibility
- CurrencyCode
- CurrencyCodeField
- CurrencyCodeTable

PROPERTY	DESCRIPTION
Adjustment	Specify whether the string field should be left-aligned or right-aligned when it's stored in the database. For example, if the 11-character string "hello world" is stored in a right-aligned field that has a **StringSize** setting of **40**, 29 space characters are stored as the prefix. **Note:** The **Adjustment** setting affects the search results when you search for a value in a table by using the >, <, >=, and <= relational operators. It doesn't affect the search results when you use the == operator. The **Adjustment** setting is ignored when the **StringSize** property is set to **(Memo)**.
AliasFor	Specify the table field that the field is an alias for.
AllowEdit	Specify whether users are allowed to modify data in an existing record on a page.
AllowEditOnCreate	Specify whether users are allowed to enter data in the field when a new record is created from a page.

PROPERTY	DESCRIPTION
AnalysisDefaultTotal	For report models, use this property to specify how field data is aggregated when an automatic total for the table is displayed in a report that is built by using SSRS and report models. The default value is **No**, which indicates that the field isn't automatically shown as a total. For OLAP cubes, use this property to specify the aggregate function for a measure. Use this property when the **AnalysisUsage** property is set to **Measure**. The following options are available: • **Sum** – Return the sum of all the values in a set. • **Count** – Return the number of non-null items in a set. • **CountDistinct** – Return the number of distinct non-null items in a set. • **Min** – Return the minimum value in a set. • **Max** – Return the maximum value in a set. • **None** – No aggregate function is applied. • **Auto** – This option applies to derived EDTs. The value of the **AnalysisUsage** property for the parent EDT is used.
AnalysisLabel	Specify the label to use as the caption in an SSAS cube for the table field. The label is applied to either a dimension attribute or a measure. This property is intended for situations where one of the following conditions is true: • The **Label** property isn't defined. • The **Label** property doesn't work as a caption for a dimension attribute or a measure in a SSAS cube.
AnalysisUsage	Specify the role of the field in a cube. The following options are available • **Attribute** – The field is a dimension attribute. • **Measure** – The field is a measure. • **Both** – The field is both a dimension attribute and a measure. • **None** – The field is neither a dimension attribute nor a measure. • **Auto** – The value of the **AnalysisUsage** property for the EDT or enumeration that the field is based on should be used.
ConfigurationKey	Set the configuration key for the field.
CountryRegionCodes	Specify the codes for the countries/regions where the table field is applicable or valid. This property is implemented as a comma-separated list of ISO country codes in a single string. The values must match data in the global address book. The client framework and application might use this property to enable or disable country/region-specific features.
CountryRegionContextField	Specify the field that is used to identify the country/region context. See the description of the **CountryRegionCodes** property.

PROPERTY	DESCRIPTION
ExtendedDataType	Specify the EDT to use for this field.
GroupPrompt	Specify a label that is used for the field when it appears in a group. **Tip:** You can use this property to help guarantee that a field label doesn't repeat text that appears in the label for a field group. For example, if a field group on a page is labeled **Customer**, don't include this text in the **GroupPrompt** property for fields that are included in the field group.
HelpText	Specify the Help string for the field. The Help string is shown when the field is used on a page.
ID	The system-generated field ID.
IgnoreEDTRelation	This property is used during the migration of EDT relations. When you migrate relations from an EDT node to a table node, you can skip an invalid relation for a given table field. To skip invalid relations, set this property to **Yes**. The default value is **No**.
Label	Specify a label for the field. This label will appear on pages and reports. Also see the description of the **AnalysisLabel** property earlier in this table.
Mandatory	Specify whether a user must add data to a field on a page. Set this property to **Yes** to indicate that the default or initialization value for each data type isn't acceptable for persistence into the database. The following list shows some default values that can't be used for mandatory fields on a page: • Empty isn't acceptable for a str (string) field. • The minimum date-time isn't acceptable for date-time fields such as date and utcdatetime. • A value of 0 (zero) isn't acceptable for numeric fields such as int, real, and enum. Finance and Operations doesn't support the semantics for the **null** value that is standard in most SQL database products. Field can't be nulled in the database. Therefore, the **Mandatory** property has nothing to do with the concept of a **null** value. **Caution:** A mandatory table field can have its **EnumType** property set to an enumeration. You might define a field as an enum type that includes an item that has the integer value **0**. In this case, **0** isn't an item that's available for selection on the page. The forms system automatically calls the **validateWrite** method to enforce the setting of the **Mandatory** property. However, the **Mandatory** property has no effect on the behavior of direct X++ SQL that inserts or updates the value of a table field. In your direct X++ SQL, you can include calls to the **validateWrite** method on your table buffer variable. Your buffer variable inherits the method from the **xRecord** class.

PROPERTY	DESCRIPTION
MinReadAccess	Specify the mode of the automatic authorization feature. Automatic authorization has two modes of operation: surrogate foreign key and lookup. If a table in a query is tagged for surrogate foreign key authorization, and the user doesn't have access to that table but hasn't been explicitly denied, view access is granted to the table. However, not all fields will be visible. The visibility is determined by the following rules: • If **MinReadAccess** is set to **No**, no access is granted to the field. • If **MinReadAccess** is set to **Yes**, view access is granted to the field. • Otherwise, view access is granted if the field is part of the natural key automatic identification group, if it's a title field, or if it's a system field. If a table in a query is tagged for lookup authorization, access is determined by the following rules: • If **MinReadAccess** is set to **No**, no access is granted to the field. • Otherwise, view access is granted to the field.
Model	Specify the model that the table field is in. A model is a logical grouping of elements in a layer. Examples of elements include a table or class. An element can exist in exactly one model in a layer. The same element can exist in a customized version in a model that is in a higher layer.
Name	Specify the name of the field.
RelationContext	Specify the mapping of a field to a specific table relation. Typically, this property is used in unit-of-measure scenarios to model data that is related to currency codes or quantities. The relation that is associated with the field can then be used to show a lookup of currency codes or quantities. There is no default value.
SaveContents	Specify whether the field data is saved in the database or treated as virtual field data. Virtual field data is calculated at run time when the field is displayed. This data has no physical representation in the database. **Tip:** Instead of virtual fields, you can use display and edit methods.
StringSize	Set the field length, in the number of characters. The maximum field length depends on the database. A value of **(Memo)** indicates that the field length is unlimited.
Type	Specify the base type of a field.
Visible	Specify whether the field should be visible in the user interface.

Table index properties

The following table describes the properties that are available for indexes on tables.

PROPERTY	DESCRIPTION
AllowDuplicates	If you set this property to **Yes**, the index can be non-unique. If you don't create at least one unique index, a unique index is created by combining the first index and the RecId.
AlternateKey	Specify whether this index is part of an alternate key. The index field must have a unique value in every record.
ConfigurationKey	Set the configuration key. An index field that is disabled through a configuration key is automatically removed from the index.
Enabled	You can use this property to disable the index.
ID	The internal identifier of the object.
Model	Specify the model that the table index is in. A model is a logical grouping of elements in a layer. Examples of elements include a table or class. An element can exist in exactly one model in a layer. The same element can exist in a customized version in a model that is in a higher layer.
Name	Specify the index name.
UniqueAcrossCompanies	This property is for internal Microsoft use only. The available values are **Yes** and **No**. The default value is **No**. The value of this property is ignored when the **AllowDuplicates** property is set to **No**. However, when **AllowDuplicates** is set to **Yes**, a value of **Yes** for **UniqueAcrossCompanies** can improve the performance of some cross-company queries. The performance improvement is caused by changes to the caching of data.
ValidTimeStateKey	Specify whether this index key is used to determine the valid time state relationship with the parent table. The default value is **No**. **Tip:** To enable this property, you must set the **AllowDuplicates** property to **No** and the **AlternateKey** property to **Yes**.
ValidTimeStateMode	Specify whether gaps are allowed between two date-effective records. The default value is **NoGap**. **Tip:** To enable this property, you must set the **AllowDuplicates** property to **No**, the **AlternateKey** property to **Yes**, and the **ValidTimeStateKey** property to **Yes**.

NOTE

Pages sort on the first index.

Table relation properties

List of properties

The following table describes the properties for a table relation in Application Explorer.

PROPERTY	DESCRIPTION
Cardinality	The number of times that each primary key value from the referenced table must occur in the foreign key column of the current table. For example, the **OneMore** value means one or more, but not zero. This value indicates that every parent key value must occur in the child table's foreign key column at least one time. A relation node under a SalesLine table might use the **OneMore** value when the business rule requires that every record in the parent SalesTable table relate to at least one item that is being sold. Currently, the **Cardinality** property is not used. However, future releases might use this property and the **RelatedTableCardinality** property.
CreateNavigationPropertyMethods	A value of **Yes** instructs the system to generate navigation methods on the table buffer class for each foreign key relation node.
EDTRelation	If the value is set to **Yes**, a software tool was used to migrate this relation to its current location from an old EDT relation.
EntityRelationshipRole	This property is used to clarify the semantics of a relationship that is defined on a table. A role name should be either a noun or a noun phrase. The role name should indicate the role of the associated table in relation to the associating object. Alternatively, the role name should be a short phrase that starts with a present-tense verb that indicates the role that the table plays in the relationship. Role names aren't required when the relationship is unambiguous.
Model	The model that this relation is part of.
Name	A descriptive name that you choose for the relation.
NavigationPropertyMethodNameOverride	Specify the name of the navigation method. If no value is specified, the navigation method uses the value from the **RelatedTableRole** property.
RelatedTableCardinality	Specify whether the foreign key field value in the current table can be **null** in some or all records of the current table. The following options are available: • **ZeroOne** means zero or one. This value indicates that the foreign key field in a child record can be **null**. • **ExactlyOne** indicates that the foreign key field can't be **null** in any child record.

PROPERTY	DESCRIPTION
RelatedTableRole	Enter a text value to describe the purpose of the referenced parent table in this relationship. When a table has only one relation that references a given parent table, you can use the name of the parent table. Sometimes, a table has more than one relation to a given referenced parent table. this case, the value of the **RelatedTableRole** property should describe the relation well enough to distinguish the relation's purpose from the other relation to the same parent table. The value of this property can be used as the value of the **JoinRelation** property of a data source relation under an Application Explorer query. In standard cases, this usage is recommended, because it reduces denormalization. This property interacts with the **UseDefaultRoleNames** property.
RelationshipType	Select a value that describes the subtle relationship between two tables. For example, the **Composition** value indicates that the child record can't meaningfully exist unless it's related to a specific parent record. The record for the fourth floor in the Floor table can't exist unless it references a record in the parent Building table. **Note:** The DeleteActions should be compatible with this property setting. For a Composition relationship, the DeleteActions should include delete cascade behavior. Currently, the **RelationshipType** property is not used. However, a future release might use this property.
Role	Specify a name that describes the meaning or role of the relation. For example, one relation to a Department table could track the department that the employee currently belongs to. Another relation could track the department that the employee has requested a transfer to. Although both these relations are relations to the Department table, they fill different roles. As the value of this property, it's a good idea to join the names of the child table and parent table by using an underscore (_) character. For example, enter **SalesTable_SalesLine**. This property interacts with the **UseDefaultRoleNames** property.
Table	The table that the relation refers to.
UseDefaultRoleNames	A value of **Yes** indicates that the system must generate default values for the **Role** and **RelatedTableRole** properties. Even when this property is set to **Yes**, the values for that are generated for **Role** and **RelatedTableRole** don't appear in the **Properties** window. Additionally, the **TreeNode** class doesn't use the generate values. However, the **DictRelation** reflection class does use the generated values.

PROPERTY	DESCRIPTION
Validate	A value of **Yes** indicates that when a page inserts a record into the child table, the insertion is rejected unless the related record exists in the referenced parent table. Additionally, when a page deletes a record from the parent table, the deletion is either rejected or cascades to the related records in the child table. Set the value to **No** when the **RelationshipType** property is set to **Link**. You might also set the value to **No** in special temporary cases, such as during some upgrade scenarios. When the value is set back to **Yes**, no validation occurs for records that were inserted or deleted while the value was **No**. **Caution:** A value of **Yes** for the **Validate** property doesn't prevent direct X++ SQL data operations from deleting parent records or inserting child records that violate the integrity of foreign key data.

> **NOTE**
>
> When the **SaveDataPerCompany** property is set to **Yes** for both tables, the system adds the **DataAreaId** field to each relationship.

RelatedTableRole and query JoinRelation

This section describes how you can use the **RelatedTableRole** property to simplify the creation of a new query. If you enter an explicit value for the **RelatedTableRole** property on a table relation, you can use that value to populate the **JoinRelation** property on a data source relation under a **Queries** > **MyQuery** node in Application Explorer. You can use this method to specify the fields of the join in one location. If the join fields ever change, you must update the join in only one location. Before you can set a value for the **JoinRelation** property, you must delete the values of the **Field** and **RelatedField** properties.

CreateNavigationPropertyMethods and RelatedTableRole

When you set the **CreateNavigationPropertyMethods** property to **Yes** on a table relation, the system generates navigation methods for the table buffer class. A navigation method links two table buffer instances by using their foreign key relationship. The **UnitOfWork** class is one area where this navigation linkage is used. The name of a navigation method is copied from the value of the **RelatedTableRole** property on the table relation. This behavior is used when the **RelatedTableRole** value is explicitly set in the **Properties** window, and when the system generates the **RelatedTableRole** value because the **UseDefaultRoleNames** property is set to **Yes**. The property values generate the following navigation method on the child CustTable buffer. Most directly, the navigation method name is copied from the value of the **RelatedTableRole** property.

```
public final CustBankAccount BankAccounts([CustBankAccount relatedTable])
```

NavigationPropertyMethodNameOverride property

The following list describes cases where you must override the name that the system generates for a navigation method on a table buffer class:

- The table class already has a method name that matches the values of the **RelatedTableRole** property.
- The value of the **RelatedTableRole** property exceeds the maximum length that can be used for a method name.

In these cases, you must choose a valid name for the navigation method and assign that name as the value of the **NavigationPropertyMethodNameOverride** property on the table relation.

Understanding the RelationshipType enumeration

When you add a node under table relations, you can set the value of the **RelationshipType** property for the new relation. The list of possible values for the **RelationshipType** property is the list of elements in the **RelationshipType** enumeration. This section describes the meaning of each element in the **RelationshipType** enumeration.

Description of elements

The following table describes the elements of the **RelationshipType** property.

ELEMENT NAME	DESCRIPTION	AUTOMATIC INFERENCE
NotSpecified	This element is often the default value of the **RelationshipType** property.	When the **RelationshipType** property has a value of **NotSpecified**, the system infers an appropriate value. The system infers the value in the following sequence: 1. Specialization 2. Link 3. Composition 4. Aggregation 5. Association For example, if the criteria for both Composition and Aggregation are met, the system infers Composition, because Composition occurs earlier in the list.
Specialization	This element applies only to table inheritance, to relationships between base and derived tables.	The system sets the **RelationshipType** property to **Specialization** whenever table inheritance is involved.
Link	This element is a non-relational relationship. It requires that the **Validate** property be set to **No**. This type of relationship supports navigation between pages that list many records from a table and pages that provide detail fields for one record from the table.	Link is used only to support the migration of EDT link relations during upgrade from earlier versions. Migration tools create this type relationship, but you must not.
Composition	This element is a stronger type of Aggregation relation. A table must not have more than one Composition relation. For example, a building is composed of rooms, and a given room can't exist in more than one building.	If the criteria for Composition are met, but you manually assign a value of **Aggregation** or **Association**, the system leaves the value as **Aggregation** or **Association**.

ELEMENT NAME	DESCRIPTION	AUTOMATIC INFERENCE
Aggregation	This element is appropriate when the child table is considered subordinate to the entity of the parent table.	The system infers Aggregation when one of the following conditions is true: • The parent table has a delete action node that is defined to use this relation node. • Any foreign key field for this relation in the child table has the **Mandatory** property set to **Yes**. If the criteria for Aggregation are met, but you manually assign a value of **Association**, the system leaves the value as **Association**.
Association	This element is the concept of a standard foreign key.	You must set the **RelationshipType** property to **Association** if the system doesn't set the value of the property to anything, and if both Aggregation and Composition are inappropriate.

View properties

The properties for views are the same as the properties for tables. However, because views are read-only, most of their properties can't be changed. Some of these properties have fixed values, and some are inherited from the data sources that are used in the query that defines the view. The following properties for views are related to data analysis when you're using SSRS. All these properties can be changed.

- AnalysisVisibility
- AnalysisSelection
- TypicalRowCount
- IsLookup
- SingularLabel

The following table describes the properties that can be set for a view.

PROPERTY	DESCRIPTION
AOSAuthorization	Use this property to specify which data access operations require verification of user permissions.
CacheLookup	The record cache level for the table.
ClusterIndex	The cluster index of the table, if there is a cluster index.
ConfigurationKey	Set the configuration key for the view.
CountryRegionCodes	Specify the codes for the countries/regions where the menu is applicable or valid. This property is implemented as a comma-separated list of ISO country codes in a single string. The values must match data in the global address book. The client uses this property to enable or disable country/region-specific features.

PROPERTY	DESCRIPTION
CountryRegionContextField	Specify the field that is used to identify the country/region context. See the description of the **CountryRegionCodes** property.
DeveloperDocumentation	Describe the purpose of a view, and explain how it's used in the program. Typically, a description contains no more than five sentences and is written as a single paragraph.
EntityRelationshipType	Classify a view according to common entity relationship (ER) data model notation. A view is classified as either an entity or a relationship. An entity represents an object, whereas a relationship represents an association between two objects.
FormRef	Specify the default page for the view. The default page is the page that is shown when the user activates Jump to Main Table by using the shortcut menu for a field on a page. The page is referenced through a menu item of the **Display** type. If you leave this property blank, MorphX tries to activate a page that has the same name as the table that you're referring to.
ID	The internal identifier of the object.
Label	Specify a user-friendly name for the view.
ListPageRef	Specify a display menu item that points to a page that can show a list of this record type.
Model	Specify the model that the view is in. A model is a logical grouping of elements in a layer. An element can exist in exactly one model in a layer. The same element can exist in a customized version in a model that is in a higher layer.
Name	Specify the name of the view. This name is used when you refer to the view from the X++ language.
PreviewPartRef	Specify the info part or form part to use in the enhanced preview. An info part shows a collection of data fields from a specified query. It uses metadata to describe how the data appears. A form part represents a pointer to a page.
PrimaryIndex	Specify the primary index of the view. Only a unique index can be selected. This property is used for database optimization and to indicate which unique index should be used as the caching key. If you don't specify a primary index, the unique index that has the lowest ID is used as the caching key.
Query	Specify the query that is the source of data for the view. You can use this property instead of adding data sources directly to the view.
ReportRef	The name of the default report for the table.

PROPERTY	DESCRIPTION
SaveDataPerCompany	Set this property to **Yes** for company-specific tables. Set it to **No** if the data is related to cross-companies, installation, a database, Application Explorer, tracing, or OLAP. For example, the SysTraceTable or OLAPServerTable table specifies whether data should be saved for that table on a per-company basis, or whether the data should be available without any company affiliation. If the **SaveDataPerCompany** property on a table is set to **Yes**, that table has a **DataAreaId** column that contains the company identifier. If the table property is set to **No**, the **DataAreaId** column is removed from the table.
SaveDataPerPartition	A value that indicates whether the view has a system field that is named **Partition**. This property is intended to be read-only. If the view has a **Partition** field, each record is assigned to one partition. Each record is hidden from data access operations that are run under the context of other partitions.
SearchLinkRefName	The name of the menu item that links to information on a website about a table record that is listed in the Enterprise Portal search results.
SearchLinkRefType	The type of the menu item that links to information on a website about a table record that is listed in the Enterprise Portal search results.
SystemTable	A value that indicates whether a table is a system table. System tables can be filtered during export and import, and are always synchronized when you sign in. Therefore, this property might be useful for tables that you use as soon as you sign in.
TableContents	Specify how setup/parameter data can be reused from one customer to another. The following options are available: • **Not specified** – Use this option for most tables. • **Default Data** – Use this option for customer-independent data, such as postal codes, units, and time intervals. • **Base Data** – Use this option for customer-dependent data, such as calendars, groups, and parameters. • **Default+Base data** – Use this option for data where the local perception varies. For example, Chart of Accounts is customer-independent in Germany but is customer dependent in most other places.
TableGroup	Specify the group that the view belongs to. Table groups categorize tables and views according to the type of data that they contain. Views can belong to the same table groups as a table.

PROPERTY	DESCRIPTION
TitleField1, TitleField2	The information that is shown in the window caption for the view. The caption is constructed from the following elements: • The **TitleField1** label, followed by colon (:) and a space • The value of the current record in the column that is used for **TitleField1**, followed by a comma (,) • The value of the current record in the column that is used for **TitleField2**
ValidTimeStateEnabled	Specify whether the view supports the valid time state feature of the underlying table. The default value is **No**. You can set this property to **Yes** only if both the following conditions are true: • The underlying table is a valid time state table. • The view has **ValidFrom** and **ValidTo** in its **Fields** list.
Visible	Specify the access rights when the table is used as a data source on a page or a report. If the table is used as a data source on a page, the access rights on the page can't exceed the access rights that are defined for the table.

Data set properties

This section contains descriptions of the properties on data set elements in Application Explorer. The **Data Sets** node is a high-level node in Application Explorer. Data sets are used to access data in Enterprise Portal.

Description of properties

The following table describes the properties that are available on data set nodes in Application Explorer.

PROPERTY	DESCRIPTION
Name	Set the name of the data set.

Data Sources properties

The following table describes the properties for the **Data Sources** node of the data set.

PROPERTY	DESCRIPTION
ChangeGroupMode	Specify how changes to the data sources are committed. The following options are available: • **None** – The changes to any data source for the data set are committed independently of changes to the other data sources. • **ImplicitInnerOuter** – All the data sources that are inner-joined or outer-joined work as a single unit. All changes are committed successfully, or they are rolled back if an error occurs.

Data set data source properties

The following table describes the properties that are available for data set data sources.

PROPERTY	DESCRIPTION
AllowCheck	Specify whether security checks occur before the data set is accessed. The following options are available: • **Yes** – The user's read permissions are verified before the data set is accessed. • **No** – The user's read permissions are verified only after the data set is accessed. No data is retrieved if the user lacks sufficient permission for the underlying data sources. **Yes** is the default value and is usually recommended.
AllowCreate	Specify whether users can create new records in the data source (that is, in the table for the data source).
AllowDelete	Specify whether users can delete records in the data source (that is, in the table for the data source).
AllowEdit	Specify whether users can modify the data. **Tip:** You can set the **AllowEdit** property for the whole data source here. The same property also exists on each field in the data source, so that you can prohibit modifications for individual fields.
AutoNotify	This property isn't used for data sets.
AutoQuery	This property isn't used for data sets.
AutoSearch	This property isn't used for data sets.
CounterField	Specify one of the fields in the data source as a counter for the data set. The field must be an index on the underlying table for the data source, and it must be of the **real** type. This property helps guarantee that a record that is inserted in a data set has a line number that corresponds to the actual sequential position in the data. For example, if a new line is inserted between lines 3 and 4, the new line becomes line number 3.5.
CrossCompanyAutoQuery	Specify whether the data source retrieves data from more than one company database.
DelayActive	Use this property to delay execution of the active method for the data source. If you set this property to **Yes**, the active method is activated only after a delay of 20 milliseconds. When a user scrolls through a data source, the active method isn't called on every record. Instead. it's called only on the final record that the user selects. **Tip:** The **DelayActive** property is particularly useful when two data sources are linked (that is, when the **LinkType** property is set to **Delayed**). This property is part of the AutoJoin system.

PROPERTY	DESCRIPTION
Index	Set the index that is used to specify a sorting order. You can choose any of the indexes on the table. If you specify an index in this manner, it's used as an index hint on each query to the database. The index specifies both an access path and a sort order for the records in the data set, based on this data source. The initial sort order for the records is prioritized in this manner: 1. If sort fields are added to the data source query, the sort specification is used. 2. If an index is specified in the **Index** property on the data source, the sort order that is implicitly specified in that index is used. 3. If the data source is autojoined with another data source, the system finds the most appropriate index for this join and then sorts the data according to that index. 4. If nothing else is specified, the sort order that is implicitly specified in the first index (the index that has the lowest ID) on the table that is used in the page data source is used. When no index hints are specified, the database management system locates an applicable access path. This access path is based on the information in the query that is supplied. The user can change the sort order for a page by using the query dialog box.
InsertAtEnd	Specify whether a new record is created when the user moves focus past the last record in the table.
InsertIfEmpty	Specify whether a blank record is inserted if there are no records in the table. If you set this property to **No**, you must manually create a new record.
JoinSource	Use this property to join two data sources. Set this property when two or more tables are used as the data source, and you want to join them.
LinkType	Use this property to maintain an active link between two data sources. When focus changes in the first data source, the corresponding record or records in the second data source are selected. For example, a customer table and a table of transactions is used for each customer. When the user scroll from one customer to the next, the transaction list is automatically updated to show transactions for the current customer. Set this property to **Delayed** for the outer (externally linked) data source. The linked data source is updated only after a delay of 100 milliseconds. This delay helps guarantee that the linked data source isn't updated while the user is scrolling through a data source. The update occurs only after the user finally focuses on a record. This property is part of the AutoJoin system.
Name	Set the name of the data source. This name should be the same as the name of the underlying table.

PROPERTY	DESCRIPTION
OnlyFetchActive	Specify whether to fetch all fields in the data source or only those fields that are used by the data set. When this property is set to **Yes**, records can't be deleted from the data set. This restriction helps preserve data integrity, because it helps guarantee that a delete operation is never tried on incomplete records.
OptionalRecordMode	Specify the create and delete behavior for records on an outer-joined table. The following options are available: • **ImplicitCreate** – When no record is saved in the database, create an outer-joined record and joined tables as soon as the parent record becomes active. If the outer-joined record or its children aren't changed, they will be deleted when the parent record is no longer active. • **ExplicitCreate** – When no record is saved in the database, treat this record as disabled until the user explicitly triggers creation by using the **Optional Record** check box. When the record exists, clearing the check box will delete this record. • **None** – No special create or delete behavior occurs for an outer-joined record.
StartPosition	Specify whether the first record or the last record should be the current record when the data set is accessed.
Table	Set the table that is used as the data source.
ValidTimeStateAutoQuery	Specify the types of queries for date effectivity (**AsOfDate** or **DateRange**).
ValidTimeStateUpdate	Specify the types of updates for an existing date-effective record. The following options are available: • **CreateNewTimePeriod** – On the record that is becoming the previous record, the **ValidTo** date field is set to a date that is no later than the current date. In the same transaction, the new current record has its **ValidFrom** field set to immediately after **ValidTo** date of the previous record. • **Correction** – The **ValidFrom** or **ValidTo** value of existing rows must be modified to keep the date-effective data valid after the record set is updated. • **EffectiveBased** – Records in the past can't be edited. Records that are currently active are edited in a manner that resembles CreateNewTimePeriod mode. Future records are edited in a manner that resembles Correction mode. The default value is **CreateNewTimePeriod**.

Form properties

This section describes the properties that you set on forms in Application Explorer. To provide a uniform application interface, many properties have **Auto** values. You can create forms by using a drag-and-drop operation and then manually setting several properties. To specify the name of a form, you set the **Name** property in the **Properties** window for the form. All other properties on the top-level node for the form are

system properties and are read-only.

Form design properties

Most properties on the **Design** node for a form also exist on the individual controls. Examples include the **Width** and **Height** properties. However, when you set a property on the **Design** node instead of setting it on a control, the setting affects the whole form. A few properties exist only on the **Design** node. The following table describes these properties.

PROPERTY	DESCRIPTION
AlignChild	Specify whether a control within a group follows the **AlignChildren** property setting for the group or for the overall form design. For example, **AlignChildren** is set to **Yes** on the **Design** node for the form, but you don't want a particular group to be arranged together with the other groups. In this case, set **AlignChild** to **No** for that group.
AlignChildren	Align the child controls within a container.
AllowDocking	Specify whether a form can be attached to the client workspace. The default value is **No**.
AllowFormCompanyChange	Specify whether the form supports company changes when it's used as a child form with a cross-company dynamic-link library (DLL). The default value is **No**.
AllowUserSetUp	Specify whether a user can move controls on a form and can change the value of control properties. This property is also found on the design of a form. The following options are available: • **No** – Users can't customize any controls in this container. • **Restricted** – Users can change properties of individual controls, but they can't move controls. • **Yes** – There are no restrictions on the user setup. The default value is **Yes**. **Caution:** Full user setup isn't allowed if any of the parent containers for the control have restrictions on the user setup level. The **AllowAdd** property on form data sources determines whether a user can add a field to a form.
AlwaysOnTop	Specify whether the form always appears on top of other windows in the z-order. The default value is **No**.
ArrangeMethod	Specify whether to arrange child field groups in columns or in rows.
ArrangeWhen	Specify when the controls in the container should be arranged. The following options are available: • Startup • On demand • Never • Default • Auto The default value is **Startup**.

PROPERTY	DESCRIPTION
BackgroundColor	Specify the color that is used for the background of the control. To make the background opaque or transparent, use the **BackStyle** property.
BottomMargin	Set the bottom margin of the form in pixels. The default value is **Auto**.
Caption	Specify the heading for grouped controls. Use a label for this property.
ColorScheme	Specify the color palette for the control. To change the color palette for the whole form, set the **ColorScheme** property for the largest container, and keep the default values for the individual controls.
Columns	Specify the number of columns that show the information. **Caution:** Field groups on the underlying table are never split into more than one column.
ColumnSpace	Set the amount of space between columns in container controls.
DataSource	Specify the table that data in the control comes from. To set a particular field within the table, use the **DataField** property. If the control opens another form, relations between the data source for the control, as specified by this property, and the data source on the other form help guarantee that records in the second form are dynamically selected. For example, a customer is selected in one form, and the control opens a form that shows customer transactions. In this case, the second form shows a range of customer transactions that apply to the current customer. **Caution:** If you set the **DataSource** and **DataField** properties, their settings override any settings for the **DataMethod** or **ExtendedDataType** properties.
Font	Change the font properties for the control by using the **Font** dialog box. Use the dialog font to specify the font, font style, and font size.
Frame	Specify the frame style that the form uses.
Height	Specify the height of the form or control in pixels.
HideIfEmpty	Use this property to hide a container control if it's empty. This property has no affect if the **Width** and **Height** properties of the container are set to **Auto**, because the size of the control is 0 (zero) in this case.
HideToolBar	Hide form-specific buttons on the toolbar.

PROPERTY	DESCRIPTION
ImageMode	Define how the bitmap that is specified by the **ImageName** property appears in a control. The following options are available: • Normal • Size to fit • Side by side • Center The default value is **Normal**.
ImageName	Specify the image that is shown for a control. You can select only .bmp files. To use one of the resource files, use the **ImageResource** property instead.
ImageResource	Use one of the images from the image resource file as the image for a control. Specify the ID of the image. You can select only an image from the integrated resource file. To use another file type, use the **ImageName** property.
LabelFont	Change the font for the text that is supplied in the **Label** property.
Left	Change the position of the upper-left corner of the form. There are several predefined settings. You can also specify an exact position in pixels. The following predefined settings are available: • Auto (left) • Auto (right) • Left edge • Right edge • Center The default value is **Auto (left)**.
LeftMargin	Change the default left margin of the form. The margin is specified in pixels.
MaximizeBox	Specify whether to include the maximize box in the upper-right corner of the enclosing window. The default value is **Yes**.
MinimizeBox	Specify whether to include the minimize box in the upper-right corner of the enclosing window. The default value is **Yes**.
Mode	Specify the data entry mode for the form.
Model	Specify the model that the form is in. A model is a logical grouping of elements in a layer. An element can exist in exactly one model in a layer. The same element can exist in a customized version in a model that is in a higher layer.
RightMargin	Change the default right margin of the form. The margin is specified in pixels.
SaveSize	Set this property to **Yes** to save the size of the form.

PROPERTY	DESCRIPTION
ScrollBars	Specify whether scroll bars are enabled in the form.
SetCompany	Cause the system to change the company when the form receives focus. **Note:** If the **SaveDataPerCompany** property on a table is set to **Yes**, the **SetCompany** property on a form design that uses the table as a data source must also be set to **Yes**.
StatusBarStyle	Specify how the status bar appears in a form. Use this property to hide the status bar, show only Help information, show status bar elements according to the **WindowType** setting, or always show the full status bar. **Note:** Forms that have a WindowType setting of **ListPage**, **ContentPage**, or **Workspace** ignore this property.
Style	Specify the style of the form. This property controls the form design pattern that is used for the form. The following options are available: • Auto • DetailsFormMaster • DetailsFormTransaction • Dialog • DropDialog • FormPart • ListPage • Lookup • SimpleList • SimpleListDetails • TableOfContents The default value is **Auto**.
TitleDataSource	Specify the data source to use in the form caption.
Top	Change the position of the top of the form. There are several predefined settings. You can also specify an exact position in pixels. The following predefined settings are available: • Auto • Top edge • Bottom edge • Center The default value is **Auto**.
TopMargin	Set the top margin of the form in pixels. The default value is **Auto**.
UseCaptionFromMenuItem	Specify whether to replace the form caption with the label from the calling menu item. This property enables the caption of the form to be changed when the form is opened. The default value is **No**.

PROPERTY	DESCRIPTION
ViewEditMode	Specify whether the form opens in read-only mode or as a form that allows you to change fields. The following options are available: • **View** – Open the form as read-only. • **Edit** – Open the form in edit mode. • **Auto** – Open the form in the appropriate mode. The default value is **Auto**.
Visible	Use this property to hide the form. **Caution:** You can't use the **Visible** property to enforce access restrictions. The user can change the visibility for the controls in the **Form Setup** dialog box. To enforce access restrictions, use the **Enabled** and **NeededAccessLevel** properties instead.
Width	Change the width of the form in pixels.
WindowResize	Specify whether the form can be resized.
WindowType	Specify the type of window.
WorkflowDataSource	Set the root data source for the workflow on a form. The root data source that you specify should be the same root data source that is specified in the query that used for the **Document** property on the workflow template.
WorkflowEnabled	Set this property to **Yes** to enable the workflow menu bar on the form. The default value is **No**.
WorkflowType	Specify the workflow type, which determines the following items and behaviors: • The workflow document to use. The workflow document exposes calculated fields and identifies the query that exposes data fields for the workflow. • Whether the user can configure tasks and approvals. • The workflow categories to use when a workflow type is assigned to a specific module. • Menu items and event handlers.

Help document set properties

A document set is a collection of Help documentation that is associated with a workspace. When you publish a content element, you use metadata to add your content element or table of contents information to a document set. To manage the relationship between a workspace and a document set, Application Explorer includes a node that is named **Help Document Sets**. Each document set in the **Help Document Sets** node includes a collection of properties. You edit these properties when you add a new document set or change the relationship between a document set and a workspace. **Caution:** A workspace can be associated with only one document set. Although Application Explorer lets you add a new document set and associate it with a workspace, you will no longer see documentation from the document set that you replaced. Typically, you use **UserDocumentation** as the document set for any content element or table of contents entries that you publish to the Help server. The following table describes the properties for a document set in the **Help Document Sets** node of Application Explorer.

PROPERTY	TYPE	DESCRIPTION
DocumentSetName	String	A name that uniquely identifies the document set. The name is limited to 40 characters and must not contain whitespace. Use the value of this property when you set the value of the **DocumentSets** metadata element in a content element or table of contents file.
DocumentSetDescription	String	The text or label to display for the document set. This value appears in the **Search content from** list of the **Options** menu of the Help viewer.
AddToApplicationHelpMenu	Boolean	Set this property to **Yes** if you want the document set to appear on the **Help** menu of the application workspace.
AddToDeveloperHelpMenu	Boolean	Set this property to **Yes** if you want the document set to appear on the **Help** menu of the developer workspace.
UserDocumentSet	Boolean	Set this property to **Yes** to associate the document set with the application workspace. If you set this property to **No**, you can't view the context-sensitive (F1) Help that was published by Microsoft.
DeveloperDocumentSet	Boolean	Set this property to **Yes** to associate the document set with the development workspace. If you set this property to **No**, you can't view the context-sensitive (F1) Help that was published by Microsoft.
ContentLocation	Enumeration	An enumeration value that specifies where to retrieve documentation. The following table describes the enumeration.

VALUE	LABEL	DESCRIPTION

PROPERTY	TYPE	DESCRIPTION		
		VALUE	LABEL	DESCRIPTION
		1	Help server	The documentation is stored on the Help server. This option is used together with the **UserDocumentation** document set and any document set that files have been published for on the Help server.
		2	World Wide Web	The documentation is stored on MSDN or a similar website. This option is required for the **DeveloperDocumentation** documentation set and should not be used with any other document set.

Menu properties

The following table describes the properties that are available for menus under the **Menus** node in Application Explorer.

PROPERTY	DESCRIPTION
ConfigurationKey	Set the configuration key for the menu.

PROPERTY	DESCRIPTION
CountryRegionCodes	Specify the codes for the countries/regions where the menu is applicable or valid. This property is implemented as a comma-separated list of ISO country codes in a single string. The values must match data in the global address book. The client uses this property to enable or disable country/region-specific features.
DisabledImage	Specify the button image that is used when the menu is disabled. If this property isn't set, the system uses the setting of the **NormalImage** property to generate an image.
DisabledImageLocation	Specify the location of the image that is used for a disabled control. You can use images from a file, the **Resources** node in Application Explorer, or an embedded resource. The value that you select for this property determines the values that are available for the **DisabledImage** property. If the property isn't set, the system uses the setting of the **ImageLocation** property to generate an image.
ImageLocation	Specify the location of the image that is used. You can use images from a file, the **Resources** node in Application Explorer, or an embedded resource. The value that you select for this property determines the values that are available for the **NormalImage** property.
Label	Set the name of the menu that is shown to the user.
MenuItemName	Specify the menu item to include on the menu. The values that are available depend on the value of the **MenuItemType** property.
MenuItemType	Specify the type of the menu item. There are three categories of menu items: • Display • Output • Action The value that you set for this property determines the list of menu item names that appears in the list for the **MenuItemName** property.
Model	Specify the model that the menu is in. A model is a logical grouping of elements in a layer. Examples of elements include a table or class. An element can be located in exactly one model in a layer. The same element can be located in a customized version in a model that is in a higher layer.
NormalImage	Specify the image that is used when the menu is enabled.
Parameters	Specify one or more values that are passed to an object. These values resemble the parameters that are passed to a method. A parameter supplies a value that is then used to perform the task. There is no default value.

PROPERTY	DESCRIPTION
SetCompany	If you set this property to **Yes**, every time that the menu is opened, the company is changed to the company that was specified when the menu was first started.
Shortcut	Specify the keyboard shortcut that opens the menu. For example, you can press Ctrl+F3 to open the menu. There is no default value.
ShowParentModule	Specify whether to update the navigation pane, based on the parent module of the menu item. The following options are available: • **Yes** – Always update the navigation pane, based on the parent module of the menu item. • **No** – Leave the navigation pane unchanged, even if the parent module of the menu item differs from the current module. The default value is **Yes**.

Menu item properties

The following properties are available for all menu items (display, output, and action), even menu items that are used for web menus.

PROPERTY	DESCRIPTION
ConfigurationKey	Select the configuration key that is required in order to enable the menu item. Use the key for the module that the object belongs to.
CopyCallerQuery	Specify whether to copy the query from the calling form to the target form. This property enables the target form to show the same data that was viewed in the original form. The default value is **Auto**.
CorrectPermissions	Specify whether correct permission should be available for selection when privileges are assigned to the menu item. The following options are available: • **Auto** – The permission will be available for selection as a privilege on this menu item's **Privileges** node under the **Entry Points** node. • **No** – The permission won't be available for selection as a privilege on the menu item. The default value is **Auto**.
CountryConfigurationKey	Optional: Set a country/region-specific key in addition to or instead of a standard configuration key.
CountryRegionCodes	Specify the codes for the countries/regions where the menu item is valid. This property is implemented as a comma-separated list of ISO country codes in a single string. The values must match data in the global address book. The client uses this property to enable or disable country/region-specific features.

PROPERTY	DESCRIPTION
CreatePermissions	Specify whether create permission should be available for selection when privileges are assigned to the menu item. The following options are available: • **Auto** – The permission will be available for selection as a privilege on this menu item's **Privileges** node under the **Entry Points** node. • **No** – The permission won't be available for selection as a privilege on the menu item. The default value is **Auto**.
DeletePermissions	Specify whether delete permission should be available for selection when privileges are assigned to the menu item. The following options are available: • **Auto** – The permission will be available for selection as a privilege on this menu item's **Privileges** node under the **Entry Points** node. • **No** – The permission won't be available for selection as a privilege on the menu item. The default value is **Auto**.
DisabledImage	Specify the image that is used when the menu item is disabled. If this property isn't set, the system uses the setting of the **NormalImage** property to generate an image.
DisabledImageLocation	Specify the location of the image that is used for a disabled control. You can use images from a file, the **Resources** node in Application Explorer, or an embedded resource. The value that you select for this property determines the values that are available for the **DisabledImage** property. If the property isn't set, the system uses the setting of the **ImageLocation** property to generate an image.
EnumTypeParameter and EnumParameter	Optional: Select an enumerated type as a parameter for the object, and then select an enumeration value as the value of the **EnumParameter** property. Typically, these properties are used when one form is used in several situations. You can change the behavior of the form, depending on the **EnumParameter** value. For example, the **PriceDiscGroup** form is used by three display menu items (**PriceDiscGroup_***), each of which has a different **EnumParameter** value. In the form's **init** method, a switch construct validates the value, and then the form is created.
ExtendedDataSecurity	Specify whether the menu item appears under all companies instead of in the context of a single company. The default value is **No**.
FormViewOption	Specify the form mode to use. The following options are available: • Auto • Grid • Details The default value is **Auto**.

PROPERTY	DESCRIPTION
HelpText	Create a Help string for the menu item. The text appears on the status bar when you select the object that is opened by the menu item (for example, a form). **Note:** To write a Help topic for the menu item, in Application Explorer, in the **Application Documentation/Menu Items** node, find the topic that has the same name as your menu item. This topic will then be shown instead of any Help topic that was written about the object that is opened by the menu item.
ImageLocation	Specify the location of the image that is used for a control. You can use images from a file, the **Resources** node in Application Explorer, or an embedded resource. The value that you select for this property determines the values that are available for the **NormalImage** property.
Label	Select the label to use as the name that appears for the item on menus and buttons.
LinkedPermissionObject	If the permissions of another object (for example, a form or report) should be applied to this menu item, select the object. Typically, this property is used for action menu items.
LinkedPermissionType	Specify the type of the object that is specified by the **LinkedPermissionObject** property.
MultiSelect	Select whether the menu item can be used on multiple record selections in forms.
Model	Specify the model that the table is in. A model is a logical grouping of elements in a layer. Examples of elements include a table or class. An element can be located in exactly one model in a layer. The same element can be located in a customized version in a model that is in a higher layer.
Name	The name of the menu item.
NeededAccessLevel	Define the minimum access that is required for the menu item to appear on a menu or a button. This property is used to set access to the menu item for different user groups.
NeedsRecord	Specify whether a button that represents the menu item is enabled if no record is present. The default value is **No**. You can use this property to help guarantee that an action can be completed. For example, you have a menu item button that opens a detail form. You might want to disable the button if there are no records on the list page.
NormalImage	Specify the image that is used when the menu item is associated with an enabled button control.
Object	Select an object of the object type that is specified in the **Class** property.

PROPERTY	DESCRIPTION
ObjectType	Select the type of object that the menu item opens. **Caution:** You should use **SSRSReport** for a menu item for an SSRS report. Don't use **SQLReportLibraryReport** for new menu items. The **SQLReportLibraryReport** option is obsolete and will be removed in a future version.
OpenMode	Specify the view mode of the target form. You use this property to specify whether the target form opens in edit mode or read-only mode. The following options are available: • Auto • View • Edit • New The default value is **Auto**.
Parameters	Optional: Specify the arguments that are passed to the object.
Query	Select the query that is passed to the target form for the **InitialQuery** method.
ReadPermissions	Specify whether read permission should be available for section when privileges are assigned to the menu item. The following options are available: • **Auto** – The permission will be available for selection as a privilege on this menu item's **Privileges** node under the **Entry Points** node. • **No** – The permission won't be available for selection as a privilege on the menu item. The default value is **Auto**.
ReportDesign	Select the report design to use for a specific SSRS report model.
RunOn	Select whether to run the menu item on the client, the server, or the location that it's called from. This property is mainly used for menu items that open reports. This property determines where the application object is run from only if the **RunOn** property of the object is set to **Called from**. • A form is instantiated and run on the client, because the **FormRun** class always runs on the client. • A report is instantiated and run as specified by the menu item's **RunOn** property, because the **ReportRun** class always runs where it was called from. You should set the property to **Called from**. If you set the report to run on the client, and the report is run in a batch, the report will fail. If you set the report to run on the server, and the report is shown on the screen, the report will fail. • A class's **main** method is run as specified by its modifier. The class itself is instantiated as specified by its **RunOn** property. The instantiation might occur in the **main** method.

PROPERTY	DESCRIPTION
UpdatePermissions	Specify whether update permission should be available for section when privileges are assigned to the menu item. The following options are available: • **Auto** – The permission will be available for section as a privilege on this menu item's **Privileges** node under the **Entry Points** node. • **No** – The permission won't be available for section as a privilege on the menu item. The default value is **Auto**.
Web	Specify the URL that is opened when you run the menu item. The value of this property is no longer used. Don't use this property.
WebConfigurationKey	Optional: Select a web-specific configuration key in addition to a standard configuration key. This property applies to web menu items only.
WebMenuItemName	Specify the menu item to include on a web menu. The available values depend on the setting of the **WebMenuItemType** property.
WebMenuItemType	Specify the type of the web menu item. There are two categories of web menu items: • URL • Action The value that you select determines the web menu item names that are available for the **WebMenuItemName** property.
WebPage	Specify the webpage that is linked to the menu item. The value of this property is no longer used. Don't use this property.
WebSecureTransaction	Select whether the menu item requires secure transactions (SSL). This property applies to web menu items only.

NOTE

When you use the **Parameters** or **EnumParameter** property, errors such as type mismatches can be found only at run time, not at compile time.

Query properties

Within a query, you can set properties on the query itself, the data sources, the fields that are used for sorting, and the ranges that are used to delimit the query.

Query properties

Query properties determine the overall behavior of the query. For example, you can specify the form that is shown to users so that they can interact with the query.

PROPERTY	DESCRIPTION
AllowCheck	This property is ignored for queries. It's effective on forms and reports.
AllowCrossCompany	Specify whether data is retrieved for all companies that the user has authority to read from. If the property is set to **false**, which is the default value, data is retrieved only for the current session company.
Description	Optional: Describe the query, what it returns, and so on. This property is useful in Microsoft Office Add-in scenarios.
Form	Specify that query form that MorphX should show when users interact with the query. The default value is **SysQueryForm**.
Interactive	Specify whether users can interact with the report by delimiting queries, setting printer options, and so on.
Literals	Specify how literals are represented in SQL statements. The **forceLiterals** option instructs the kernel to reveal the actual values that are used in **where** clauses to the Microsoft SQL Server database at the time of optimization. The **forcePlaceholders** option instructs the kernel not to reveal the actual values. **Note:** We don't recommend that you use the **forceLiterals** option, because it could expose code to an SQL injection security threat.
Model	Specify the model that the query is in. A model is a logical grouping of elements in a layer. Examples of elements include a table or class. An element can exist in exactly one model in a layer. The same element can exist in a customized version in a model that is in a higher layer.
QueryType	Specify the type of the query. The following options are available: • Join • Union The default value is **Join**.
Searchable	Specify whether the query can be part of a set of queries that is used to search the Microsoft SharePoint Business Catalog. This property is useful when you use the Enterprise Search feature. The default value is **No**.
Title	The heading for the query.
UserUpdate	Specify whether the query form should retain its state when it's reopened. If you set this property to **Yes**, the previous settings are restored. If you set it to **No**, the data can be viewed but not edited.
Version	The version is increased every time that the query is updated. This property is read-only.

Data source properties

The following properties control the characteristics of a data source. Additional properties are available on embedded data sources and relations between data sources. You can also set one property on fields in the data source.

PROPERTY	WHERE IT'S AVAILABLE	DESCRIPTION
AllowAdd	Data source	Specify whether users can add fields to sorting and ranges at run time.
Company	Data source	Specify the company to retrieve data from.
Dynamic	Fields node in a data source	Specify whether all fields in the table in the data source are used. If you set this property to **Yes**, all the fields in the data source are used. If you set it to **No**, you can remove some of the fields. When the data source is a base table, a value of **Yes** means that all fields from the derived tables are used.
Enabled	Data source	If you set this property to **No**, the data source (and all embedded data sources) are ignored.
FetchMode	Embedded data source	Specify whether the data sources should be related through a 1:1 relation or a 1:n relation. **Note:** For data sources that are used on reports, use a join relation that uses 1:1 fetch mode.
Field, RelatedField	Relations on an embedded data source	The name of the fields from the parent data source and related data source that are used in the relation.
FirstFast	Data source	If you set this property to **Yes**, the database receives a hint that the first record from the query should be retrieved before the other records. This setting enables some database systems to optimize record retrieval and therefore helps improve performance.
FirstOnly	Data source	If you set this property to **Yes**, the database receives a hint that only the first record from the query is required. This setting enables some database systems to optimize record retrieval and therefore helps improve performance.
JoinMode	Embedded data source	Specify the strategy that is used to join the output from a data source.
Name	Data source	Specify the name of the data source.

PROPERTY	WHERE IT'S AVAILABLE	DESCRIPTION
Relations	Embedded data source	Specify whether the query system should use the relations that are defined for tables and EDTs. If you set this property to **Yes**, the query is automatically updated if a relation is changed.
Table	Data source	Specify the table, map, or view that is used as a data source. This property can't be modified after a sorting order or a range has been defined.
Table, RelatedTable	Relations on an embedded data source	The name of the parent data source and the related data source.
UniqueId	Data source	The unique number of the data source. This property is read-only.
Update	Data source	Specify whether the query can update records in the database.

Range properties

The following properties determine the characteristics of the range specification. For example, you can specify whether users are allowed to modify the range at run time.

PROPERTY	DESCRIPTION
Enabled	Use this property to disable a field in a range specification.
Field	Specify the field to define a range on.
Label	Enter a label for the range.
Status	Specify whether users are allowed to modify the range in the query dialog box at run time. The following options are available: • **Open** – Users can view and edit the range. • **Lock** – Users can only view the range. • **Hide** – Users can't view or edit the range.
Value	Specify the range for the records that are retrieved. If you use enumerations, don't use text strings. The enumeration ID must be used.

Report properties

Most of the properties for a report are set on the design, design section, and control nodes in Application Explorer. For information about system properties that are available on reports, see the "System and common properties" section. The following table describes the properties of a report.

PROPERTY	DESCRIPTION
AllowCheck	Specify whether a message is shown when users try to run reports that they don't have permission to view. Select **Yes** to specify that a message is shown.
AutoJoin	Specify whether a record that is returned by the **element.args** method is used to set the range on the report query.
Interactive	Specify whether users can select which records to show by modifying the query that is associated with a report.
Model	Specify the model that the report is in. A model is a logical grouping of elements in a layer. An element can exist in exactly one model in a layer. The same element can exist in a customized version in a model that is in another layer.

Report control properties

The following table describes report control properties. For information about additional properties that are available for controls, see the "Form control properties" section.

PROPERTY	DESCRIPTION
Alignment	Specify the alignment of a value that is shown in a control.
AllowNegative	Specify whether the control accepts negative values. This property is available only for integer and real controls.
ArrayIndex	Specify the array element that is shown in a control. The control is based on an extended data type that has array elements. This property isn't available for text and shape controls.
AutoDeclaration	Specify whether a variable is created that has the same name as the control. When you set this property to **Yes**, it's easier to access the report controls from X++ code, and you can find errors at compile time.
AutoInsSeparator	Specify whether a decimal separator is shown. This property is available only for real controls.
BackgroundColor	Specify the background color for a control. The setting of this property can be overridden by using the **BackStyle** property.
BackStyle	Specify whether the control background is opaque or transparent. When you set this property to **Transparent**, the behavior depends on the type of control: • For bitmap controls, pixels that have the same color are transparent. • For all other controls, the foreground color is used as the background color.
Bold	Specify bold text formatting.

PROPERTY	DESCRIPTION
BottomMargin	Specify the margin for a control.
ChangeCase	Specify the case of text that a user enters. This property is available only for string, enum, text, and prompt controls.
ChangeLabelCase	Specify whether the label for the control should be modified when the report is printed. The following options are available: • Auto • None • UPPER CASE • lower case • Title Case The default value is **Auto**.
ColorScheme	Specify the color palette for a control.
ConfigurationKey	Specify a configuration key for the control.
CSSClass	Specify the Cascading Style Sheet (CSS) to use to render the value in HTML.
DataField	Specify a table field for the control. This property isn't available for text, shape, box, and bitmap controls.
DataMethod	Specify a display method that shows data in a control. This property isn't available for text, shape, and box controls.
DateDay	Specify the format for the day. This property is available only for date controls.
DateFormat	Specify the format for a date. This property is available only for date controls.
DateMonth	Specify the format for the month. This property is available only for date controls.
DateSeparator	Specify the separator that appears between the month, day, and year. This property is available only for date controls.
DateYear	Specify the format for the year. This property is available only for date controls.
DecimalSeparator	Specify the symbol that is used to separate decimal values. This property is available only for real controls.
DisplaceNegative	Specify a new position for a value in a grid control when the value is a negative number. This property is available only for integer and real controls.

PROPERTY	DESCRIPTION
DynamicHeight	Specify whether the control is resized to show additional lines of text. When you set this property to **Yes**, page headers, page footers, and repeating column headings are automatically added as required. This property is available only for string controls.
ExtendedDataType	Specify the EDT that the field that is associated with the control should be based on.
ExtraSumWidth	Modify the default width that is allowed for sums. This property is available only for integer and real controls.
Font	Specify the font.
FontSize	Specify the font size.
ForegroundColor	Specify the foreground color for a control.
FormatMST	Specify whether values are formatted by using standard currency format. This property is available only for real controls.
Height	Specify the height of a control. When a control is associated with an EDT, the **Height** property of the control overrides the **DisplayLength** property of the EDT. If you set the **Height** property to **Auto** for a bitmap control, the size of the control is based on the size of the graphic.
ImageName	Specify the file name for an image. This property is available only for bitmap controls.
ImageResource	Specify the ID for a system resource to show. The resource macro provides a list of these IDs. Macros are located under the **Macros** node in Application Explorer. This property is available only for bitmap controls.
Italic	Specify italic text formatting.
Label	Specify a title for the control. If a label isn't specified here, it's inherited from the field.
LabelBold	Set or return a value that indicates the bold setting for the label in the control.
LabelCSSClass	Specify the CSS to use to render the label in HTML.
LabelFont	Set or return a string data type value that indicates the font for the label text in a form combo box control.
LabelFontSize	Set or return the font size, in points, for the label text in a form combo box control.
LabelItalic	Set or return a value that indicates whether the text in the control label should be italic.

PROPERTY	DESCRIPTION
LabelLineBelow	Specify the format of the underline for the control title.
LabelLineThickness	Specify the format of the line below column headings.
LabelPosition	Set or return the position of the label for the control. Valid values are **Left** and **Above**.
LabelTabLeader	Specify whether to append a series of dots to control labels. The following options are available: • Auto • Do not append • Do append The default value is **Auto**.
LabelUnderline	Set or return a value that indicates whether the text in the control label should be underlined.
LabelWidth	Specify the width of the label for the control.
Left	Specify the left alignment of a control.
LeftMargin	Specify the left margin for a control.
Line	Specify the appearance of the lines that form a shape. This property is available only for shape controls.
LineAbove	Specify the type of line for the top border of a control. If your report has many lines or boxes, consider using a shape control inside the individual sections.
LineBelow	Specify the type of line for the bottom border of a control. If your report has many lines or boxes, consider using a shape control inside the individual sections.
LineLeft	Specify the type of line for the left border of a control. If your report has many lines or boxes, consider using a shape control inside the individual sections.
LineRight	Specify the type of line for the right border of a control. If your report has many lines or boxes, consider using a shape control inside the individual sections.
MenuItemLabel	Specify the label for a menu item.
MenuItemName	Specify the name of the menu item. The available menu items vary, depending on the setting of the **MenuItemType** property.
MenuItemType	Specify whether the menu item is an action, display, or output menu item. A display menu item is for a form, and an output menu item is for a report. An output menu item is for a class, job, or query.

PROPERTY	DESCRIPTION
MinNoOfDecimals	Specify the minimum number of decimal places that are shown. Trailing zeros aren't shown.
ModelFieldName	Specify a field that is used to determine the left alignment and width of a control.
NoOfDecimals	Specify the number of decimal places that are shown. The default value is **20**. This property is available only for real controls.
ResizeBitmap	Specify whether an image can be resized to fit the dimensions of a control. This property is available only for bitmap controls.
RightMargin	Specify the margin for a control.
RotateSign	Specify whether the sign for the control is inverted. This property is available only for integer and real controls.
ShowLabel	Set or return a value that indicates whether the label for the control is shown in the form. A value of **True** indicates that the label will be shown.
ShowPicAsText	Specify whether the file name for an image is shown instead of the image. This property is available only for bitmap controls.
ShowZero	Specify whether a 0 (zero) value is shown. This property is available only for integer and real controls.
SignDisplay	Specify how the sign of a number is shown. This property is available only for integer and real controls.
SumAll	Specify whether the sum of all values is calculated. This property is available only for integer and real controls.
SumNeg	Specify whether the sum of all negative values is calculated. This property is available only for integer and real controls.
SumPos	Specify whether the sum of all positive values is calculated. This property is available only for integer and real controls.
Table	Specify a data source for the control. This property isn't available for text, shape, box, and bitmap controls.
Text	Specify the text string that is shown in a control. This property is available only for text controls.
TimeFormat	Specify whether times are shown in 24-hour format or AM/PM format. This property is available only for time controls.
TimeHours	Specify whether hours are shown. This property is available only for time controls.

PROPERTY	DESCRIPTION
TimeMinutes	Specify whether minutes are shown. This property is available only for time controls.
TimeSeconds	Specify whether seconds are shown. This property is available only for time controls.
TimeSeparator	Specify the symbol that is used to separate hours, minutes, and seconds. This property is available only for time controls.
Thickness	Specify the thickness of a control border.
ThousandSeparator	Specify the symbol that is used to separate thousands. This property is available only for real controls.
Top	Specify the top alignment of a control.
TopMargin	Specify the margin for a control.
Type	Specify the type of shape that is shown. This property is available only for shape controls.
TypeHeaderPrompt	Specify whether a line of dots is added to fill the space between the control title and the control value. This property is available only for text and prompt controls.
Underline	Specify underline text formatting.
Visible	Set or return a value that indicates whether the control is visible. A value of **True** indicates that the control is visible.
WarnIfMissing	Specify whether a message is shown if an image is missing from the report. This property is available only for bitmap controls.
WebMenuItemName	Specify the menu item to include on a web menu. The available values depend on the setting of the **WebMenuItemType** property.
WebMenuItemType	Specify the type of the menu item. There are two categories of web menu items: • URL • Action The value that you select determines the web menu item names that are available for the **WebMenuItemName** property.
WebTarget	Specify the location of the control on a web report.
Width	Specify the width of a control. When a control is associated with an EDT, the **Width** property of the control overrides the **DisplayLength** property of the EDT. If you set the **Width** property to **Auto** for a bitmap control, the size of the control is based on the size of the graphic.

Report design properties

The following table describes the report design properties.

PROPERTY	DESCRIPTION
ArrangeMethod	Specify the layout for the controls in a report section.
ArrangeWhen	Specify when report controls are arranged.
BottomMargin	Specify the bottom margin. If you set this property to **Auto**, the default value that is stored in the system table is used.
Caption	Specify the name that is shown for the report in the user interface.
ColorScheme	Specify the color palette.
Columns	Specify the number of columns.
ColumnSpace	Specify the space between columns.
Font, FontSize, Italic, Underline and Bold	Specify the text formatting. The settings of the **Font** and **FontSize** properties override the values that you can set by clicking **Options** > **Fonts** on the **Tools** menu.
ForegroundColor	Specify the foreground color.
Height	Specify the height.
LeftMargin	Specify the left margin. If you set this property to **Auto**, the default value that is stored in the system table is used.
LineAbove	Specify the type of line for the top border of a section. If a report has many lines and boxes, consider using the shape control inside a section.
LineBelow	Specify the type of line for the bottom border of a section. If a report has many lines and boxes, consider using the shape control inside a section.
LineLeft	Specify the type of line for the left border of a section. If a report has many lines and boxes, consider using the shape control inside a section.
LineRight	Specify the type of line for the right border of a section. If a report has many lines and boxes, consider using the shape control inside a section.
ResolutionX, ResolutionY	Specify the distance between gridlines.
RightMargin	Specify the right margin. If you set this property to **Auto**, the default value that is stored in the system table is used.

PROPERTY	DESCRIPTION
Ruler	Specify the unit for the ruler that is shown when you edit a design. To edit a design, right-click **AutoDesignSpecs** or **Generated Design**, and then click **Edit**.
Thickness	Specify the thickness of a section border.
TopMargin	Specify the top margin. If you set this property to **Auto**, the default value that is stored in the system table is used.

Report design section properties

The following table describes properties for report design sections. For information about additional properties that are available for report designs, see the "Report design properties" section.

PROPERTY	DESCRIPTION
ArrangeMethod	Specify the layout for the controls in a report section.
ArrangeWhen	Specify when the controls in the container should be arranged. The available options are **Startup**, **On demand**, and **Never**.
Bold	Get or set the weight of the font that was used to show text in the control.
Bottom	Change the position of the bottom of the report.
BottomMargin	Specify the bottom margin. If you set this property to **Auto**, the default value that is stored in the UserInfo system table is used.
ColorScheme	Specify the color palette.
ColumnHeadingsStrategy	Specify the layout of column headings. If you set this property to **WordWrap**, a heading wraps when it's longer than the longest field in the column. Headings can wrap to a maximum of eight lines. Headings that are longer than eight lines are truncated. **Note:** The heading length varies, depending on the language.
Columns	Specify the number of columns.
Columnspace	Specify the space between columns.
Font	Specify the text formatting. The settings of the **Font** and **FontSize** properties override the values that you can set by clicking **Options** > **Fonts** on the **Tools** menu.
FontSize	Specify the text formatting. The settings of the **Font** and **FontSize** properties override the values that you can set by clicking **Options** > **Fonts** on the **Tools** menu.
ForegroundColor	Specify the foreground color.

PROPERTY	DESCRIPTION
GrandHeader	Specify whether the value of the **HeaderText** property is shown. The **GrandHeader** property is available only when a report has multiple data sources that aren't nested.
GrandTotal	Specify whether the value of the **FooterText** property is shown. The **GrandTotal** property is available only when a report has multiple data sources that aren't nested.
HeaderText	Specify the text that is shown above the first record in a section when the **GrandHeader** property is set to **Yes**. This property is available only when a report has multiple data sources that aren't nested.
Height	Specify the height.
Italic	Specify the text formatting. The settings of the **Font** and **FontSize** properties override the values that you can set by clicking **Options** > **Fonts** on the **Tools** menu.
LabelTopMargin, LabelBottomMargin	Specify the margins above and below column headings.
LeftMargin	Specify the left margin. If you set this property to **Auto**, the default value that is stored in the UserInfo system table is used.
LineAbove, LineBelow, LineLeft, LineRight	Specify the type of line for a section border. If a report has many lines and boxes, consider using the shape control inside a section.
Map	Specify the map to use to show data. You can associate a map field with a field in one or more tables. This property lets you use the same field name to access fields that have different names in different tables.
NoOfHeadingLines	Specify the number of lines that are used to show column headings. If you set the property to **0** (zero), column headings aren't displayed. For reports that include several fields, increase the number of lines to make sure that all fields are shown.
RightMargin	Specify the right margin. If you set this property to **Auto**, the default value that is stored in the UserInfo system table is used.
ResolutionX	Specify the distance between gridlines.
ResolutionY	Specify the distance between gridlines.
Ruler	Specify the unit for the ruler that is shown when you edit a design. To edit a design, right-click **AutoDesignSpecs** or **Generated** Design, and then click **Edit**.
Table	Specify the data source for a section.
Thickness	Specify the thickness of a section border.

PROPERTY	DESCRIPTION
Top	Change the position of the top of the report.
TopMargin	Specify the top margin. If you set this property to **Auto**, the default value that is stored in the UserInfo system table is used.
Underline	Specify the text formatting. The settings of the **Font** and **FontSize** properties override the values that you can set by clicking **Options** > **Fonts** on the **Tools** menu.

Report query properties

The following table describes report query properties. For information about additional report properties, see the "Report properties" and "System and common properties" sections.

PROPERTY	DESCRIPTION
AllowCheck	Get or set the Allow check flag.
AllowCrossCompany	Get or set the Allow cross-company flag. This flag indicates whether query execution will be across companies.
Description	A textual explanation of the query. This optional property is often used in Office Add-ins scenarios.
Form	Specify the form that is used for user interaction.
Interactive	Specify whether users can interact with the report by delimiting queries, setting printer options, and so on.
Literals	Specify how literals are represented in SQL statements.
Model	Specify the model that the report query is in. A model is a logical grouping of elements in a layer. Examples of elements include a table or class. An element can exist in exactly one model in a layer. The same element can exist in a customized version in a model that is in another layer.
QueryType	Specify the type of the query. The following options are available: • Join • Union The default value is **Join**.
Searchable	Specify whether the query can be part of a set of queries that can be used to search the SharePoint Business Catalog. This property is useful when you use the Enterprise Search feature. The default value is **No**.
Title	Specify the title of the query.

PROPERTY	DESCRIPTION
UserUpdate	Specify whether users can update a query.
Version	This is a read-only internal property.

Security code permission properties

A code permission is a group of permissions that are associated with a menu item or a service operation. When a security role has access to a menu item, it also has access to other Application Explorer items that are mentioned within the code permission for that menu item. The degree of access is controlled by the specific permissions that are defined under the code permission node.

Securable objects

Code permissions are used to give access to securable objects. The following list shows the hierarchy of code permission nodes in Application Explorer:

- Security
  - Code Permissions
    - YourCodePermission
      - Tables
      - Server Methods
      - Associated Objects
        - Forms
        - Web Controls
        - Reports

Code permissions can also override the access levels to securable objects under the **Associated Objects** node.

Code permission properties

This following table describes the properties for the node at **Security** > **Code Permissions** > **YourCodePermission** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Name	Yes	The name of the code permission. The code permission lets users run the class method that is specified in the **Method** property.
Class	Optional	The class that is associated with this code permission.
Method	Optional	The method that is associated with this code permission.

Table properties

The following table describes the properties for the node at **Security** > **Code Permissions** > **YourCodePermission** > **Tables** > **YourTable** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Table	Yes	The name of the table.
EffectiveAccess	Yes	The permission value. The following options are available: • Read • Update • Create • Correct • Delete • NoAccess The permission values for the **EffectiveAccess** property represent a hierarchy. Read is the weakest permission, and Delete is the strongest. Delete permission includes every other permission. Create permission includes Update and Read. You can set the permission value to **NoAccess** to prevent all access to the table.
ManagedBy	Optional	This property is used by automation tools.

Server method properties

The following tables describes the properties for the node at **Security** > **Code Permissions** > **YourCodePermission** > **Server Methods** > **YourServerMethod** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Class	Yes	The name of the server class.
Method	Yes	The secure server method that is tagged with the **SysEntryPointAttribute** attribute.
EffectiveAccess	Yes	The permission value. The following options are available: • **Invoke** – The server method can be called. • **NoAccess** – The server method can't be called.
ManagedBy	Optional	This property is used by automation tools.

Form properties

The following table describes the properties for the node at **Security** > **Code Permissions** > **YourCodePermission** > **Associated Objects** > **Forms** > **YourForm** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Form	Yes	The name of the form.

PROPERTY	REQUIRED	DESCRIPTION
AccessLevel	Yes	The permission value. The following options are available: • Read • Update • Create • Correct • Delete • NoAccess The permission values for the **EffectiveAccess** property represent a hierarchy. Read is the weakest permission, and Delete is the strongest. Delete permission includes every other permission. Create permission includes Update and Read. You can set the permission value to **NoAccess** to prevent all access to the form.
ManagedBy	Optional	This property is used by automation tools.

Web control properties

The following table describes the properties for the node at **Security** > **Code Permissions** > **YourCodePermission** > **Associated Objects** > **Web Controls** > **YourWebControl** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
WebControl	Yes	The name of the web control.
AccessLevel	Yes	The permission value. The following options are available: • Read • Update • Create • Correct • Delete • NoAccess The permission values for the **EffectiveAccess** property represent a hierarchy. Read is the weakest permission, and Delete is the strongest. Delete permission includes every other permission. Create permission includes Update and Read. You can set the permission value to **NoAccess** to prevent all access to the web control.
ManagedBy	Optional	This property is used by automation tools.

Report properties

The following table describes the properties for the node at **Security** > **Code Permissions** > **YourCodePermission** > **Associated Objects** > **Reports** > **YourReport** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Name	Yes	The name of the report design.
Report	Yes	The full name of the report.
ManagedBy	Optional	This property is used by automation tools.

Security duty properties

Security permissions are combined into privileges, and privileges are combined into duties. Duties are defined as groups of related privileges that provide a user with access to a specific business function. In Application Explorer, these privileges are organized into the nodes of a duty.

Best practices

This section describes the best practice rules for duties.

- All duties should be assigned to a role.
- All duties should be part of a process cycle.
- Because a duty represents a specific business function, the name of the duty should rarely or never change. For example, your company pays bills. Although the details of how you pay bills might change, the essential function of paying bills won't change. Instead of creating a new duty, you should change the privilege subnodes of the duty.
- The name of a process cycle should rarely or never change.

Duty hierarchy in Application Explorer

The following list shows the hierarchy of duty nodes in Application Explorer:

- Security
  - Duties
    - YourDuty
      - Privileges

Duty properties

The following table describes the properties for the node at **Security** > **Duties** > **YourDuty** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Name	Yes	The name of the duty.
Label	Yes	Text that is shown for the duty in the user interface.
Description	Yes	A description of the duty.
Enabled	Yes	A value that indicates whether the duty is enabled. The following options are available: • **Yes** – Enable the duty. • **No** – Disable the duty.

Privilege properties

The following table describes the properties for the node at **Security** > **Duties** > **YourDuty** > **Privileges** > **YourPrivilege** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Name	Yes	The name of the privilege.
Enabled	Yes	A value that indicates whether the duty is enabled. The following options are available: • **Yes** – Enable the privilege. • **No** – Disable the privilege.

Security privilege properties

A privilege is a group of permissions. The nodes that are below each privilege node identify the securable objects that a user can access and set the level of access for each object.

Best practices

This section describes the best practice rules for privileges.

- You can use privileges to specify the access that is required in order to perform a job.
- You can use privileges to group the permissions for related securable objects. For example, menu items and their controls are closely related.
- You can assign privileges directly to security roles. However, security settings are easier to maintain if you assign duties or process cycles instead of privileges.

Securable objects

Privileges are used to give access to securable objects. The following list shows the hierarchy under the **Security** > **Privileges** node in Application Explorer:

- Security
  - Privileges
    - YourPrivilege
      - Entry Points
      - Permissions
        - Tables
        - Server Methods
        - Forms

Privileges can also override the access levels to securable objects as they are defined elsewhere in Application Explorer. For example, a privilege can override a permission that is defined by the **EffectiveAccess** property under **Forms** > **YourForm** > **Permissions** > **Update** > **Tables** > **YourTable** in Application Explorer.

Privilege properties

The following table describes the properties for the node at **Security** > **Privileges** > **YourPrivilege** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Name	Yes	The name of the privilege.

PROPERTY	REQUIRED	DESCRIPTION
Label	Yes	Text that is shown for the privilege in the user interface.
Description	Yes	A description of the privilege.
Enabled	Yes	A value that indicates whether the duty is enabled. The following options are available: • **Yes** – Enable the privilege. • **No** – Disable the privilege.

Entry point properties

The following table describes the properties for the node at **Security** > **Privileges** > **YourPrivilege** > **Entry Points** > **YourEntryPoint** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Name	Yes	The name of the entry point.
ObjectType	Yes	The object type of the entry point. The following options are available: • MenuItemDisplay • MenuItemOutput • MenuItemAction • ServiceOperation • WebActionItem • WebURLItem • WebManagedContent
ObjectName	Yes	The object name of the entry point.
ObjectChildName	Optional	A value that represents the service method name. **Note:** Specify a value for this property only if the **ObjectType** property is set to **ServiceOperation**.

PROPERTY	REQUIRED	DESCRIPTION
AccessLevel	Yes	The permission value. For all object types except **ServiceOperation**, the following options are available: • Read • Update • Create • Correct • Delete • NoAccess The permission values for the **AccessLevel** property represent a hierarchy. Read is the weakest permission, and Delete is the strongest. Delete permission includes every other permission. Create permission includes Update and Read. You can set the permission value to **NoAccess** to prevent all access to the entry point. The Correct permission applies only when a time state table is involved. This permission authorizes you to issue update records in a time state table. For the **ServiceOperation** object type, the following options are available: • **Invoke** – The server method can be called. • **NoAccess** – The server method can't be called.

Table properties

The following table describes the properties for the node at **Security** > **Privileges** > **YourPrivilege** > **Permissions** > **Tables** > **YourTable** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Table	Yes	The name of the table.

PROPERTY	REQUIRED	DESCRIPTION
EffectiveAccess	Yes	The permission value. The following options are available: • Read • Update • Create • Correct • Delete • NoAccess The permission values for the **EffectiveAccess** property represent a hierarchy. Read is the weakest permission, and Delete is the strongest. Delete permission includes every other permission. Create permission includes Update and Read. The Correct permission applies only when a time state table is involved. This permission authorizes you to update records in a time state table. You can set the permission value to **NoAccess** to prevent all access to the table.
ManagedBy	Optional	This property is used by automation tools.

Server method properties

The following table describes the properties for the node at **Security** > **Privileges** > **YourPrivilege** > **Permissions** > **Server Methods** > **YourServerMethod** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Class	Yes	The name of the server class.
Method	Yes	The name of the secure server method that is tagged with the **SysEntryPointAttribute** attribute.
EffectiveAccess	Yes	The permission value. The following options are available: • **Invoke** – The server method can be called. • **NoAccess** – The server method can't be called.
ManagedBy	Optional	This property is used by automation tools.

Form properties

The following table describes the properties for the node at **Security** > **Privileges** > **YourPrivilege** > **Permissions** > **Forms** > **YourForm** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Form	Yes	The name of the form.

Security process cycle properties

A process cycle is a group of duties. A process cycle represents a high-level job function. Although the details of how a given job function is run might change over time, the concept and name of that job function probably don't change.

Best practices

This section describes the best practice rules for process cycles.

- Each duty should be part of a process cycle.
- Use a process cycle to organize a group of duties for a job function.

Process cycle hierarchy in Application Explorer

The following list shows the hierarchy of process cycles nodes in Application Explorer:

- Security
  - Process Cycles
    - YourProcessCycle
      - Duties

Process cycle properties

The following table describes the properties for the node at **Security** > **Process Cycles** > **YourProcessCycle** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Name	Yes	The name of the process cycle.
Label	Yes	Text that is shown for the process cycle in the user interface.
Description	Yes	A description of the process cycle.
Enabled	Yes	A value that indicates whether the duty is enabled. The following options are available: • **Yes** – Enable the process cycle. • **No** – Disable the process cycle.

Duty properties

The following table describes the properties for the node at **Security** > **Process Cycles** > **YourProcessCycle** > **Duties** > **YourDuty** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Name	Yes	The name of the duty.

PROPERTY	REQUIRED	DESCRIPTION
Enabled	Yes	A value that indicates whether the duty is enabled. The following options are available: • **Yes** – Enable the duty. • **No** – Disable the duty.

Security policy properties

Developers and system administrators can create security policies to deny access to a subset of data records in tables.

Constrained tables of a policy

You can add tables and views under the **Constrained Tables** node of a security policy in Application Explorer. These tables and views are related to the data source table of the query that is named in the **Query** property of the policy. The following list shows the hierarchy of security policy nodes in Application Explorer:

- Security
  - Policies
    - YourPolicy
      - Constrained Tables
        - YourConstrainedTable
          - YourConstrainedSubTable
        - YourConstrainedView

Each **Constrained Tables** node can contain any number of constrained tables and views. Additionally, each constrained table can contain any number of constrained sub-tables.

Security policy properties

The following table describes the properties for the node at **Security** > **Policies** > **YourPolicy** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Name	Yes	The name of the security policy.
Label	Yes	The text that is shown for the security policy in the user interface.
PrimaryTable	Yes	The table that is specified in the data source for the security policy query.
Query	Yes	The query that the policy uses to filter data from the constrained tables that are specified in the policy.
UseNotExistJoin	Yes	A value that indicates whether the security query must be applied as a **not exists** join or an **exists** join.

PROPERTY	REQUIRED	DESCRIPTION
PolicyGroup	No	Administrators and developers can use this property to quickly identify groups of related security policies. The available options are the names of the security policy groups that the system administrator or developer has created. The system doesn't use this property at run time.
ConstrainedTable	Yes	A value that controls whether the security policy restricts the data values in records that are returned from the primary table. The following options are available: • **Yes** – The security policy is enforced on the primary table. • **No** – The security policy isn't enforced on the primary table.
Enabled	Yes	A value that controls whether the system enforces the policy at run time. The following options are available: • **Yes** – Enable the security policy. • **No** – Disable the security policy.
Operation	Yes	A value that controls which data operations the policy is enforced for. The following options are available: • Select • Insert • Update • Delete • Insert, Update and Delete • All operations
ContextType	Yes	A value that controls the context type of the security policy. The following options are available: • **ContextString** – You must specify a value for the **ContextString** property. The security policy uses a specific application context for the policy. • **RoleName** – The security policy is applied only to the application user who is assigned to the value of **RoleName**. • **RoleProperty** – This value is used in combination with the **ContextString** property to specify multiple roles context.

PROPERTY	REQUIRED	DESCRIPTION
ContextString	Yes	This property is used in combination with **ContextType** property. It can be used to specify an application or multiple roles context.

Security role properties

Roles represent a collection of permissions that can be granted to users. The nodes that are nested below each role node identify various securable objects that a user can access and specify the level of access.

Role node in Application Explorer

Roles are used to give access to securable objects. The following list shows the hierarchy of role nodes in Application Explorer:

- Security
  - Roles
    - YourRole
      - Duties
      - Privileges
      - Permissions
        - Tables
        - Forms
        - Server Methods
      - Sub Roles

Roles are typically associated with security duties, and sometimes with security privileges. Access levels to securable objects within a role are derived from the duties, privileges, or both. Roles can also override the access levels to securable objects under the **Permissions** node.

Role properties

The following table describes the properties for the node at **Security** > **Roles** > **YourRole** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Name	Yes	The name of the role.
Label	Yes	Text that is shown for the role in the user interface.
Description	Yes	A description of the role.
Enabled	Yes	A value that indicates whether the duty is enabled. The following options are available: • **Yes** – Enable the role. • **No** – Disable the role.

PROPERTY	REQUIRED	DESCRIPTION
PastDataAccess	Yes	The past data access for the tables that have date-effective fields. The following options are available: • Read • Update • Create • Correct • Delete • NoAccess The permission values for the **PastDataAccess** property represent a hierarchy. Read is the weakest permission, and Delete is the strongest. Delete permission includes every other permission. Create permission includes Update and Read. You can set the permission value to **NoAccess** to prevent all access to the table.
CurrentDataAccess	Yes	The current data access for the tables that have date-effective fields.
FutureDataAccess	Yes	The future data access for the tables that have date-effective fields.
ContextString	Optional	A user-defined string that can be used by security policies.

Duty properties

The following table describes the properties for the node at **Security** > **Roles** > **Duties** > **YourDuty** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Name	Yes	The name of the duty.
Enabled	Yes	A value that indicates whether the duty is enabled. The following options are available: • **Yes** – Enable the duty. • **No** – Disable the duty.

Privilege properties

The following table describes the properties for the node at **Security** > **Roles** > **Privileges** > **YourPrivilege** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Name	Yes	The name of the privilege.

PROPERTY	REQUIRED	DESCRIPTION
Enabled	Yes	A value that indicates whether the duty is enabled. The following options are available: • **Yes** – Enable the privilege. • **No** – Disable the privilege.

Table properties

The following table describes the properties for the node at **Security** > **Roles** > **Permissions** > **Tables** > **YourTable** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Table	Yes	The name of the table.
EffectiveAccess	Yes	The permission value. The following options are available: • Read • Update • Create • Correct • Delete • NoAccess The permission values for the **EffectiveAccess** property represent a hierarchy. Read is the weakest permission, and Delete is the strongest. Delete permission includes every other permission. Create permission includes Update and Read. You can set the permission value to **NoAccess** to prevent all access to the table.
ManagedBy	Optional	This property is used by automation tools.

Form properties

The following table describes the properties for the node at **Security** > **Roles** > **Permissions** > **Form** > **YourForm** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Form	Yes	The name of the form.

Server method properties

The following table describes the properties for the node at **Security** > **Roles** > **Permissions** > **Server Methods** > **YourServerMethod** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Class	Yes	The name of the server class.

PROPERTY	REQUIRED	DESCRIPTION
Method	Yes	The name of the secure server method that is tagged with the **SysEntryPointAttribute** attribute.
EffectiveAccess	Yes	The permission value. The following options are available: • **Invoke** – The server method can be called. • **NoAccess** – The server method can't be called.
ManagedBy	Optional	This property is used by automation tools.

Subrole properties

The following table describes the properties for the node at **Security** > **Roles** > **Sub Roles** > **YourSubRole** in Application Explorer.

PROPERTY	REQUIRED	DESCRIPTION
Name	Yes	The name of the subrole.
Enabled	Yes	A value that indicates whether the duty is enabled. The following options are available: • **Yes** – Enable the subrole • **No** – Disable the subrole.

Web menu properties

The following table describes the properties that are specific to web menus and submenus.

PROPERTY	DESCRIPTION
ConfigurationKey	Specify the configuration key that is used to control display of this menu. If a user doesn't have access to the configuration key, the menu won't be visible.
HighlightSelected	This property isn't supported.
Label	Specify the text that is shown for the top-level node of the web menu or submenu. The value can't exceed 250 characters.
MenuItemName	Specify the menu item to access when the top-level node for the menu or submenu is clicked. The options that are available depend on the setting of the **MenuItemType** property.
MenuItemType	Specify the type of menu item that is accessed by the top-level node of the menu or submenu. The available options are **Action** and **URL**.

PROPERTY	DESCRIPTION
Model	Specify the model. A model is a logical grouping of elements in a layer. Examples of elements include a table or class. An element can exist in exactly one model in a layer. The same element can exist in a customized version in a model that is in a higher layer.
SetCompany	This property causes the system to change the company when the form receives focus. If the **SaveDataPerCompany** property on a table is set to **Yes**, the **SetCompany** property on a form design that uses the table as a data source must also be set to **Yes**.
ShowParentModule	Specify whether to update the QuickLaunch, based on the parent module of the menu item. The following options are available: • **Yes** – Always update the QuickLaunch, based on the parent module of the menu item. • **No** – Leave the QuickLaunch unchanged, even if the parent module of the menu item differs from the current module. The default value is **Yes**.

Web menu item properties

The following table describes the properties that are specific to web menu items.

PROPERTY	DESCRIPTION
Big	Specify the size of the button when it's used on an Action Pane. The following options are available: • **Yes** – The button is shown at full size and is located at the start of the group. • **No** – The button is shown at the smaller size and is located on the right side of the group.
CloseDialogBehavior	Specify the action that is performed on the parent window when the dialog box closes. The following options are available: • **Auto** – Depending on how the dialog box was used, the appropriate update actions are performed when the dialog box is closed. • **RefreshDataSource** – The read-only data source on the parent form is updated. This option preserves the current selection and performs a **Research()** operation on the data source. • **RefreshPage** – Refresh the page. • **Submit** – Refresh the parent page. • **None** – No action is performed. The default value is **Auto**.
HideActionPane	Specify whether the Action Pane is visible on the page that is being opened.

PROPERTY	DESCRIPTION
HomePage	Specify whether the page is a Role Center page and is deployed to the main Enterprise Portal site.
NeedsRecord	When you set this property to **Yes**, the menu item is shown when there are no records in the data set.
PageDefinition	The page that the web menu item points to.
Parameters	Specify the arguments that are passed to the page that is being opened. Each parameter must have the following form: *name*= *value* If multiple parameters must be passed, they must be separated by an ampersand (&), as shown in the following example: mode=2&category=1
URL	Specify the URL to navigate to.
WebConfigurationKey	Select the configuration key that is required in order to enable the web menu item. Use the key for the module that the object belongs to.
WindowMode	Specify the type of window to use for the page that is being opened. The following options are available: • **Inline** – The page that is being opened will replace the existing content in the browser. If the web menu item is being accessed from a dialog box, the page that is being opened will open in a new browser window. • **Modal** – If no dialog box is open, a new dialog box will be created. If the web menu item is being accessed from a dialog box, the page that is being opened will replace the content of the current dialog box. • **NewModal** – The page that is being opened will always open in a new dialog box. • **NewWindow** – The page that is being opened will open in a new browser window.
WindowParameters	Specify additional parameters to control the appearance of the SharePoint dialog box. The parameters must be enclosed in braces ({}) and separated by commas. The following example shows how to set the **WindowParameters** property so that the dialog box has a size of 400 × 300 pixels, and so that it has no **Close** or **Maximize** button: {width:400, height:300, showClose:false, allowMaximize:false}
WindowSize	Specify the size of the window to use for the page that is being opened. The following options are available: • **Smallest** – 330 × 200 pixels • **Small** – 550 × 450 pixels • **Medium** – 800 × 630 pixels • **Large** – 930 × 630 pixels • **Maximum** – The largest size that will fit in the boundaries of the main browser window

X++ language reference

2/18/2021 • 2 minutes to read • Edit Online

X++ is an object-oriented, application-aware, and data-aware programming language used in enterprise resource planning (ERP) programming and in database applications. It provides system classes for a broad range of system programming areas, highlighted in the following table.

X++ LANGUAGE FEATURE	DESCRIPTION
Classes	In addition to system classes, there are also application classes for managing many types of business processes. Reflection on classes is supported.
Tables	X++ programmers can access the relational tables. X++ includes keywords that match most of the keywords in standard SQL. Reflection on tables is supported.
User interface	Manipulation of user interface items, such as forms and reports.
Best practice checks	X++ code is checked for syntax errors during compile time. The compile process also performs best practice checks. Violations of best practices can generate compiler messages.
Garbage collection	The X++ runtime execution engines have automatic mechanisms to discard objects that are no longer referenced, so that memory space can be reused.
Interoperability	Interoperability between classes written in X++ and in C# (or other .NET Framework languages) is supported.
File manipulation	File input and output is supported, including XML building and parsing.
Collections	Dynamic arrays are supported and the X++ includes several collection objects.

The X++ language programming guide is divided into these sections:

- Variables and data types
- Statements, loops, and exception handling
- Operators
- Classes and methods
- Data selection and manipulation
- Macros
- Attribute classes

Additional resources

- X++ Syntax
- X++ and C# Comparison

The survey will take about seven minutes. No personal data is collected (privacy statement).

X++ variables

2/18/2021 • 9 minutes to read • Edit Online

This topic describes variables in X++.

- A *variable* is an identifier that points to a memory location where information of a specific data type is stored. The size, precision, default value, implicit and explicit conversion functions, and range depend on the variable's data type.
- The *scope* of a variable defines the area in the code where an item can be accessed.
- *Instance variables* are declared in class declarations, and can be accessed from any methods in the class or from methods that extend the class.
- *Local variables* can be accessed only in the block where they were defined.
- When a variable is declared, memory is allocated, and the variable is initialized to the default value.
- You can assign values to both static fields and instance fields as part of the declaration statement.
- Variables can be declared anywhere in a code block in a method. They don't have to be declared at the beginning of a method.
- *Constants* are variables where the value can't be changed when the variable is declared. They use the **const** or **readonly** keyword.
- Constants differ from *read-only fields* in only one way. Read-only fields can be assigned a value only one time, and that value never changes. The field can be assigned its value either inline, at the place where the field is declared, or in the constructor.

When you declare variables of managed types that aren't authored in X++, you have two options. You can fully qualify the type names in the declaration by including the full namespace, or you can add a **using** statement to your file and then omit the namespace from the type name.

Variable examples

```
// An example of two valid variable names.
str variableName;
CustInfo custNumber;

// An example of simultaneously declaring and initializing a variable.
real pi = 3.14159265359; // Assigns value of pi to 12 significant digits.

// An example of initializing an object by using the new method on the class.
Access accessObject = new Access(); // Simple call to the new method in the Access class.

// An example of multiple declarations using integers.
int i,j; // Declares 2 integers, i and j.

// An example of multiple declarations using an array.
int a[100,5], b=1; // Declares array with 100 integers with 5 in memory and b as an integer with value 1.

// An example of how variable scopes work.
class ScopeExample
{
    // The variable a is declared within the class.
    int a;

    // Because the method below is declared within the class,
    // it can access all the variables defined within the class.
    void aNewMethod()
    {
```

```
        // The variable b is declared within the method.
        // It can only be accessed by this method.
        int b;
    }
}

// An example of an assignment of field members inline.
public class FieldAssignmentExample
{
    int field1 = 1;
    str field2 = "Banana";
    void new()
    {
        // ...
    }
}

class ConstantExample
{
    // An example of a constant being declared at the class level.
    public const str MyContent = 'SomeValue';
    public int ResultSoFar()
    {
        return 1;
    }
}

// The constants can then be referenced by using the double-colon syntax.
str value = ConstantExample::MyContent;
// If you're in the scope of the class where the const is defined,
// you can omit the type name prefix (ConstantExample in this example).

// An example of the using clause where the alias can denote
// namespaces and classes.
using System;
using IONS=System.IO; // Namespace alias.
using Alist=System.Collections.ArrayList; // Class alias.
public class NamespaceExample
{
    public static void Main(Args a)
    {
        Int32 I; // Alternative to System.Int32.
        Alist al; // Using a class alias.
        al = new Alist();
        str s;
        al.Add(1);
        IONS.Path::ChangeExtension(@"c:\tmp\test.xml", ".txt");
    }
}
```

var

You can declare a variable without explicitly providing the type of the variable, if the compiler can determine the type from the initialization expression. The variable is still strongly-typed into one, unambiguous type.

You can use **var** only on declarations where initialization expressions are provided. (The compiler will infer the type from the initialization expression.) In some cases, this approach can make code easier to read.

You should use **var** to declare local variables in these situations:

- When the type of the variable is obvious from the right side of the assignment
- When the exact type isn't important
- For the declarations of **for** loop counters
- For disposable objects inside **using** statements

Don't use **var** when the type isn't clear from the initialization expression.

var examples

```
// When the type of a variable is clear from
// the context, use var in the declaration.
var var1 = "This is clearly a string.";
var var2 = 27; // This is an integer (not a real).
var i = System.Convert::ToInt32(3.4);

// Don't use var when the type of the variable is not clear
// from the context. Use an explicit type instead.
int var4 = myObject.ResultSoFar();
```

Declare anywhere

Declarations can now be provided wherever statements can be provided. A declaration is syntactically a statement, a *declaration statement*.

You can provide declarations immediately before the variable is used, and you don't have to declare all the variables in one place. Therefore, you have precise control over the scope of your variables.

You can give variables smaller scopes, outside which the variables can't be referenced. The lifetime of the variable is the scope that it's declared in. Scopes can be started at the block level (inside compound statements), in **for** statements, and in **using** statements.

There are several advantages to making scopes small:

- Readability is enhanced.
- You reduce the risk that a variable will be reused in an inappropriate manner during long-term maintenance of the code.
- It's easier to refactor code. You can copy in code without having to worry that variables might be reused in contexts where they shouldn't be reused.

In the following example, we declare the loop counter inside the **for** statement that it's used in.

```
void MyMethod()
{
    for (int i = 0; i < 10; i++)
    {
        info(strfmt("i is %1", i));
    }
}
```

The scope of the variable is the **for** statement itself, and includes the condition expression and the loop update parts. The value can't be used outside this scope.

In the following example, when the compiler reaches the **info** statement, it will issue the following error message: "'i' isn't declared."

```
void MyMethod()
{
    for (int i = 0; i < 10; i++)
    {
        if (i == 7)
        {
            break;
        }
    }
    // The next statement causes a compiler error.
    info(strfmt("Found: %1", i));
}
```

You can also scope variables to a **using** statement, as shown in the following example.

```
static void AnotherMethod()
{
    str textFromFile;
    using (System.IO.StreamReader sr = new System.IO.StreamReader("c:\\test.txt"))
    {
        textFromFile = sr.ReadToEnd();
    }
}
```

When you use an object that implements **IDisposable**, you should declare and instantiate that object in a **using** statement. The **using** statement calls the **Dispose** method on the object correctly, even if an exception occurs while you're calling methods on the object. You can achieve the same result by putting the object inside a **try** block and then explicitly calling **Dispose** in a **finally** block. In fact, the compiler translates the **using** statement in just this manner.

The following example shows some of the features that we have been describing.

```
// loop variable declared within the loop: It will
// not be misused outside the loop
for(int i = 1; i < 10; i++)
{
    // Because this value is not used from outside the loop,
    // its declaration belongs in this smaller scope.
    str s = int2str(i);
    info(s);
}
```

To prevent confusion, the compiler issues an error message if you try to introduce a variable that will hide another variable in an enclosing scope, or even in the same scope. For example, the following code will cause the compiler to issue the following diagnostic message: "A local variable named 'i' can't be declared in this scope because it would give a different meaning to 'i', which is already used in a parent or current scope to denote something else."

```
{
    int i;
    {
        int i;
    }
}
```

Constants, read-only variables, and macros

The concept of macros is fully supported. Constants have the following advantages over macros:

- You can add a documentation comment to a constant but not to the value of a macro. Eventually, the language service will pick up this comment and provide useful information to the user.
- A constant is known by IntelliSense.
- A constant is cross-referenced. Therefore, you can find all references for a specific constant but not for a macro.
- A constant is subject to access modifiers. You can use the **private**, **protected**, and **public** modifiers. The accessibility of macros isn't rigorously defined.
- Constant variables have scope, whereas macros don't have scope.
- You can see the value of a constant or a read-only variable in the debugger.

Macros that are defined in class scopes (that is, in class declarations) are effectively available in all methods of all derived classes. This feature was originally a bug in the implementation of the legacy compiler macro, however, many application programmers often take advantage of it now. The X++ compiler still honors this feature, but no new code that uses it should be written. This feature also has a significant effect on the performance of the compiler.

Constants can be declared at the class level, as shown in the following example.

```
private const str MyConstant = 'SomeValue';
```

The constants can then be referenced by using the double colon (::) syntax.

```
str value = MyClass::MyConstant;
```

If you're in the scope of the class where the constant (**const**) is defined, you can omit the type name prefix (**MyClass** in the preceding example). Therefore, you can easily implement the concept of a macro library. The list of macro symbols becomes a class that has public **const** definitions.

You can also define constants as variables only. The compiler will maintain the invariant so that the value can't be modified.

```
{
    const int Blue = 0x0000FF;
    const int Green = 0x00FF00;
    const int Red = 0xFF0000;
}
```

Null values for data types

The concept of **null** values that is available in many other database management systems (DBMSs) is not supported. A variable in X++ always has a type and a value, however, for each data type, one value is considered **null** (for example, when the **validateField** table method is run).

TYPE	VALUE THAT IS TREATED AS NULL
Date	1900-01-01
Enum	An element that has its value set to **0**
Integer	0

TYPE	VALUE THAT IS TREATED AS NULL
Real	0.0
String	An empty string
Time	00:00:00
Utcdatetime	Any value that has its date portion set to **1900-01-01**, regardless of the value of the time portion. For example, the value **1900-01-01T22:33:44** is treated as **null**. Note that any **utcDateTime** value that has its date portion set to **1900-01-01** is shown as blank by the X++ **print** statement. Only the value **1900-01-01T00:00:00** is shown as blank by the **Global::info** method. That value is the value from the **DateTimeUtil::MinValue** method.

When the **validateField** method checks whether a user has entered a value in a mandatory field, **0** isn't accepted in an **integer** type field, the first entry isn't accepted in an **enum** type field, and so on. Additionally, in SQL X++ statements, the values that are listed in the previous table yield **false** in a Boolean comparison. However, in non-SQL X++ statements, the equal and relational operators work with these values, just as they work with other values. Variables of the **container** type, and classes and variables of the **table** type can be **null** in the traditional DBMS sense. A **table** type is **null** if all its fields have their **null** value.

X++ Primitive data types

2/18/2021 • 17 minutes to read • Edit Online

This topic describes primitive data types in X++. The primitive data types in X++ are **anytype**, **boolean**, **date**, **enum**, **guid**, **int**, **int64**, **real**, **str**, **timeOfDay**, and **utcdatetime**.

anytype

The **anytype** data type is a placeholder for any data type. You should use variables of this type only as arguments and return values.

To use **anytype** as a variable, you must first assign a value to it, otherwise, a run-time error occurs. After you've assigned a value to **anytype**, you can't convert it to another data type.

Although you can use **anytype** variables in expressions, they're usually used as arguments and return types. The size, precision, scope, default value, and range of **anytype** depend on the conversion type that you assign to it. You can use **anytype** just as you use the data type that you convert it to. For example, if you assign an integer, you can then apply relational and arithmetic operators to the variable.

An **anytype** variable is automatically converted to a date, enumeration (enum), integer, real, string, extended data type (EDT) (record), class, or container when a value is assigned to the type. Additionally, the following explicit conversion functions can be used: **any2date**, **any2enum**, **any2int**, **any2real**, and **any2str**. You can't change the variable to another data type after you've converted it to **anytype**.

anytype examples

```
// An example of using anytype variables.
public static str range(anytype _from, anytype _to)
{
    return queryValue(_from) + '..' + queryValue(_to);
}

// Another example of using anytype variables.
void put(int position, anytype data)
{
    record = conPoke (record, position, data);
}

public void AnytypeMethod()
{
    // An example of automatic conversion for anytype.
    anytype a;
    a = "text"; // Automatically assigns a string literal.
}
```

boolean

The **boolean** data type contains a value that is evaluated as either **true** or **false**. You can use the reserved literal keywords **true** and **false** wherever a **boolean** expression is expected. The size of a **boolean** is 1 byte. The default value is **false**, and the internal representation is a short number.

A **boolean** is automatically converted to an **int**, **date**, or **real**. It has no explicit conversion functions. The internal representation of a **boolean** is an integer. You can assign any integer value to a variable that is declared as the **boolean** type. The integer value **0** (zero) is evaluated as **false**, and all other integer values are evaluated

as **true**. Because the internal representation of a **boolean** is an integer, **boolean** values are automatically converted to integers and reals.

boolean examples

```
public void BooleanMethod()
{
    // Simple declaration of a boolean variable, b.
    boolean b;

    // Multiple declarations of booleans.
    boolean b1, b2;

    // Boolean variable is initialized to true.
    boolean b3 = true;

    // Declares a dynamic array of booleans.
    boolean b4[];

    // This example shows the most common usage of a boolean: a boolean in
    // a conditional statement and as a result of a logical expression.
    void main()
    {
        // Declares a boolean called exprValue.
        boolean exprValue;

        // Assigns ExprValue the value of (7*6 == 42), which equates to true.
        exprValue = (7*6 == 42);

        // If the conditional statement is true, print "OK".
        if (exprValue)
        {
            print "OK";  //"OK" is printed because the expression is true.
        }
    }
}
```

date

The **date** data type contains the day, month, and year. Dates can be written as literals by using the following syntax: **Date literal = day \ month \ year**. You must use four digits for the year.

The **date** data type can hold dates between January 1, 1900, and December 31, 2154. The size of a **date** is 32-bits. The default value is **null**, and the internal representation is a date.

A **date** has no implicit conversions, however, the following explicit conversion functions can be used: **str2date**, **date2str**, **date2num**, and **int2date**.

You can add and subtract integers from dates, which moves the date some days into the future and past respectively. Subtracting dates from each other will calculate the difference in days, however, adding two dates together is not possible and will lead to a compiler error.

date examples

```
public void DateMethod()
{
    // Simple declaration of a date variable, d.
    date d;

    // Multiple declaration of two date variables.
    date d1, d2;

    // A date variable, d3, is initialized to the 21st of November 1998.
    date d3 = 21\11\1998;

    // Declaration of a dynamic array of dates.
    date d4[];

    // Using arithmetic operators with integer variables and dates.
    void myMethod()
    {
        int anInteger;
        date aDate;
        // Sets the date variable aDate to January 1, 1998.
        aDate = 1\1\1998;
        // Sets the integer variable anInteger to 30.
        anInteger = 30;
        // Uses an integer value in the computation of dates.
        // This sets aDate to aDate + 30; that is the 31st of January 1998.
        aDate = aDate + anInteger;

        // Create 2 variables, set bDate, and then subtract from that date.
        date bDate;
        int dateDifference;
        bDate = 2\10\1998;
        dateDifference = bDate - aDate; // dateDifference will equal 244.
    }
}
```

enum

An **enum** is a list of literals. Before you can use an **enum**, you must declare it in Application Explorer.

The literal values are represented internally as integers. The first literal has the number 0, the next literal has the number 1, the next literal has the number 2, and so on. You can use **enum** values as integers in expressions. The default value for the first entry is **0**, and the internal representation is a short number.

An **enum** value is automatically converted to a **boolean**, **int**, or **real**. Additionally, the following explicit conversion functions can be used: **enum2str** and **str2enum**.

Hundreds of enumerable types are built into the standard application. For example, the **NoYes** enum has two associated literals: **No** has the value **0**, and **Yes** has the value **1**. You can create as many enum types as you want, and you can declare up to 251 (0 to 250) literals in a single enum type. To reference an **enum** value, enter the name of the enum, two colons, and then the name of the literal. For example, to use the literal **No** in the **NoYes** enum, enter **NoYes::No**.

Create an enum

1. In Solution Explorer, right-click the project, point to **Add**, and then click **New Item**.
2. Under **Artifacts**, select **Data Types**.
3. Click **Base Enum** to select the new item type.
4. In the **Name** field, enter a name for the enum, and then click **Add**. A new enum is added to the project, and the enum designer for the new element is opened.
5. In the enum designer, right-click the enum name, and then click **New Element**.
6. In the **Properties** window, enter the name of the enum element.

enum examples

```
public void EnumMethod()
{
    // Declare the enum (a NoYes enum) in the Application Explorer.
    NoYes done;

    // An array of Criteria enums.
    Criteria crit[100];
}
```

guid

The **guid** data type holds a *globally unique identifier* (GUID) value. A GUID is an integer that can be used across all computers and networks, wherever a unique identifier is required. It's unlikely that the number will be duplicated. A valid GUID meets all the following specifications:

- It must have 32 hexadecimal digits.
- It must have four dash characters that are embedded at the following locations: 8-4-4-4-12.
- Braces ({}) at the beginning and end of a string are optional. For example, both "12345678-BBBb-cCCCC-0000-123456789012" and "{12345678-BBBb-cCCCC-0000-123456789012}" are valid GUID strings.
- It must have a total of either 36 or 38 characters, depending on whether braces are added.
- The hexadecimal digits a–f (or A–F) can be uppercase, lowercase, or mixed.

The size of a **guid** is 16 bytes or 128-bits. The following explicit conversion functions can be used: **any2guid**, **guid2str**, **newGuid**, **str2guid**, **Global::guidFromString**, and **Global::stringFromGuid**.

guid examples

The following set of examples shows how to use the **guid** functions. The code output of these examples follows.

```
// An example of how to use the GUID functions.
static void GuidRoundTripJob(Args _args)
{
    guid guid2;
    str string3;

    // Convert a guid to a string, and back to a guid.
    guid2 = newGuid();
    info(strFmt("Info_a1:  guid2 == %1", guid2));
    string3 = guid2str(guid2);
    info(strFmt("Info_a2:  string3 == %1", string3));
    guid2 = str2guid(string3);
    info(strFmt("Info_a3:  guid2 == %1", guid2));

    // Test string representations of a guid. Mixing upper and lower case letters does not affect the guid.
    guid2 = str2guid("BB345678-abcd-ABCD-0000-bbbbffff9012");
    string3 = guid2str(guid2);
    info(strFmt("Info_b1:  8-4-4-4-12 format for dashes works (%1)", string3));
    info(strFmt("Info_b2:  Mixed upper and lower case works."));

    // Test invalid dash locations, see output is all zeros. Dash locations must be exact.
    guid2 = str2guid("CC2345678abcd-ABCD-0000-cccc9012");
    string3 = guid2str(guid2);
    info(strFmt("Info_c1:  These embedded dash locations are required.  %1", string3));

    // Braces {} are optional.
    guid2 = str2guid("{DD345678-abcd-ABCD-0000-ddddaaaa9012}");
    string3 = guid2str(guid2);
    info(strFmt("Info_d1:  Braces {} are optional (%1)", string3));
}
```

guid code output

The following output appears in the Infolog. Note that the string includes the optional braces.

```
Message (02:26:46 pm)
Info_a1:  guid2 == {93945629-734B-475E-99CE-6AA7AFA43259}
Info_a2:  string3 == {93945629-734B-475E-99CE-6AA7AFA43259}
Info_a3:  guid2 == {93945629-734B-475E-99CE-6AA7AFA43259}
Info_b1:  8-4-4-4-12 format for dashes works ({BB345678-ABCD-ABCD-0000-BBBBFFFF9012})
Info_b2:  Mixed upper and lower case works.
Info_c1:  These embedded dash locations are required.  {00000000-0000-0000-0000-000000000000}
Info_d1:  Braces {} are optional ({DD345678-ABCD-ABCD-0000-DDDDAAAA9012})
```

int and int64

Integers are numbers that have no decimal places. There are two integer types: **int** and **int64**. Integers are used as control variables in repetitive statements or as indexes in arrays.

You can also use *integer literals* anywhere that an integer expression is expected, and both relational and arithmetic operators can be applied. An integer literal is the integer as it's entered directly in the code, such as **32768**. An **int** is 32-bits wide, and an **int64** is 64-bits wide. The default value is **0**, and the internal representation is a long number. An integer is automatically converted to a **boolean**, **enum**, or **real**.

Additionally, the following explicit conversion functions can be used: **str2int**, **int2str**, **str2int64**, and **int642str**. The range of an **int** is [-2,147,483,647 : 2,147,483,647], and the range of an **int64** is [-9,223,372,036,854,775,808 : 9,223,372,036,854,775,808]. All integers in either of these ranges can be used as literals.

int and int64 examples

The following example shows how to declare integers and use them in expressions. If you try to assign the largest integer plus 1 to an **int64**, you get the wrong result, because the number is interpreted as a 32-bit number. Therefore, the number is wrapped around and stored instead as -2,147,483,647. To prevent this behavior, add "u" to the end of the number. For example, enter **int64 i = 0x8000 0000u** (0x8000 0000 is 2,147,483,648).

```
public void IntegerMethod()
{
    // Declaration of an integer variable, i.
    int i;

    // Declaration of two int64 variables.
    int64 i1, i2;

    // An integer variable is initialized to the value 100.
    int i3 = 100;

    // Declaration of a dynamic array of integers.
    int i4[];
    void element()
    {
        // Two integer variables are declared and initialized.
        int k = 1, j = 2;

        // j is assigned the result of j + ((i + i) DIV 2).
        j +=(i + i) div 2;

        // This results in: j=3.

        if (j > 2 )
        {
            print "J is greater than 2";
        }
        else
        {
            print "J is NOT greater than 2";
        }
    }
}
```

real

A **real** variable can hold decimal values in addition to integers. You can use *decimal literals* anywhere that a **real** is expected. A decimal literal is the decimal as it's entered directly in the code, such as **2.123876**. Real literals can also be written by using exponential notation, such as **1.0e3**.

Reals can be used in all expressions, and they can be used with both relational and arithmetic operators. A **real** has a precision of 16 significant digits. The default value for a **real** is **0.0**, and the internal representation is a binary-coded digital (BCD) number. The BCD encoding enables exact representations of values that are multiples of 0.1. The range of a **real** variable is $-(10)^{127}$ through $(10)^{127}$. All reals in this range can be used as literals in X++.

A **real** variable is automatically converted to a **boolean**, **enum**, or **int**. If the result is an integer, or if the operator is an integer operator, the **real** is converted to an integer. If the result is a **boolean**, the **real** is converted to a **boolean**, and so on. Additionally, the following explicit conversion functions can be used: **str2num** and **num2str**.

Direct assignments between X++ **real** and the Microsoft .NET Framework **System.Decimal** convert the value correctly. A call to a conversion function isn't required. A *decimal number* is a floating-point value that consists of a sign, a numeric value where each digit is in the range 0 through 9, and a scaling factor that indicates the position of a floating decimal point that separates the integral and fractional parts of the numeric value. The binary representation of a **real** value consists of a 1-bit sign, a 96-bit integer number, and a scaling factor. The scaling factor is used to divide the 96-bit integer and specify what part of it is a decimal fraction. The scaling factor is implicitly the number 10 raised to an exponent in the range 0 through 28. Therefore, the binary representation of a decimal value represents ([-2^{96} through 2^{96}] ÷ 10(0\ through\ 28)), where $-(2^{96}-1)$ is the minimum value that can be expressed and $2^{96}-1$ is the maximum value.

> **NOTE**
>
> The type that is used to represent **real** values in Finance and Operations applications has changed from the interpreted X++ of Microsoft Dynamics AX 2012. However, you don't have to rewrite any code, because the new type can express all the values that the old type could express. We provide this material in the interest of full disclosure only.

All instances of the **real** type are now implemented as instances of the .NET decimal type (**System.Decimal**). Just as the **real** type in previous versions, the decimal type in a binary-coded decimal type is resilient to rounding errors. The range and resolution of the decimal type differ from previous versions. The original X++ **real** type supported 16 digits and an exponent that defined the position of the decimal point. However, the X++ **real** type for Finance and Operations applications can represent decimal numbers in the range 79,228,162,514,264,337,593,543,950,335 (2^{96}-1) through -79,228,162,514,264,337,593,543,950,335 (-[2^{96}-1]).

Rounding is still required for the new **real** type. For example, the following code produces a result of 0.99999999999999999999999999 instead of 1. No number of decimals will suffice to represent the value of 1/3 accurately. The discrepancy obtained here is due to the fact that only a finite number of decimals are provided. You should use the **round** function to round to the number of decimals required.

```
// An example of using the debugger to show the value of the variables.
public static void UseTheDebugger(Args a)
{
    real dividend = 1.0;
    real divisor = 3.0;
    str stringvalue;
    System.Decimal valueAsDecimal;
    real value = dividend/divisor * divisor;
    valueAsDecimal = value;
    info(valueAsDecimal.ToString("G28"));
    // An example of using the Round function to round to the number of decimals required.
    value  = round(value, 2);
}
```

real examples

```
public void RealMethod()
{
    // Simple declaration of a real variable, r.
    real r;

    // Multiple declaration of two real variables.
    real r1, r2;

    // A real variable is initialized to the approximate value of pi.
    real r3 = 3.1415;

    // Declaration of a dynamic array of reals.
    real r4[];

    // An example of a real literal written using exponential notation.
    real r;
    r = 1.000e3;
    r = 1.2345e+3;
    r = 1.2345e+03;
    r = 1234.5e4;
    r = 1.0e1; // Means 1.0E1
}

// An example of automatic conversions.
void main()
{
    // Declares a variable of type integer with the name exprValue.
```

```
    int exprValue;

    // Declares a real variable with the name area.
    real area = 3.141528;
    exprValue = Area/3;

    // The expression Area/3 is a real expression because
    // division is a real operator, and the result is 1.047176. This result is
    // automatically converted (actually truncated) to an integer with the value 1,
    // because exprValue is an integer.
}

// An example of a real being converted to .NET System.Decimal.
void AnotherMain(Args _args)
{
    real real9;
    System.Decimal sysdec1;

    // Direct assignments supported between these types.
    sysdec1 = 2.3456;
    real9 = sysdec1;
    info(strFmt("strFmt says real9 == %1", real9));
}

/***
Message (05:48:43 pm)
strFmt says real9 == 2.35
***/

// An example of using reals in expressions.
void myMethod()
{
    // Two real variables are declared and initialized.
    real i = 2.5, j = 2.5;

    // j is assigned the result of j * i, so j=6.25.
    j = j * i;
    if (j > (i * 2)) // If j > 5
    {
        print "Great"; // "Great" is printed.
    }
    else
    {
        print "Oops"; // else "Oops" is printed.
    }
}
```

str

A **str** variable (a *string*) is a sequence of characters that are used as texts, help lines, addresses, telephone numbers, and so on.

To declare a string, use the **str** keyword.

String literals are characters that are enclosed in quotation marks (""). String literals can be used wherever string expressions are expected. Examples of string literals include "StringLit" and "Hello World". If you want the string to span more than one line, precede it with an at sign (@). You can use strings in logical expressions, such as comparisons. You can also concatenate strings by using the + operator.

The default value for a string is **empty**, and the internal representation is a list of characters. There are no automatic conversions for strings, however, the following explicit conversion functions can be used: **str2int**, **str2int64**, **int2str**, **str2num**, **num2str**, **str2date**, and **date2str**.

A string can hold an unlimited number of characters, however, you can specify the maximum length of a string

in the variable declaration. The string is then truncated to that maximum length. An example is shown in the next section.

str examples

```
void StringMethod()
{
    // Declare a dynamic string of unlimited length.
    str unlimitedString;

    // Declare a string with a maximum of 64 characters
    // in order to force a truncation, initialized to "A".
    str 64 maxLengthString = "A";

    // Declare an array of 100 strings.
    str 30 hundredStrings[100];

    // Using strings in expressions.
    void myMethod()
    {
        // Two strings are declared and initialized.
        str a="Hello", b="World";

        // The concatenation of a, " " and b is printed in a window.
        print a+" "+b;
    }
}
```

timeOfDay

The **timeOfDay** (time) data type is an integer value that represents the number of seconds that have passed since midnight. Like integers, **timeOfDay** variables can be used as literals. Relational and arithmetic operators can be applied to **timeOfDay** variables. A **timeOfDay** variable can also be used in expressions. The range of a **timeOfDay** data type is in the closed interval [0; 86,400]. Values above 86,400 (23:59:59) can't be interpreted. A **timeOfDay** variable is automatically converted to a **boolean**, **enum**, or **real**. Additionally, the following explicit conversion functions can be used: **str2time** and **time2str**.

timeOfDay examples

```
public void TimeofdayMethod()
{
    // Declaration of a timeOfDay variable, time1.
    timeOfDay time1;

    // Declaration and initialization of a timeOfDay variable to 00:21:35.
    timeOfDay time2 = 1295;
}
```

utcdatetime

The **utcdatetime** data type combines the **date** type and the **timeOfDay** type. A **utcdatetime** variable also holds information about the time zone, however, this information can't be accessed in code.

The format for a **utcdatetime** literal is **yyyy-mm-ddThh:mm:ss**. The uppercase "T" is required. This format can be written without quotation marks. The minimum value is **1900-01-01T00:00:00**, and the maximum value is **1900-01-01T00:00:00**. This maximum value matches the upper range of **date** and **timeOfDay**. The smallest unit of time in **utcdatetime** is one second.

A **utcdatetime** variable that has been declared but hasn't been initialized has the default value **1900-01-**

01T00:00:00. This value is the value that is returned by **DateTimeUtil::minValue()**. Some functions treat an input parameter of this minimum value as **null**. For example, the **DateTimeUtil::toStr** method returns an empty string, however, the **DateTimeUtil::addSeconds** method returns a usable **utcdatetime** value.

There are no implicit conversions for the **utcdatetime** data type. The **DateTimeUtil** class provides many methods that you can use to manipulate **utcdatetime** values.

The following explicit conversion functions can also be used: **str2datetime** and **datetime2str**.

Additionally, the **Global** class provides the **utcDateTime2SystemDateTime** and **CLRSystemDateTime2UtcDateTime** conversion methods to support common language runtime (CLR) interop.

Comparison operators are the only type of operators that can be used with the **utcdatetime** data type. The following operators can be used to compare two **utcdatetime** values: !=, <, <=, ==, >, and >=. When you add a **utcdatetime** field to a table, we recommend that you base the field on an EDT.

utcdatetime examples

```
public void UtcdatetimeMethod()
{
    // Declaring a utcdatetime literal.
    utcdatetime myUtc2 = 1988-07-20T13:34:45;

    // Another example of declaring a utcdatetime literal.
    int iDay = DateTimeUtil::day(1988-07-20T13:34:45);

    // utcdatetime using a quoted string parameter into the DateTimeUtil::parse method.
    utcdatetime myUtc4 = DateTimeUtil::parse("1988-07-20T13:34:45");
}
```

X++ composite data types

2/18/2021 • 21 minutes to read • Edit Online

This topic describes composite data types in X++. The composite data types in X++ are arrays, containers, classes as data types, delegates as data types, and tables as data types.

Array

An *array* is a variable that contains a list of items that have the same data type. The elements of an array are accessed by using integer indexes. You use a separate statement to initialize each element in an array. When you use a container data type or an array object to create a collection, you can initialize multiple elements by using a single statement. By default, all the items in an array have the default value of the data type in the array. There are three kinds of arrays: *dynamic arrays*, *fixed-length arrays*, and *partly on disk arrays*.

- **Dynamic arrays** – These arrays are declared by using an empty array option. In other words, they have only brackets ([]).
- **Fixed-length arrays** – These arrays can hold the number of items that is specified in the declaration. Fixed-length arrays are declared like dynamic arrays, but a length option is included in the brackets.
- **Partly on disk arrays** – These arrays are declared as either dynamic arrays or fixed-length arrays that have an extra option that declares how many items should be held in memory. The other items are stored on disk and are automatically loaded when they are referenced.

X++ supports only one-dimensional arrays. However, you can mimic the behavior of multiple array indexes. (For more information, see the Multiple array indexes section). Variables in objects and tables can be declared as arrays. For example, this functionality is used in address lines in the standard application. An array collection class lets you store objects in an array.

Array indexes begin at 1. The first item in the array is referenced as [1], the second item is referenced as [2], and so on. The following syntax is used to access an array element: **ArrayItemReference = ArrayVariable [Index]**. In this syntax, **ArrayVariable** is the identifier of the array, and **Index** is the number of the array element. **Index** can be an integer expression. Item zero [0] is used to clear the array. If a value is assigned to index 0 in an array, all elements in the array are reset to their default value.

Array examples

```
public void ArrayMethod()
{
    int myArray[10]; // Fixed-length array with 10 integers.
    myArray[4] = 1; // Accessing the 4th element in the array.
    myArray[0] = 0; // Resets all elements in intArray.

    // Dynamic array of integers.
    int intArray[];

    // Dynamic array of variables of type Datatype.
    //Datatype arrayVariable[];

    // Fixed-length arrays.
    boolean boolArray[100]; // Fixed-length array of booleans with 100 items.

    // Two examples of Partly On Disk Arrays.
    // Dynamic integer array with only 100 elements in memory.
    int arrayVariable [ ,100];
    // Fixed-length string array with 1000 elements, and only 200 in memory.
    str arrayVariable2 [1000,200];

    // A dynamic array of integers.
    int i[];
    // A fixed-length real array with 100 elements.
    real r[100];
    // A dynamic array of dates with only 10 elements in memory.
    date d[,10];
    // A fixed length array of NoYes variables with 100 elements and 10 in memory.
    NoYes ny[100,10];
}
```

Multiple array indexes

Some languages, such as C++ and C#, let you declare arrays that have more than one index. In other words, you can define "arrays of arrays." In X++, you can't directly create multiple array indexes because only one-dimensional arrays are supported. However, you can implement multiple indexes by using the method that is described in this section. For example, you want to declare an array that has two dimensions, to hold an amount that is earned by country by dimension. There are 10 countries and three dimensions. In C++ and C#, you declare the following array.

```
// This is C# or C++ code, not X++ code.
real earning[10, 3];
```

However, X++ doesn't support this declaration. Instead, you can define a one-dimensional array where the number of elements is the product of the elements in each dimension. Here is an example.

```
public void MultipleArrayMethod()
{
    // Step 1: define a one-dimensional array with the number
    // of elements that is the product of the elements in each dimension.
    real earnings[10*3];

    // Step 2: to refer to a specific element, such as earnings[i,j], write the following:
    // declare i and j (maybe) and assign the value to something
    int i = 1;
    int j = 2;
    real element = earnings[(i-1)*3 + j];
}

// This can be written into a macro like this:
#localmacro.earningIndex
(%1-1)*3+%2
#endmacro

public void CallTheMacro()
{
    // Next, call the specific element within the macro like this:
    int i = 1;
    int j = 2;
    real element = earnings[#earningIndex(i,j)];

    // The previous scheme can be extended to any number of dimensions.
    // The element a[i1, i2, ..., ik] can be accessed by computing the
    // offset into an array containing (d1*d2*...*dk) elements.
    //(i1 - 1)*d2*d3*..*dk +
    //(i2 - 1)*d3*d4*...*dk + .... +
    //(ik-1 -1)*dk +
    //(ik-1)
}
```

Container

A *container* object is a dynamic list of items that contains primitive data types or composite data types. A container is useful when you must pass various types of values between the client and server tiers. However, if you plan to repeatedly add to a list in a loop, a container isn't a good choice. Containers are most suitable for processes that don't involve excessive modification to the size or contents of the container. When a container undergoes excessive additions of data, overall system performance can decrease because container data must be repeatedly copied and new space must be repeatedly allocated.

A container isn't a class. A container contains an ordered sequence of primitive values or other containers. Because of the flexibility of **anytype**, a container offers a good way to store values of different types together. A container can be stored in the database. A container is one of the column types that you can select when you use Application Explorer to add a column to a table. A container slightly resembles an array, or collections, such as the **List** or **Stack** classes. However, you can never change the size or content of a container after the container is created.

X++ statements that appear to modify a container are internally building a new container and copying values as required. Even an assignment of a container to another container variable creates a new copy of the container. All these operations can affect performance. In the functions that provide access to a container (such as **conPeek**), the container is 1-based, not 0-based. Indexing is 1-based for arrays. The default value of a container is **empty**. The container doesn't contain any values. Some statements that use containers might appear to modify a container, however, inside the system, containers are never modified. Instead, the data from the original container is combined with data from the command to build a new container. You can create a new container by using one of the following functions: **conDel**, **conIns**, or **conPoke**.

Additionally, the **Global** class has static methods for handling containers. These methods include

con2ArraySource, **con2Buf**, **con2List**, **con2Str**, **containerFromXmlNode**, **conView**, and **str2Con**. There are several intrinsic functions for handling a container, such as **conIns** and **conPeek**. The X++ **conPeek** function returns an **anytype** type, therefore, it's easier to read the values from a container when you don't know the type of each value. An **anytype** can be assigned to any X++ value type, provided that the value can be converted. Your code is easier to read when it avoids explicit data type conversions. Therefore, assign values from a container to the same data type that was used to put the value into the container. You must not assign a container to an **anytype** because the system might not be able to determine the correct conversions. In these cases, unexpected behavior or errors might occur.

Comparing container to other options

The **container** type resembles other constructs, such as arrays and collection classes, such as **List** and **Stack**. The difference between a **container** and **List** is that an instance of the **List** class is mutable. A **List** object first allocates more space than its data consumes. Then, as data is added, the space is filled. This behavior is more efficient than allocating more space every time that an element is added. An update of a **List** performs faster than similar operations on a container.

When you construct a **List** object, you determine the one type of data that the **List** object can store. This restriction is less flexible for a **List** than it is for a container. However, you can store objects in a **List**, whereas a container can store only value types. The difference between a container and an array is that an array can hold only items of its declared type. You can allocate memory space for an array and fill that space with values later. For example, you can fill in values in a loop. This behavior is efficient and performs well. When you want to build a new container by appending new data, you can use either the **+=** operator or the **conIns** function. The **+=** operator is the faster alternative. Use the **conIns** function only when you want to add new data before the last index of the original data.

In Dynamics AX 2012, although you could use the X++ compiler to store object references in containers, the result would fail at run time. However, in Finance and Operations applications, when the compiler sees an attempt to store an object reference in a container, it issues an error message. If the type of the element that is added to the container is **anytype**, the compiler can't determine whether the value is a reference type. In this case, the compiler allows the attempt. Although the compiler doesn't diagnose the code as erroneous, an error will be thrown at run time.

Container examples

```
public void ContainerExample()
{
    // First, declare the variables you are using.
    container myContainer;
    container myContainer4;
    container myContainer5;
    // Three ways to declare a container.
    myContainer = [1];
    myContainer += [2];
    myContainer4 = myContainer5;

    // Declare a container.
    container cr3;

    // Assign a literal container to a container variable.
    cr3 = [22, "blue"];

    // Declare and assign a container.
    container cr2 = [1, "blue", true];

    // Mimic container modification (implicitly creates a copy).
    cr3 += [16, strMyColorString];
    cr3 = conIns(cr3, 1, 3.14);
    cr3 = conPoke(cr3, 2, "violet");

    // Assignment of a container (implicitly creates a copy).
```

```
    cr2 = cr3;

    // Read a value from the container.
    str  myStr = conPeek(cr2, 1);

    // One statement that does multiple assignments from a container.
    str myStr;
    int myInt;
    container cr4 = ["Hello", 22, 20\07\1988];
    [myStr, myInt] = cr4; // "Hello", 22

    // Example of applying the = operator to a container. The example
    // initializes myContainer2 and myContainer33.
    myContainer2 = [2, "apple"];

    // Next, you make a copy of myContainer33 and assign the copy to myContainer2.
    myContainer33 = [33, "grape"];
    myContainer2 = myContainer33;  // The container that myContainer2 had been holding is no longer
available and cannot be recovered.
    // An example of building a new container by
    // assigning a new value to myContainer33 through the += operator.
    myContainer33 += [34, "banana"];
}

// Container example. In this example, variable2 and variable33 hold different containers.
static void JobC(Args _args)
{
    container variable2, variable33;
    variable2 += [98];
    variable33 = variable2;
    variable2 += [97];
}

// List class example. In this example, variable2 and variable33 refer to the same List object.
static void JobL(Args _args)
{
    List variable2,variable33;
    variable2 = new List(Types::Integer);
    variable2.addEnd(98);
    variable33 = variable2;
    variable2.addEnd(97);
}

// The automatic type conversion by anytype also applies to the special syntax for making multiple
// assignments from a container in one statement. This is shown in the following code example,
// which assigns a str to an int, and an int to a str.
static void JobContainerMultiAssignmentUsesAnytype(Args _args)
{
    container con2;
    int int4;
    str str7;
    con2 = ["11", 222];
    [int4, str7] = con2;
    info(strfmt("int4==11==(%1), str7==222==(%2)", int4, str7));
}

/***  Output:
Message (10:36:22 am)
int4==11==(11), str7==222==(222)
***/

static void UseQuery()
{
    // An example of how the compiler diagnoses attempts to store object in containers
    container c = [new Query()];   // This statement will cause the error message shown below.
    /*** Instance of type 'Query' cannot be added to a container. ***/

    // An example of a code that won't cause an error message, but will
    // cause an error message to be thrown at runtime.
```

```
    anytype a = new Query();
    container d = [a];
}
```

Classes as data types

A *class* is a type definition that describes both variables and methods for instances of the class. (The instances of a class are also known as *objects*.) A class is only a definition for objects, and all objects are **null** when they are declared. In Application Explorer, every application class under the **Classes** node is a data type. You can declare variables of these types in your code. You can construct instances of a class and assign the instances to variables.

Classes can be nested in source code. Nested classes are available only inside forms (such as a class that extends **FormRun**), and are used to represent controls, data sources, or data fields. An attribute decoration, such as the attribute decoration on a class or a method, can omit the suffix of the attribute name if the suffix is **Attribute**. Therefore, X++ allows **[MyFavorite]** instead of requiring **[MyFavoriteAttribute]**. Additionally, attributes are now applied to the handlers of delegates and methods, to map the handlers to those targets.

In AX 2012 and earlier versions, you could designate a method to run on either the client or the server. However, in Finance and Operations applications, all compiled X++ code is run as .NET Common Intermediate Language (CIL) on the server. There is no longer any code that is evaluated at the client site or in the browser. Therefore, the **client** and **server** keywords are now ignored. Although these keywords don't cause a compile error if they are used, they should not be used in any new code.

Private and protected member variables

Previously, all member variables that were defined in a class were protected. You can now make the visibility of member variables explicit by adding the **private**, **protected**, and **public** keywords. The interpretation of these modifiers is obvious and is aligned with the semantics for methods:

- **private** – The member variable can be used only within the class where it's defined.
- **protected** – The member variable can be used in the class where it's defined and all subclasses of that class.
- **public** – The member variable can be used anywhere. It's visible outside the confines of the class hierarchy where it's defined.

By default, member variables that aren't adorned with an explicit modifier are still protected. However, as a best practice, you should explicitly specify the visibility. As we described earlier, when a member variable is defined as **public**, it can be accessed outside the class where it's defined. In this case, you must specify a qualifier that designates the object that is hosting the variable. To specify the qualifier, use the dot notation, as you do for method calls.

In the following example, **field1** is accessed by using the explicit **this** qualifier. In this case, it might not be a good idea to make a member variable public, because that approach exposes the internal workings of the class to its consumers, and therefore creates a strong dependency between the class implementation and its consumers. You should always try to depend only on a contract, not an implementation.

```
public class AnotherClass3
{
    int field1;
    str field2;
    void new()
    {
        this.field1 = 1;   // Explicit object designated.
        field2 = "Banana";  // 'this' assumed, as usual.
    }
}
```

Static constructors and static fields

Static fields are fields that are declared by using the **static** keyword. Conceptually, static fields apply to the class, not to instances of the class. Static constructors are guaranteed to run before any static calls or instance calls are made to the class. The execution of the static constructor is relative to the user's session. You never call the static constructor explicitly. Instead, the compiler will generate code to make sure that the constructor is called exactly one time, before any other method on the class is called. A static constructor is used to initialize any static data or perform an action that must be performed only one time. You can't provide parameters for the static constructor, and it must be marked with the **static** keyword.

```
// An example of how a singleton (call instance in the example below)
// can be created using the static constructor.
public class Singleton
{
    private static Singleton instance;
    private void new()
    {
    }
    static void TypeNew()    // This is the static constructor.
    {
        instance = new Singleton();
    }

    public static Singleton Instance()
    {
        return Singleton::instance;
    }
}

// The singleton ensures that only one instance of the class
// will be called, which is consumed by the following.
{
    // Your code here.
    Singleton i = Singleton::Instance();
}
```

Class elements in Application Explorer

Under most class nodes in Application Explorer, there are two special nodes: a **classDeclaration** node and a **new** node. A **classDeclaration** always contains the X++ **class** keyword. Additional keywords, such as **extends**, can be included to modify the class. This node can also contain declarations of member variables.

In the following example, the variables **m_priority** and **m_rectangle** are members of the class.

```
// An example of a classDeclaration.
public class YourDerivedClass extends YourBaseClass
{
    int m_priority;
    Rectangle m_rectangle;
    void new(int _length, int _width)
    {
        this.m_rectangle = new Rectangle(_length, _width);
    }
}
```

A **new** operator contains logic that is run when the **new** operator is used to create an instance of the class. The logic in the **new** method might construct an object and assign that object to a variable that is declared in the **classDeclaration**. Each class can have only one **new** method. However, in the **new** method, you often should call the **new** method of the base class. To call the **new** method of the base class, call **super()**.

The following example shows the **new** method for the **YourDerivedClass** class in the previous **classDeclaration** example. In this **new** method, the code constructs an instance of the **Rectangle** class. The instance is assigned to the **m_rectangle** variable. The **this** keyword that is used in the example is optional,

however, if you include it, IntelliSense might be more helpful.

```
// An example of the new method from the previous classDeclaration example.
void new(int _length, int _width)
{
    this.m_rectangle = new Rectangle(_length, _width);
}
```

Garbage collection

Eventually during run time, most objects no longer have any variable that points to them. The system scans for these objects and erases them from memory. The memory space then becomes available for other uses. The **Object** class has a method that is named **finalize**. However, the **finalize** method isn't a destructor. The runtime never calls the **finalize** method, even when an object is collected as garbage.

System classes

In Application Explorer, under **System Documentation** > **Classes**, there is a list of the kernel classes or system classes. System classes aren't written in X++, and you can't see their source code. You can't add system classes. System classes usually have a **new** method, but they don't have a **classDeclaration** node. Every application class implicitly extends the **Object** system class. Some system classes are extended by an application class that has a similar name. For instance, **xClassFactory** is extended by **ClassFactory**. In these cases, you should not use the system class. For more information, see "Substitute application classes for system classes" in Classes and methods.

Extension methods

The extension method feature lets you add extension methods to a target class by writing the methods in a separate extension class. The following rules apply:

- The extension class must be static.
- The name of the extension class must end with the ten-character suffix **_Extension**, however, there's no restriction on the part of the name that precedes the suffix.
- Every extension method in the extension class must be declared as **public static**.
- The first parameter in every extension method is the type that the extension method extends. However, when the extension method is called, the caller must not pass in anything for the first parameter. Instead, the system automatically passes in the required object for the first parameter.
- The target of an extension method must be a class, table, view, or map application object type.

An extension class can contain private or protected static methods. These methods are typically used for implementation details and aren't exposed as extensions. The extension method technique doesn't affect the source code of the class that it extends, therefore, the addition to the class doesn't require over-layering.

Upgrades to the target class are never affected by any existing extension methods. If an upgrade to the target class adds a method that has the same name as your extension method, your extension method can no longer be reached through objects of the target class. The extension method technique uses the same dot-delimited syntax that you often use to call regular instance methods. Extension methods can access all public artifacts of the target class, but they can't access anything that is protected or private. Therefore, extension methods can be considered a type of syntactic sugar. Regardless of the target type, an extension class is used to add extension methods to the type. For example, an extension table isn't used to add methods to a table, and there's no such thing as an extension table.

```
// An example of an extension class holding a few extension methods.
public static class AtlInventLocation_Extension
{
    public static InventLocation refillEnabled(
        InventLocation _warehouse,
        boolean _isRefillEnabled = true)
    {
        _warehouse.ReqRefill = _isRefillEnabled;
        return _warehouse;
    }

    public static InventLocation save(InventLocation _warehouse)
    {
        _warehouse.write();
        return _warehouse;
    }
}
```

Delegates as data types

A *delegate* collects methods that subscribe to it. The delegate specifies the parameter signature that all its subscriber methods must share. When the delegate is called, the delegate calls each of its subscribers. A delegate never returns a value and **can't have a default value**. At first, every delegate has no subscribed methods. There is no limit on the number of parameters that a delegate can declare, and there is no limitation on the type of those parameters. The delegate body is always empty, because the delegate's only purpose is to define the contract that subscribers must conform to. A delegate doesn't have to be defined in a class. Delegates can also be defined in a table, form, or query.

Delegate examples

```
abstract class VarDatClass
{
    // delegatemethod examples
    // An example of declaring a delegate.
    delegate void notifyChange(utcdatetime _dateTime, str _changeDescription)
    {
    }

    // An example of subscribing an event handler to a delegate.
    public static void notifyStatic(utcDateTime _dateTime, str _changeDescription)
    {
        info("A notification has occurred calling static handler:" +
            DateTimeUtil::toStr(_dateTime) +
            " Message:" +
            _changeDescription);
    }
}
```

Tables as data types

All tables can be treated as class definitions. A table variable can be considered an instance (object) of the table (class) definition. For every field in a table variable, the default value is **empty**. You can address fields and create methods on tables. The methods can be invoked on instances of the table. To manipulate (that is, read, update, insert, and delete) records in tables, you must declare at least one table variable that can hold the record in focus. As a best practice, you should use the name of the table as the name of the variable but use an initial lowercase letter. Here are a few important differences between tables and objects:

- You can't allocate space for table variables. Allocation is done implicitly.
- Fields in table variables are public. You can reference them anywhere.

- Fields in table variables can be referenced by using expressions.

There is no automatic conversion, but table variables that are declared as **Common** can hold data from any table.

Scope of table variables

In most respects, table variables can be considered objects, however, unlike objects, they aren't explicitly allocated. Only a variable declaration is required. All tables are compatible with the **Common** table, just as all objects are compatible with the **Object** class. Table variables are declared as common buffers and can be used to hold data from any table. You can't access tables that don't have table variables. The principles for declaring table variables and objects are the same, except with regard to the allocation of space.

Table examples

The syntax enables various possibilities for referencing fields in records. For example, you can use the **TableName.(FieldId)** syntax.

The following example prints the contents of the fields in the current record in the Customer table.

```
// Declares and allocates space for one CustTable record.
public void myMethod()
{
    CustomerTable custTable;
}

// An example of referencing table variables.
public void printAccountNo()
{
    CustomerTable custTable;
    print custTable.AccountNo;  // Prints the field reference.
}
```

The following example uses the **fieldCnt** and **fieldCnt2Id** methods. The **fieldCnt** method counts the number of fields in a table, whereas **fieldCnt2Id** returns the ID for a field number. For example, you can use the **fieldCnt2Id** method to learn that field number 6 in a table has the ID 54. This conversion is required, because there is no guarantee that the IDs of the fields in a table are consecutive.

```
// An example of the various possibilities for referencing fields in records.
public void printCust()
{
    int i, n, k;
    CustomerTable custTable;
    DictTable dictTable;
    dictTable = new DictTable(custTable.TableId);
    n = dictTable.fieldCnt();
    print "Number of fields in table: ", n;
    for(i=1; i<=n; i++)
    {
        k = dictTable.fieldCnt2Id(i);
        print "The ", dictTable.fieldName(k),
        " field with Id=",k, " contains '",
        custTable.(k), "'";
    }
}
```

X++ collection classes

2/18/2021 • 2 minutes to read • Edit Online

This topic describes collection classes in X++.

The X++ language syntax provides two composite types: arrays and containers. These composite types are useful for aggregating values of primitive types. However, you can't store class objects in arrays or containers.

Collection classes are used to store objects. They let you create arrays, lists, sets, maps, and structs that can hold any data type, even objects. For maximum performance, the classes are implemented in C++ (they are system classes). Collection classes were previously known as *foundation classes*. The collection classes are **Array**, **List**, **Map**, **Set**, and **Struct**.

- **Array** – This class resembles the **array** type in the X++ language, but it can hold values of any single type, even objects and records. Objects are accessed in a specific order.
- **List** – This class contains elements that are accessed sequentially. Unlike an array, the **List** class provides an **addStart** method. Like the **Set** class, the **List** class provides the **getEnumerator** and **getIterator** methods. You can use an iterator to insert and delete items from a **List** object.
- **Map** – This class associates a key value with another value.
- **Set** – This class holds values of any single type. Values aren't stored in the sequence in which they are added. Instead, the **Set** object stores the value in a manner that optimizes performance for the **in** method. A **Set** object ignores any attempt to add a value that the **Set** object is already storing. Unlike the **Array** class, the **Set** class provides the **in** and **remove** methods.
- **Struct** – This class can contain values of more than one type. It's used to group information about a specific entity.

The constructor for every collection class except **Struct** takes a type parameter that is an element of the **Types** system enum. The collection instance can store items of that type only. The **Types::AnyType** enum element is a special case that can't be used to construct a collection object, such as a **Set** object. The **null** value can't be stored as an element in a **Set** object. Additionally, **null** can't be a key in a **Map** object. You can iterate through a collection object by using an iterator or enumerator. Here are typical examples that show how you can obtain an iterator.

```
new MapIterator(myMap)
myMap.getEnumerator()
```

For **Set** objects, if any elements are added or removed after an iterator is created, the iterator instance can no longer be used to read from or step through the collection.

For **Map** objects, as for **Set** objects, if any elements are removed, the iterator is no longer valid. However, a **MapIterator** object remains valid even after a call to the **Map.insert** method, regardless of whether the key is new, or whether the key already exists and only the value is being updated in the **Map** element. Code that calls **Map.insert** and depends on the iterator object remaining valid might fail if it's run as .NET Framework CIL.

You can use the collection classes to form more complex classes. For example, you can easily implement a stack by using a list where elements are always added to the beginning of the list. The newest element then occupies the top of the stack.

You can also extend the collection classes. For example, you can extend the **List** class to create a list of customer records where the operations are type-safe. In this case, the derived collection class will accept only customer records.

X++ extended data types

2/18/2021 • 2 minutes to read • Edit Online

This topic describes extended data types in X++.

Extended data types are user-defined types that are based on the **boolean**, **int**, **int64**, **real**, **str**, and **date** primitive data types, and on the **container** composite type. An EDT is a primitive data type or container that has a supplementary name and additional properties. For example, you can create a new EDT that is named **Name** and base it on a string. You can then use the new EDT in variable and field declarations in the development environment.

You can also base EDTs on other EDTs. EDTs are standard data types, but they have a specific name and additional properties. EDTs undergo the same value and type conversions as the standard data types that they are based on. Here are the benefits of EDTs:

- Code is easier to read, because variables have a meaningful data type. For example, the data type is **Name** instead of **str**.
- The properties that you set for an EDT are used by all instances of that type. Therefore, EDTs help reduce work and promote consistency. For example, account numbers (**AccountNum** data type) have the same properties throughout the system.
- You can create hierarchies of EDTs. The EDTs can inherit the appropriate properties from the parent, and you can change other properties. For example, the **ItemCode** data type is used as the basis for the **MarkupItemCode** and **PriceDiscItemCode** data types.

Create an EDT

This feature isn't implemented as a language construct. To create an EDT, follow these steps.

1. In Solution Explorer, right-click on the project, point to **Add**, and then click **New item**.
2. In the **Add New Item** dialog box, select **Installed** and then **Artifacts** in the left pane.
3. In the middle pane, select the EDT type to create.
4. Enter a name, and then click **Add**.

EDT example

```
public void EdtMethod()
{
    // Example of declaring EDT variables where
    // a UserGroupID (integer) variable is declared and initialized to 1.
    UserGroupID groupID = 1;

    // An Amount (real) variable is declared.
    Amount currency;
}
```

Comments, using, and print statements

2/18/2021 • 5 minutes to read • Edit Online

This topic describes statements in X++.

Comments

It's a good practice to add comments to your code. Comments make a program easier to read and understand. Comments are ignored when the program is compiled. Your comments can use either the **//** style or the **/*** style. However, a best practice is to use the **//** style for comments, and even for multiline comments.

```
// This is an example of a comment.
/* Here is another example of a comment. */
```

print statements

You use the **print** statement to output text through **System.Diagnostics.WriteLine** to the Visual Studio **Output** window. During testing, the **print** statement is an alternative to the **Global::info** method, which shows text in the **Infolog** window. The following table compares the **print** statement and the **info** method.

FEATURE	PRINT STATEMENT	INFO METHOD
Ease of invocation	The **print** statement automatically converts various data types into strings. It can convert multiple data types in one invocation.	The **info** method requires that the input parameter be a string.
Ability to copy contents to the clipboard	Text is easily copied from the **Output** window to the clipboard.	Text is easily easily copied from the **Infolog** window to the clipboard.
Typical usage	The **print** statement is used for convenience during testing. It can help you debug small issues without having to run a formal debugger.	The **info** method is appropriate for use in production.

Example of a print statement

The following code example demonstrates the print statement automatically converting any date type to a string. You do not need to prefix **info** with **Global::** when you call it.

```
str hello = "Hello";
int fortytwo = 42;
utcDateTime now = DateTimeUtil::utcNow();
Dialog dialog = new Dialog();

print "The print statement automatically converts data types to strings.";
print hello, " -- ", fortytwo, " -- ", now, " -- ", dialog;
// Output to the Print window:
// The print statement automatically converts data types to strings.
// Hello -- 42 -- 10/3/2011 09:18:10 pm -- 1

// int2Str converter is needed when using info().
info("Hello");
info(int2Str(fortytwo));

// Output to Infolog window:
// Hello
// 42
```

TODO comments

The compiler recognizes the string **TODO** when it occurs at the start of a comment. The **TODO** string prompts the compiler to report the rest of the comment text in the **Task List** window in Microsoft Visual Studio. To open the **Task List** window, select **View**, and then select **Task Window**. The **Task Window** reports the line number where the **TODO** comment can be found in the code.

Here are the rules for using **TODO** in comments:

- The **TODO** string can appear in a comment that uses either the **//** style or the **/*** style.
- The **TODO** string must be the very first non–white space string in the comment. A carriage return, a line feed, a tab, and a space are all considered white space.
- No white space is required between the start of the comment and the **TODO**.
- The **TODO** string is case-insensitive. However, the convention is to type **TODO** in all uppercase letters, instead of **ToDo** or another variation.
- The **TODO** string can have any characters appended to it. However, the convention is either to append a colon to the **TODO** string or to follow it with a white space.
- The rest of the comment after the **TODO** string is reported as the task description. If the comment is longer than 200 characters, it might appear truncated on the **Tasks** tab.
- The **TODO** task description can be spread over multiple lines when the **/*** comment style is used.

Examples of TODO comments

The following examples show **TODO** comments.

```
// An example of using TODO in the // style of comment.
public boolean isLate()
{
    // TODO: Finish this stub.
    return true;
}

// An example of using TODO in the /* */ style of comment.
public boolean isLate()
{
    /* TODO Finish this stub */
    return true;
}
```

Unsupported statements: changeSite, pause, and window

The **changeSite**, **pause**, and **window** keywords are no longer a part of the X++ language. These keywords will cause compilation errors if you use them.

using clauses

You use **using** clauses so that you don't have to provide the fully qualified name of a type. The **using** clause must precede the class that it applies, and it's required in every source file that you want it to apply to. Typically, all **using** clauses are put at the beginning of the source file. You can also provide aliases that introduce a short name for a fully qualified name. Aliases can denote namespaces or classes.

The following example shows a **using** clause, a namespace alias, and a class alias.

```
using System;
using IONS=System.IO; // Namespace alias
using Alist=System.Collections.ArrayList; // Class alias

class UsingClass
{
    public static void test()
    {
        Int32 I;                  // Alternative to System.Int32
        Alist al = new Alist();   // Using a class alias
        al.Add(1);
        str s = IONS.Path::ChangeExtension(@"c:\tmp\test.xml", ".txt"); // Using a namespace alias
    }
}
```

using statements

The **using** statement helps guarantee that objects that implement **IDisposable** are disposed of correctly. When you use an **IDisposable** object, you should declare and instantiate it in a **using** statement. The **using** statement calls the **Dispose** method on the object in the correct way, even if an exception occurs while you're calling methods on the object. You can achieve the same result by putting the object inside a **try** block and then explicitly calling **Dispose** in a **finally** block. The **using** statement simplifies the syntax and disposes of the object correctly. Here is the syntax for a **using** statement:

using (*expression* **) { *statement* }**

In this syntax, *statement* can be a block of statements, and *expression* declares and instantiates an object that implements **IDisposable**. The following example creates and uses a **StreamReader** object.

```
static void AnotherMethod()
{
    str textFromFile;
    using (System.IO.StreamReader sr = new System.IO.StreamReader("c:\\test.txt"))
    {
        textFromFile = sr.ReadToEnd();
    }
}
```

X++ conditional statements

2/18/2021 • 4 minutes to read • Edit Online

This topic describes conditional statements in X++. The conditional statements are **if**, **if...else**, **switch**, and the ternary operator (**?**). You use conditional statements to specify whether a block of code is executed. Different conditional statements offer advantages in different situations.

if and if...else statements

The **if** statement evaluates a conditional expression, and then executes a statement or a set of statements if the conditional expression is evaluated as **true**. You can use the **else** clause to provide an alternative statement or set of statements that is executed if the condition is evaluated as **false**. The syntax for an **if...else** statement is:

if (*expression* **)** *statement* **[else** *statement* **]**

In this syntax, both occurrences of *statement* can be compound statements (statements enclosed in braces). The *expression* in the parentheses (the conditional expression) can be any valid expression that is evaluated as **true** or **false**. All numbers except 0 (zero) are **true**. All non-empty strings are **true**. You can nest **if** statements. However, if the nesting of **if** statements becomes too deep, you should consider using a **switch** statement instead.

Examples of if and if...else statements

```
// if statement
if (a > 4)
{
   info("a is greater than 4");
}

// if... else statement
if (a > 4)
{
   info("a is greater than 4");
}
else
{
   info("a is less than or equal to 4");
}
```

switch statements

The **switch** statement is a multibranch language construct that has the same behavior as nested **if**. The expression of the **switch** statement is evaluated and checked against each case value. The case values must be constants that the compiler can evaluate.

- If a case constant matches the **switch** expression, the **case** statement is executed.
- If the case contains a **break** statement, the program then jumps out of the switch.
- If the case doesn't contain a **break** statement, the program continues and executes the next **case** statements.
- If no matches are found, the **default** statement is executed.
- If there are no matches and no **default** statement, none of the statements inside the **switch** statement are executed.

Here is the syntax for a **switch** statement:

switch (*expression*) { { **case** } [**default**: *statement*] }

The syntax for a **case** statement is:

case *expression* { , *expression* } : *statement*

In the syntax for both a **switch** statement and a **case** statement, every occurrence of *statement* can be replaced with a block of statements by enclosing the block in braces ({}).

Examples of switch statements

When you include the **break** keyword in a switch statement, the execution of the case branch terminates, and the statement following the switch is executed. As shown in the following example, if the Debtor account number is 1000, the program executes "do something", and then continues execution after the switch statement.

```
switch (Debtor.AccountNo)
{
    case "1000":
        // do something
        break;
    case "2000":
        // do something else
        break;
    default:
        // default statement
        break;
}
```

The following code examples makes the execution drop through the first case branch by omitting a break statement. If x is 10, b is assigned to a, and d is assigned to c. If x is 11, d is assigned to c. If x is 12, f is assigned to e.

```
 switch (x)
 {
     case 10:
         a = b;
     case 11:
         c = d;
         break;
     case 12:
         e = f;
         break;
 }
```

If you do not use the break statement, the program flow in the switch statement continues into the next case. Code segments A and B have the same behavior.

```
// Code segment A (break omitted)
case 13:
case 17:
case 21:
case 500:
    info("g");
    break;

// Code segment B (the values are comma-delimited)
case 13, 17, 21, 500;
    info("g");
    break;
```

Ternary operator (?)

The ternary operator (**?**) is a conditional statement that is resolved to one of two expressions. The result can be assigned to a variable. By contrast, an **if** statement provides conditional branching of the program flow but can't be assigned to a variable. Here is the syntax for the ternary operator:

expression1 **?** *expression2* **:** *expression3*

In this syntax, *expression1* must return a value of **true** or **false**. If *expression1* is **true**, the whole ternary statement returns *expression2*. Otherwise, the statement returns *expression3*. Both *expression2* and *expression3* must have the same type.

Examples of the ternary operator (?)

The following code example returns one of two strings based on a Boolean return value from a method call. The Boolean expression indicates whether the CustTable table has a row with a RecId field value of 1. If this Boolean expression is true (meaning RecId != 0), found is assigned to result. Otherwise, the alternative not found is assigned to result.

```
result = (custTable::find("1").RecId) ? "found" : "not found";
```

You can nest statements with the ternary operator. The following example assigns one of three values to **level** based on the value of **x**.

```
int x = 1001;
str level = x <= 1000 ? "A" : (x <= 2000 ? "B" : "C");
info(level);
// Output is "B".
```

X++ loop statements

2/18/2021 • 3 minutes to read • Edit Online

This topic describes loop statements in X++.

There are three loop statements: **for**, **while**, and **do...while**. A loop repeats its statement until the condition that is set for the loop is **false**. Within the loop statements, you can use **break** and **continue** statements.

for loops

The syntax of a **for** loop is:

for (*initialization* **;** *test* **;** *increment* **) {** *statement* **}**

The **for** loop repeatedly executes **statement** for as long as the conditional expression *test* is **true**. *statement* can be a block of statements. The body of the **for** loop (*statement*) might be executed zero or more times, depending on the results of *test*.

A **for** loop differs from other loops because an initial value can be assigned to a control variable, and because there is a statement for incrementing or decrementing the variable. These additions make a **for** loop especially useful for traversing lists, containers, and arrays because they have a fixed number of elements.

You can also apply a statement to each element and increment your way through the elements, setting the condition to test for the last element.

Example of a for loop

In the following code example, the items in an array of integers are printed.

```
int integers[10];
for (int i = 0; i < 10; i++)
{
    info(int2str(integers[i]));
}
// The output is a series of 0's.
```

while loops

The syntax of a **while** loop is:

while (*expression* **)** *statement*

A **while** loop repeatedly executes *statement* for as long as the conditional *expression* is **true**. *statement* can be replaced by a block of statements. *statement* is executed as many times as the condition is met (zero to many).

Example of a while loop

The following code example demonstrates a **while** loop that traverses a container and prints out the contents of the container.

```
container cont = ["one", "two", "three"];
int no = 0;
while (no <= conlen(cont))
{
    info(conPeek(cont, no));
    no++;
}
// The output is "one", "two", "three".
```

do...while loops

The syntax of the **do...while** loop is:

do { *statement* } **while** (*expression*) ;

The **do**...**while** loop is similar to the **while** loop, but the condition appears after the *statement* that must be executed. *statement* can be a block of statements. The *statement* is always executed at least one time, because the condition is tested after *statement* is executed. The **do**...**while** loop is well-suited to tasks that must always be done at least one time, such as getting parameters for a report.

Example of a do...while loop

The following code example finds the smallest power of 10 that is larger than `realNumber`.

```
int FindPower(real realNumber)
{
    int exponent = -1;
    real curVal;

    do
    {
        exponent++;
        curVal = power(10, exponent);
    }
    while (realNumber > curVal);

    return exponent;
}
```

continue statement

The **continue** statement causes execution to move directly to the next iteration of a **for**, **while**, or **do**...**while** loop. For **do** or **while**, the test is executed immediately. For a **for** statement, the increment step is executed.

Example of a continue statement

In the following code example, if `Iarray[i] <= 0`, the remaining statements in the loop are not executed, and `i` is incremented before the **if** statement is tried again.

```
int Iarray[100];
for (int i = 0; i < 100; i++)
{
    if (Iarray[i] <= 0)
    {
        Info("Will continue.");
        continue;
    }

    info("Did not continue.");
}
// The output is "Will continue." for all 100 interations.
```

break statement

The **break** statement within a loop is used to terminate that loop. Execution then moves to the first statement after the loop.

Example of a break statement

This example is uses a **break** statement within a **while** loop. When used within a loop, the loop is terminated and execution continues from the statement following the loop. This works for **do... while** and **for** loops as well.

```
var mainMenu = SysDictMenu::newMainMenu();
var enum = mainMenu.getEnumerator();
var found = false;
while (enum.moveNext())
{
    var menuItem = enum.current();
    if (menuItem.label() == "StringOfInterest")
    {
        found = true;
        break;
    }
}
if (found)
{
    // do something
}
```

X++ exception handling

2/18/2021 • 13 minutes to read • Edit Online

This topic describes exception handling in X++. You handle errors by using the **throw**, **try**...**catch**, **finally**, and **retry** statements to generate and handle exceptions.

An *exception* is a regulated jump away from the sequence of program execution. The instruction where program execution resumes is determined by **try**...**catch** blocks and the type of exception that is thrown. An exception is represented by a value of the **Exception** enumeration, or an instance of .NET's System.Exception class or a derived class. One exception that is often thrown is the **Exception::error** enum value. A common practice is to write diagnostic information to the Infolog before the exception is thrown.

The **Global::error** method is often the best way to write diagnostic information to the Infolog. For example, your method might receive an input parameter value that isn't valid. In this case, the method can throw an exception to immediately transfer control to a **catch** code block that contains logic for handling this error situation. You don't necessarily have to know the location of the **catch** block that will receive control when the exception is thrown.

throw statements

You use the **throw** keyword to throw an **Exception** enum value. For example, the following statement throws an error exception.

```
throw Exception::error;
```

Instead of throwing an enum value, a best practice is to use the output of the **Global::error** method as the operand for **throw**.

```
throw Global::error("The parameter value is invalid.");
```

The **Global::error** method can automatically convert a label into the corresponding text. This functionality helps you write code that can be localized more easily.

```
throw Global::error("@SYS98765");
```

The static methods on the **Global** class can be called without the **Global::** prefix. For example, the **Global::error** method can be called like this.

```
error("My message.");
```

In Platform update 31 or later versions, the **throw** keyword can be used to throw .NET exceptions.

```
throw new InvalidOperationException("This function is not allowed");
```

Also in Platform update 31 or later, the **throw** keyword can be used by itself inside a catch block. In such a case, **throw** will behave like the **rethrow** statement in C#. The original exception, exception message and its context such as call stack will be rethrown and be available to any catch statements in calling code.

```
try
{
    throw Exception::error;
}
catch
{
    // locally handle exception
    // then rethrow for caller
    throw;
}
```

try, catch, finally, and retry statements

When an exception is thrown, it's first processed through the **catch** list of the innermost **try** block. If a **catch** block is found that handles the kind of exception that is being thrown, program control jumps to that **catch** block. If the **catch** list has no block that specifies the exception, the system passes the exception to the **catch** list of the next-innermost **try** block. The **catch** statements are processed in the same sequence as they appear in the code.

It's a common practice to have the first **catch** statement handle the **Exception::Error** enum value. One strategy is to have the last **catch** statement leave the exception type unspecified. In this case, the last **catch** statement handles all exceptions that aren't handled by any earlier **catch** statement. This strategy is appropriate for the outermost **try**...**catch** blocks.

An optional ***finally*** clause can be included in **try**...**catch** statements. The semantics of a **finally** clause are the same as they are in C#. The statements in the **finally** clause are executed when control leaves the **try** block, either normally or through an exception.

The **retry** statement can be written only in a **catch** block. The **retry** statement causes control to jump up to the first line of code in the associated **try** block. The **retry** statement is used when the cause of the exception can be fixed by the code in the **catch** block. The **retry** statement gives the code in the **try** block another opportunity to succeed. The **retry** statement erases all messages that have been written to the Infolog since program control entered the **try** block.

> **NOTE**
> You must make sure that your **retry** statements don't cause an infinite loop. As a best practice, the **try** block should include a variable that you can test to find out whether you're in a loop.

```
try
{
    // Code here.
}
catch (Exception::Numeric)
{
    info("Caught a Numeric exception.");
}
catch
{
    info("Caught an exception.");
}
finally
{
    // Executed no matter how the try block exits.
}
```

The system exception handler

If no **catch** statement handles the exception, it's handled by the system exception handler. The system exception handler doesn't write to the Infolog. Therefore, an unhandled exception can be hard to diagnose. We recommended that you follow all these guidelines to provide effective exception handling:

- Have a **try** block that contains all your statements in the outermost frame on the call stack.
- Have an unqualified **catch** block at the end of your outermost **catch** list.
- Avoid throwing an **Exception** enum value directly.
- Throw the enum value that is returned from one of the following methods on the **Global** class: **Global::error**, **Global::warning**, or **Global::info**. (You can omit the implicit **Global::** prefix).
- When you catch an exception that hasn't been shown in the Infolog, call the **Global::info** function to show it.

Exception::CLRError, **Exception::UpdateConflictNotRecovered**, and system kernel exceptions are examples of exceptions that aren't automatically shown in the Infolog.

Exceptions and CLR interop

You can call Microsoft .NET Framework classes and methods that reside in assemblies that are managed by the common language runtime (CLR). When a .NET Framework **System.Exception** instance is thrown, your code can catch it by declaring a variable of type **System.Exception** to catch any .NET exception, or one of its derived classes to catch a specific .NET exception type as shown in the following example.

```
System.ArgumentException ex;
try
{
    throw new System.ArgumentException("Invalid argument specified");
}
catch(ex)
{
    error(ex.Message);
}
```

In releases prior to Platform update 31, .NET exceptions can be caught by referencing **Exception::CLRError**. Your code can obtain a reference to the **System.Exception** instance by calling the **CLRInterop::getLastException** method.

```
try
{
    // call to .NET code which throws exception
}
catch(Exception::CLRError)
{
    System.Exception ex = CLRInterop::getLastException();
    error(ex.Message);
}
```

Ensuring that exceptions are shown

Exceptions of the **Exception::CLRError** type aren't shown in the Infolog, because these exceptions aren't issued by a call to a method such as **Global::error**. In your **catch** block, your code can call **Global::error** to report the specific exception.

Global class methods

This section describes some **Global** class methods in more detail. These class methods include **Global::error**, **Global::info**, and **Global::exceptionTextFallThrough**.

Global::error method

The following code shows how the **error** method is declared.

```
static Exception error
    (SysInfoLogStr txt,
    URL helpURL = '',
    SysInfoAction _sysInfoAction = null)
```

The return type is the **Exception::Error** enum value. The **error** method doesn't throw an exception. It just provides an enum value that can be used in a **throw** statement. The **throw** statement throws the exception. Here are descriptions of the parameters for the **error** method. Only the first parameter is required.

- **SysInfoLogStr** txt is a **str** of the message text. It can also be a label reference, such as **strFmt("@SYS12345", strThingName)**.
- The **URL** helpUrl is a reference to the location of a Help topic in Application Explorer, such as **"KernDoc:\\\\Functions\\substr"**. The parameter value is ignored if _sysInfoAction is supplied.
- The **SysInfoAction** is an instance of a class that extends the **SysInfoAction** class. The method overrides that we recommend for the child class are the **description** method, the **run** method, the **pack** method, and the **unpack** method.

Global::info method

The **Global::info** method is often used to show text in the Infolog. In programs, it's often written as **info("My message.");**. Although the **info** method returns an **Exception::Info** enum value, you will rarely want to throw **Exception::Info**, because nothing unexpected has occurred.

Global::exceptionTextFallThrough method

Occasionally, you want to do nothing inside your **catch** block. However, the X++ compiler generates a warning if you have an empty **catch** block. To avoid this warning, call the **Global::exceptionTextFallThrough** method in the **catch** block. The method does nothing, but it satisfies the compiler and explicitly states the intention.

Exceptions inside transactions

If an exception is thrown inside a transaction, the transaction is automatically canceled (that is, a **ttsAbort** operation occurs). This behavior applies for both exceptions that are thrown manually and exceptions that the system throws. When an exception is thrown inside a **ttsBegin**-**ttsCommit** transaction block, no **catch** statement inside that transaction block can process the exception, (unless it is a **UpdateConflict** or a **DuplicateKeyException**). Instead, the innermost **catch** statements that are outside the transaction block are the first **catch** statements that are tested.

Examples of exception handling

Showing exceptions in the Infolog

The following code example shows exceptions in the Infolog.

```
// This example shows that a direct throw of Exception::Error does not
// display a message in the Infolog. This is why we recommend the
// Global::error method.
static void TryCatchThrowError1Job(Args _args)
{
/***
    The 'throw' does not directly add a message to the Infolog.
    The exception is caught.
***/
    try
    {
        info("In the 'try' block. (j1)");
        throw Exception::Error;
    }
    catch (Exception::Error)
    {
        info("Caught 'Exception::Error'.");
    }

/**********  Actual Infolog output
Message (03:43:45 pm)
In the 'try' block. (j1)
Caught 'Exception::Error'.
**********/
}
```

Using the error method to write exception information to the Infolog

The following code example uses the **error** method to write exception information to the Infolog.

```
// This example shows that the use of the Global::error method
// is a reliable way to display exceptions in the Infolog.
static void TryCatchGlobalError2Job(Args _args)
{
    /***
    The 'Global::error()' does directly add a message to the Infolog.
    The exception is caught.
    ***/
    try
    {
        info("In the 'try' block. (j2)");
        throw Global::error("Written to the Infolog.");
    }
    catch (Exception::Error)
    {
        info("Caught 'Exception::Error'.");
    }

/***  Infolog output
Message (03:51:44 pm)
In the 'try' block. (j2)
Written to the Infolog.
Caught 'Exception::Error'.
***/
}
```

Handling a CLRError

The following code example handles a **CLRError** exception.

```
// This example shows that a CLRError exception is not displayed
// in the Infolog unless you catch the exception and manually
// call the info method. The use of the CLRInterop::getLastException
// method is also demonstrated.
static void TryCatchCauseCLRError3Job(Args _args)
{
    /***
    The 'netString.Substring(-2)' causes a CLRError,
    but it does not directly add a message to the Infolog.
    The exception is caught.
    ***/
    System.String netString = "Net string.";
    System.Exception netExcepn;
    try
    {
        info("In the 'try' block. (j3)");
        netString.Substring(-2); // Causes CLR Exception.
    }
    catch (Exception::Error)
    {
        info("Caught 'Exception::Error'.");
    }
    catch (Exception::CLRError)
    {
        info("Caught 'Exception::CLRError'.");
        netExcepn = CLRInterop::getLastException();
        info(netExcepn.ToString());
    }

/**********  Actual Infolog output (truncated for display)
Message (03:55:10 pm)
In the 'try' block. (j3)
Caught 'Exception::CLRError'.
System.Reflection.TargetInvocationException: Exception has been thrown by the target of an invocation. --->
    System.ArgumentOutOfRangeException: StartIndex cannot be less than zero.
Parameter name: startIndex
    at System.String.InternalSubStringWithChecks(Int32 startIndex, Int32 length, Boolean fAlwaysCopy)
    at System.String.Substring(Int32 startIndex)
    at ClrBridgeImpl.InvokeClrInstanceMethod(ClrBridgeImpl* , ObjectWrapper* objectWrapper, Char*
pszMethodName,
    Int32 argsLength, ObjectWrapper** arguments, Boolean* argsAreByRef, Boolean* isException)
**********/
}
```

Using a retry statement

The following code example uses a **retry** statement.

```
// This example shows how to use the retry statement. The print
// statements are included because retry causes earlier Infolog
// messages to be erased.
static void TryCatchRetry4Job(Args _args)
{
    /***
    Demonstration of 'retry'. The Infolog output is partially erased
    by 'retry', but the Print window is fully displayed.
    ***/
    Exception excepnEnum;
    int nCounter = 0;
    try
    {
        info("        .");
        print("        .");
        info("In the 'try' block, [" + int2str(nCounter) + "]. (j4)");
        print("In the 'try' block, [" + int2str(nCounter) + "]. (j4)");
        nCounter++;
        if (nCounter >= 3) // Prevent infinite loop.
        {
            info("---- Will now throw a warning, which is not caught.");
            print("---- Will now throw a warning, which is not caught.");
            throw Global::warning("This warning will not be caught. [" + int2str(nCounter) + "]");
        }
        else
        {
            info("Did not throw a warning this loop. [" + int2str(nCounter) + "]");
            print("Did not throw a warning this loop. [" + int2str(nCounter) + "]");
        }
        excepnEnum = Global::error("This error message is written to the Infolog.");
        throw excepnEnum;
    }
    catch (Exception::Error)
    {
        info("Caught 'Exception::Error'.");
        print("Caught 'Exception::Error'.");
        retry;
    }
    info("End of job.");
    print("End of job.");

/**********  Actual Infolog output
Message (04:33:56 pm)
            .
In the 'try' block, [2]. (j4)
---- Will now throw a warning, which is not caught.
This warning will not be caught. [3]
**********/
}
```

Throwing an exception inside a transaction

The following code example throws an exception in a transaction block.

```
// This examples uses three levels of try nesting to illustrate
// where an exception is caught when the exception is thrown inside
// a ttsBegin-ttsCommit transaction block.
static void TryCatchTransaction5Job(Args _args)
{
    /***
    Shows an exception that is thrown inside a ttsBegin - ttsCommit
    transaction block cannot be caught inside that block.
    ***/
    try
    {
        try
        {
            ttsbegin;
            try
            {
                throw error("Throwing exception inside transaction.");
            }
            catch (Exception::Error)
            {
                info("Catch_1: Unexpected, caught in 'catch' inside the transaction block.");
            }
            ttscommit;
        }
        catch (Exception::Error)
        {
            info("Catch_2: Expected, caught in the innermost 'catch' that is outside of the transaction
block.");
        }
    }
    catch (Exception::Error)
    {
        info("Catch_3: Unexpected, caught in 'catch' far outside the transaction block.");
    }
    info("End of job.");

/**********  Actual Infolog output
Message (04:12:34 pm)
Throwing exception inside transaction.
Catch_2: Expected, caught in the innermost 'catch' that is outside of the transaction block.
End of job.
**********/
}
```

Using Global::error with a SysInfoAction parameter

When your code throws an exception, it can write messages to the Infolog. You can make those Infolog messages more helpful by using the **SysInfoAction** class.

In the following example, a **SysInfoAction** parameter is passed in to the **Global::error** method. The **error** method writes the message to the Infolog. When the user double-clicks the Infolog message, the **SysInfoAction.run** method is run.

In the **run** method, you can write code that helps diagnose or fix the issue that caused the exception. The object that is passed in to the **Global::error** method is constructed from a class that you write that extends **SysInfoAction**.

The following code sample is shown in two parts.

- The first part shows a job that calls the **Global::error** method and then throws the returned value. An instance of the **SysInfoAction_PrintWindow_Demo** class is passed in to the **error** method.
- The second part shows the **SysInfoAction_PrintWindow_Demo** class.

Part 1: Calling Global::error

```
static void Job_SysInfoAction(Args _args)
{
    try
    {
        throw Global::error
            ("Click me to make the Print window display."
            ,""
            ,new SysInfoAction_PrintWindow_Demo()
            );
    }
    catch
    {
        warning("Issuing a warning from the catch block.");
    }
}
```

Part 2: The SysInfoAction_PrintWindow_Demo class

```
public class SysInfoAction_PrintWindow_Demo extends SysInfoAction
{
    str m_sGreeting; // In classDeclaration.
    public str description()
    {
        return "Starts the Print Window for demonstration.";
    }
    public void run()
    {
        print("This appears in the Print window.");
        print(m_sGreeting);

        /********** Actual Infolog output
        Message (03:19:28 pm)
        Click me to make the Print window display.
        Issuing a warning from the catch block.
            ***************/
    }
    public container pack()
    {
        return ["Packed greeting."]; // Literal container.
    }
    public boolean unpack(container packedClass, Object object = null)
    {
        [m_sGreeting] = packedClass;
        return true;
    }
}
```

List of exceptions

The following table shows the exception literals that are the values of the **Exception** enumeration.

EXCEPTION LITERAL	DESCRIPTION
Break	The user pressed Break or Ctrl+C.
CLRError	An error occurred while the CLR functionality was being used.
CodeAccessSecurity	An error occurred while the **CodeAccessPermission.demand** method was being used.

EXCEPTION LITERAL	DESCRIPTION
DDEerror	An error occurred while the **DDE** system class was being used.
Deadlock	A database deadlock occurred, because several transactions are waiting for each other.
DuplicateKeyException	An error occurred in a transaction that is using Optimistic Concurrency Control. The transaction can be retried (use a **retry** statement in the **catch** block).
DuplicateKeyExceptionNotRecovered	An error occurred in a transaction that is using Optimistic Concurrency Control. The code won't be retried. This exception can't be caught inside a transaction.
Error	A fatal error occurred. The transaction has been stopped.
Info	This exception literal holds a message for the user. Don't throw an **info** exception.
Internal	An internal error occurred in the development system.
Numeric	An error occurred while the **str2int**, **str2int64**, or **str2num** function was being used.
Sequence	
UpdateConflict	An error occurred in a transaction that is using Optimistic Concurrency Control. The transaction can be retried (use a **retry** statement in the **catch** block).
UpdateConflictNotRecovered	An error occurred in a transaction that is using Optimistic Concurrency Control. The code won't be retried. This exception can't be caught within a transaction.
Warning	An exceptional event has occurred. Although the user might have to take action, the event isn't fatal. Don't throw a **warning** exception.
SQL connection error X++ exception	An error occured when during the query execution. The transaction will be canceled. This exception can't be caught within a transaction.

SQL connection error X++ exception

2/18/2021 • 2 minutes to read • Edit Online

This topic describes the SQL connection error exception types in X++.

TransientSqlConnectionError X++ exception

During an X++ SQL query execution, when a transient SQL connection error occurs on the server side, a TransientSqlConnectionError X++ exception will occur. Depending on the application requirements, the application should catch and handle the exception.

This exception usually occurs during a large transaction or when the database is under a lot of processing pressure.

The TransientSqlConnectionError exception is not catchable within the transaction. The X++ transaction that encounters this exception is canceled (calling **ttsAbort**) before the exception occurs. This means that you need to use the catch block to identify the transient SQL connection error instead of a generic X++ error exception, and then retry the outermost transaction or retry application code logic in a new session. This exception allows the application to be designed for transient server failures.

If an application transaction takes a long time to process, you can use multiple incremental delays to catch the TransientSqlConnectionError exception. Retrying your application code in a new session is most likely to succeed after you have caught the exception.

Example

```
public static void LargeTransactionWrapper()
{
    try
    {
        LargeTransaction();
    }
    catch (Exception::TransientSqlConnectionError)
    {
        info("Caught transient SQL connection error, ttslevel=" + int2Str(appl.ttsLevel()));
        // At this point, transaction is canceled
        // Code that indicates retry is possible
    }
    finally
    {
        // Do clean up
    }
}
```

X++ operators

2/18/2021 • 14 minutes to read • Edit Online

This topic describes the operators supported in X++.

Assignment operators

An assignment changes the value of a variable or field. The following table shows the X++ assignment operators. There is no difference between prefix and postfix operators.

OPERATOR	DESCRIPTION
`=`	Assign the expression on the right of the equal sign to the variable on the left.
`+=`	Assign the current variable value plus the expression on the right to the variable on the left.
`++`	Increment the variable by 1.
`-=`	Assign the current variable value minus the expression on the right to the variable on the left.
`--`	Decrement the variable by 1.

Code examples for assignment operators

```
// An example of assignment operators and their output.
static void Example1()
{
    int i = 1;
    // Using the = operator. i is assigned the value of i, plus 1. i = 2.
    i = i + 1;
    info(strFmt("Example 1: The result is "), i); // The result is 2.
}

static void Example2()
{
    int i = 1;
    // Using the += operator. i is assigned the value of i, plus 1.
    // i = 2 (i = i + 1).
    i += 1;
    info(strFmt("Example 2: The result is "), i); // The result is 2.
}

static void Example3()
{
    int i = 1;
    // Using the ++ operator. i is incremented by 1, and then
    // by 1 again in the second statement. The final value of i is 3.
    i++;
    ++i;
    info(strFmt("Example 3: The result is "), i); // The result is 3.
}

static void Example4()
{
    int i = 1;
    // Using the -= operator. i is assigned the value of i minus 1.
    // i = 0 (i = i - 1).
    i -= 1;
    info(strFmt("Example 4: The result is "), i); // The result is 0.
}

static void Example5()
{
    int i = 1;
    // Using the -- operator. i is decremented by 1, and then by
    // 1 again in the second statement. The final value of i is -1.
    i--;
    --i;
    info(strFmt("Example 5: The result is "), i); // The result is -1.
}
```

Arithmetic operators

You use arithmetic operators to perform numeric calculations. Most of the operators are binary and take two operands. However, the **not** (`~`) operator is unary and takes only one operand. Syntax for binary operators: *expression1 ArithmeticOperator expression2* Syntax for unary operators: *ArithmeticOperator expression1*

OPERATOR	DESCRIPTION
`<<`	The **left shift** operator performs *expression2* left shift (multiplication by 2) on *expression1*.
`>>`	The **right shift** operator performs *expression2* right shift (division by 2) on *expression1*.

OPERATOR	DESCRIPTION
`\*`	The **multiply** operator multiplies *expression1* by *expression2*.
`/`	The **divide** operator divides *expression1* by *expression2*.
`DIV`	The **integer division** operator performs an integer division of *expression1* by *expression2*.
`MOD`	The **integer remainder** operator returns the remainder of an integer division of *expression1* by *expression2*.
`~`	The **not** operator, or unary operator, performs a binary not operation.
`&`	The **binary AND** operator performs a binary and operation on *expression1* and *expression2*.
`^`	The **binary XOR** operator performs a binary XOR-operation on *expression1* and *expression2*.
`|`	The **binary OR** operator performs a binary or operation on *expression1* and *expression2*.
`+`	The **plus** operator adds *expression1* to *expression2*.
`-`	The **minus** operator subtracts *expression2* from *expression1*.
`?`	The **ternary** operator takes three expressions: *expression1* ? *expression2* : *expression3*. If *expression1* is true, *expression2* is returned. Otherwise, *expression3* is returned.

Code examples for arithmetic operators

```
int a = 1 << 4;      // Perform four left shifts on 1 (1*2*2*2*2). a=16.
int b = 16 >> 4;     // Perform four right shifts on 16 (16/2/2/2/2). b=1.
int c = 4 * 5;       // Multiply 4 by 5. c=20.
int d = 20 / 5;      // Divide 20 by 5. d=4.
int e = 100 div 21;  // Return the integer division of 100 by 21. e=4 (4*21 = 84, remainder 16).
int f = 100 mod 21;  // Return the remainder of the integer division of 100 by 21. f=16.
int g = ~1;          // Binary negate 1 (all bits are reversed). g=-2.
int h = 1 & 3;       // Binary AND. Return the bits that are in common in the two integers. h=1.
int i = 1 | 3;       // Binary OR. Return the bits that are set in either 1 or 3. i=3.
int j = 1 ^ 3;       // Binary XOR. Return the bits that are set in 1 and NOT set in 3, and vice versa. j=2.
int k = 1 + 3;       // Add 1 and 3. k=4.
int l = 3 - 1;       // Subtract 1 from 3. l=2.
int m = (400 > 4) ? 1 : 5;  // If 400>4, 1 is returned. Otherwise, 5 is returned. Because 400>4, 1 is
returned. m=1.
```

Expression operators

The `as` and `is` expression operators control downcast assignments. Downcast assignments involve class or table inheritance. Assignment statements that implicitly downcast can cause errors that are difficult to predict and diagnose. You can use the `as` keyword to make your downcasts explicit. You can use the `is` keyword to

test whether a downcast is valid at run time.

The as keyword

Use the `as` keyword for assignments that downcast from a base class variable to a derived class variable. The `as` keyword tells other programmers and the compiler that you believe that the downcast will be valid during run time.

- The compiler reports an error for downcast assignment statements that lack the `as` keyword.
- At run time, the `as` keyword causes the downcast assignment statement to assign `null` if the downcast isn't valid.
- This `is` keyword is often used to safely test whether the `as` keyword will work.

Code example for the as keyword

In the following code example, the **DerivedClass** class extends the **BaseClass** class. The code example contains two valid assignments between its **basec** and **derivedc** variables. The upcast assignment to **basec** doesn't require the `as` keyword, but the downcast assignment to **derivedc** does require the `as` keyword. The following code will compile and run without errors.

```
static void AsKeywordExample()
{
    // DerivedClass extends BaseClass.
    BaseClass basec;
    DerivedClass derivedc;
    // BottomClass extends DerivedClass.
    BottomClass bottomc;
    derivedc = new DerivedClass();
    // AS is not required for an upcast assignment like this.
    basec = derivedc;
    // AS is required for a downcast assignment like this.
    derivedc = basec as DerivedClass;
    bottomc = new BottomClass();
    // AS causes this invalid downcast to assign null.
    bottomc = basec as DerivedClass;
}
```

The is keyword

The `is` keyword verifies whether an object is a subtype of a specified class. The `is` expression returns **true** if the object is a subtype of the class, or if the object is the same type as the class. The compiler reports an error if an `is` keyword expression compares two types, but neither type is a subtype of the other, and they aren't of the same type. The compiler reports a similar error for any plain assignment statement between two types, where neither type is a subtype of the other, and they aren't of the same type. At run time, the type of variable that references the underlying object is irrelevant to the `is` keyword. The `is` keyword causes the system to verify the object that the variable references, not the declared type of the variable that references the object.

Code examples for the is keyword

The following code examples illustrate the conditions that control whether an `is` expression returns **true** or **false**. The code examples depend on the fact that the **Form** class and the **Query** class both extend the **TreeNode** class.

```
// The compiler issues an error for the following code.
// The compiler ascertains that the Form class and the Query class are not
// part of the same inheritance hierarchy. Both the Form class and the Query class
// extend the TreeNode class, but neither Form nor Query is a subtype of the other.
Form myForm = new Form();
info(strFmt("%1", (myForm is Query)));

// The Infolog displays 0 during run time, where 0 means false. No supertype
// object can be considered to also be of its subtype class.
TreeNode myTreeNode = new TreeNode();
info(strFmt("%1", (myTreeNode is Form)));

// The Infolog displays 0 during run time, where 0 means false. A null
// reference causes the is expression to return false.
Form myForm;
info(strFmt("%1", (myForm is Form)));

// The Infolog displays 1 during run time, where 1 means true.
// An object is an instance of its own class type.
Form myForm = new Form();
info(strFmt("%1", (myForm is Form)));

// The Infolog displays 1 during run time, where 1 means true.
// Every subtype is also of its supertype.
Form myForm = new Form();
info(strFmt("%1", (myForm is TreeNode)));

// The Infolog displays 1 during run time, where 1 means true.
// The type of the underlying object matters in the is expression,
// not the type of the variable that references the object.
Form myForm = new Form();
TreeNode myTreeNode;
myTreeNode = myForm; // Upcast.
info(strFmt("%1", (myTreeNode is Form)));
```

Code example for the is and as keywords

The following code example contains a typical use of the `is` keyword. The `as` keyword is used after the `is` keyword verifies that the `as` keyword will succeed. In this example, the `is` and `as` keywords are uppercase to make them more visible.

```
static void IsKeywordExample()
{
    DerivedClass derivedc;
    BaseClass basec;
    basec = new DerivedClass();  // An upcast.
    if (basec IS DerivedClass)
    {
        info("Test 1: (basec IS DerivedClass) is true. Good.");
        derivedc = basec AS DerivedClass;
    }
    basec = new BaseClass();
    if (!(basec IS DerivedClass))
    {
        info("Test 2: !(basec IS DerivedClass) is true. Good.");
    }
}

//Output to the Infolog
Test 1: (basec IS DerivedClass) is true. Good.
Test 2: (!(basec IS DerivedClass)) is true. Good.
```

Object class as a special case

The **Object** class can appear as a special case in inheritance functionality. The compiler bypasses type checking

for assignments to and from variables that are declared to be of type **Object**. Some classes inherit from the **Object** class, some classes inherit from another class, and some classes don't inherit from any class. Although the **Dialog** class doesn't inherit from any class, the assignment and call statements in the following code example work. However, if the assignment is `bank4 = dlog3;`, it will fail at compile time, because the **Bank** and **Dialog** classes have no inheritance relationship to each other. The compiler performs only one small validation on assignments to a variable that is declared to be of the **Object** class. The compiler verifies that the item that is being assigned to the **Object** variable is an instance of a class. The compiler doesn't allow an instance of a table buffer to be assigned to the **Object** variable. Additionally, the compiler doesn't allow primitive data types, such as `int` or `str`, to be assigned to the **Object** variable.

```
static void ObjectExample()
{
    Bank bank4;
    Object obj2;
    Dialog dlog3 = new Dialog("Test 4.");
    obj2 = dlog3;  // The assignment does work.
    obj2.run(false);  // The call causes the dialog to appear.
    info("Test 4a is finished.");
}
```

Tables

All tables inherit directly from the Common system table, unless they explicitly inherit from a different table. The Common table can't be instantiated. It doesn't exist in the underlying physical database. The Common table inherits from the **xRecord** class, but in a special way that isn't appropriate for the `is` keyword or the `as` keyword. When the `as` keyword is used to perform an invalid downcast among tables, the target variable references an unusable non-null entity. Any attempt to de-reference the target variable will cause an error that stops the program.

The is and as keywords and extended data types

Each extended data type has an **Extends** property. The style of inheritance that this property controls differs from the style of inheritance that the `is` and `as` keywords are designed for.

Relational operators

The following table lists the relational operators that can be used in X++. Most of the operators are binary and take two operands. However, the **not** (`!`) operator is unary and takes only one operand. Syntax for binary operators: *expression1 relationalOperator expression2* Syntax for unary operators: *relationalOperator expression1*

OPERATOR	DESCRIPTION
`like`	The **like** relational operator returns **true** if *expression1* is like *expression2*.
`==`	The **equal** relational operator returns **true** if both expressions are equal.
`>=`	The **greater than or equal to** relational operator returns **true** if *expression1* is greater than or equal to *expression2*.
`<=`	The **less than or equal to** relational operator returns **true** if *expression1* is less than or equal to *expression2*.

OPERATOR	DESCRIPTION
`>`	The **greater than** relational operator returns **true** if *expression1* is greater than *expression2*.
`<`	The **less than** relational operator returns **true** if *expression1* is less than *expression2*.
`!=`	The **not equal** relational operator returns **true** if *expression1* differs from (that is, if it isn't equal to) *expression2*.
`&&`	The **and** relational operator returns **true** if both *expression1* and *expression2* are true.
`||`	The **or** relational operator returns **true** if *expression1* or *expression2* is true, or if both are true.
`!`	The **not** or **unary** relational operator negates the expression. It returns **true** if the expression is false and **false** if the expression is true.

The like operator

The `like` operator can use `*` as a wildcard character for zero or more characters, and `?` as a wildcard character for one character. The maximum length of the operand is 1,000 characters. The `like` operator is evaluated by the underlying SQL, so the result might differ on different installations. If the expressions that you're comparing contain a file path, you must include four backslashes between each element, as shown in the following example.

```
select * from xRefpaths
where xRefPaths.Path like "\\\\Classes\\\\AddressSelectForm"
```

The equal (==) operator

When you use the **equal** (`==`) operator to compare objects, the object references are compared, not the objects themselves. This behavior might cause issues if you compare two objects, one of which is located on the server, and the other of which is located on the client. In these cases, you should use the **equal** method in the **Object** class. You can override this method to specify what it means for two objects to be equal. If you don't override the **equal** method, the comparison is identical to the comparison that is done by the **equal** (`==`) operator.

Code examples for relational operators

```
"Jones" like "Jo?es"  // Returns true, because the ? is equal to any single character.
"Fabrikam, Inc." like "Fa*"  // Returns true, because the * is equal to zero or more characters.
(( 42 * 2) == 84)  // Returns true, because 42*2 is equal to 84.
today() >= 1\1\1980  // Returns true, because today is later than January 1, 1980.
((11 div 10) >= 1)  // Returns true, because 11 div 10 is 1 (therefore, >= 1 is true).
(11<= 12)  // Returns true, because 11 is less than 12.
((11 div 10) > 1)  // Returns false, because 11 div 10 is 1.
(11 div 10) < 1)  // Returns false, because 11 div 10 is 1.
(11 != 12)  // Returns true, because 11 is not equal to 12.
(1 == 1) && (3 > 1)  // Returns true, because both expressions are true.
```

Operator precedence

The order that a compound expression is evaluated in can be important. For example, `(x + y / 100)` gives a

different result, depending on whether the addition or the division is done first. You can use parentheses (`()`) to explicitly tell the compiler how it should evaluate an expression. For example, you can specify `(x + y) / 100`. If you don't explicitly tell the compiler the order that you want operations to be done in, the order is based on the precedence that is assigned to the operators. For example, the division operator has higher precedence than the addition operator. Therefore, for the expression `x + y / 100`, the compiler evaluates `y / 100` first. In other words, `x + y / 100` is equivalent to `x + (y / 100)`. To make your code easy to read and maintain, be explicit. Use parentheses to indicate which operators should be evaluated first. The following table lists the operators in order of precedence. The higher an operator appears in the table, the higher its precedence. Operators that have higher precedence are evaluated before operators that have lower precedence. Note that the operator precedence of X++ isn't the same as the operator precedence of other languages, such as C# and Java.

OPERATOR GROUPS, IN ORDER OF PRECEDENCE	OPERATORS
Unary	`- ~ !`
Multiplicative, shift, bitwise **AND**, bitwise exclusive **OR**	`* / % DIV << >> & ^`
Additive, bitwise inclusive **OR**	`+ -`
Relational, equality	`< <= == != > >= like as is`
Logical (**AND**, **OR**)	`&&` `||`
Conditional	`? :`

Operators on the same line have equal precedence. If an expression includes more than one of these operators, it's evaluated from left to right, unless assignment operators are used. (Assignment operators are evaluated from right to left.) For example, `&&` (logical `AND`) and `||` (logical `OR`) have the same precedence, and are evaluated from left to right. Therefore:

- `0 && 0 || 1` is equal to `1`
- `1 || 0 && 0` is equal to `0`.

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Operator precedence

2/18/2021 • 2 minutes to read • Edit Online

This topic describes operator precedence.

The order in which a compound expression is evaluated is important. If you do not explicitly tell the compiler the order that you want operations to be performed in, the order is based on operator precedence. You can use parentheses `( )` to explicitly tell the X++ compiler how you want an expression to be evaluated.

Consider the expression `x + y / 100`, which gives a different result depending on whether the addition or the division is performed first. Because the division operator has a higher precedence than the addition operator, the compiler evaluates `y/100` first. So, `x + y / 100` is equivalent to `x + (y / 100)`. If you add parentheses to make the expression `(x + y)/ 100`, then `x + y` is evaluated first.

To make your code easy to read and maintain, be explicit, and indicate with parentheses which operators should be evaluated first.

Order of operator precedence

The operators in the following table are listed in precedence order. The higher in the table an operator appears, the higher precedence it has. Operators with higher precedence are evaluated before operators with a lower precedence. The operator precedence of X++ is not the same as other languages, for example C# and Java.

OPERATORS IN PRECEDENCE ORDER	SYNTAX
unary operators	`- ~ !`
multiplicative, shift, bitwise AND, bitwise exclusive OR	`* / % DIV << >> & ^`
additive, bitwise inclusive OR	`+ -`
relational, equality	`< <= == != > >= like as is`
logical operators (AND, OR)	`&& ||`
conditional	`? :`

Operators on the same line in the table have equal precedence. If there are more than one of these operators in an expression, the expression is evaluated from left to right unless assignment operators are used. Assignment operators are evaluated from right to left. For example, `&&` (logical AND) and `||` (logical OR) have the same precedence and are evaluated from left to right. This means that `0 && 0 || 1 == 1`, and `1 || 0 && 0 == 0`

Classes and methods

2/18/2021 • 18 minutes to read • Edit Online

This topic describes how to create and use classes in X++.

A *class* is a software construct that defines the data and methods of the instances that are later constructed from that class. The *class* is an abstraction of an *object* in the problem domain. The instances that are constructed from the *class* are known as *instances* or *objects*. This topic uses the term *instance*. The data represents the state of the object, whereas the methods represent the behavior of the object.

Variables contain the data for the class. Every instance that is constructed from the class declaration has its own copy of the variables. These variables are known as *instance variables*.

Methods define the behavior of a class. They are the sequences of statements that operate on the data (instance variables). By default, methods are declared to operate on the instance variables of the class. These methods are known as *instance methods* or *object methods*.

You can declare *static methods* and *static fields*, that do not have access to *instance variables*. These are described in X++ static classes.

Declare a class

You must use the **Add new item** dialog in Visual Studio to add a class to your project.

1. In Server Explorer, right-click the project, and then click **Add**.
2. In the **New Item** dialog box, select **Installed > Dynamics 365 Items > Code** in the left navigation. Then select **Class**, and then enter a name for the class.
3. Click **Add**.

All classes are public. If you remove the **public** modifier, the system still treats the class as public. You can specify other modifiers on the class declaration, such as **final** and **extends**.

Variables

Instance variables are **protected** by default. This means that they can only be accessed in the same class or a derived class. You can modify an instance variable declaration by using the **private**, **protected**, or **public** keywords.

The following example shows how to use accessor methods to make the variable data public. The variable **firstName** is protected, so accessor (get and set) methods are implemented to allow access to the protected variable. The variable **lastName** is public, so code can directly get and set the value of the variable.

```
// This is the class definition.
public class HasAFirstName
{
    str firstName;
    public str lastName;
    public str getFirstName()
    {
        return firstName;
    }

    public void setFirstName(str newName)
    {
       firstName = newName;
    }
}

// This code creates an instance of the class and gets the variables.
public static void TestLastName()
{
    HasAFirstName hasFirstName = new HasAFirstName();
    hasFirstName.setFirstName("Dion");
    info(hasFirstName.getFirstName());
    hasFirstName.lastName = ("Townes");
    info(hasFirstName.lastName);
}
// The output is "Dion" and "Townes".
```

Constructors

To create an instance of a class, you must instantiate it by using a *constructor*.

- You can define only one **new** method (constructor) in a class.
- If you do not define a constructor, a default constructor with no parameters is created automatically by the compiler.
- You can simulate a default constructor by assigning default values to the parameters in the **new** method.

The following examples defines a parameterless constructor in the **Point** class.

```
class Point
{

    // Instance variables that are public. In practice, you would probably make this protected or private
    // and create accessor methods.
    public real x = 0.0;
    public real y = 0.0;

    void new() {
    }
}
```

Following is information about how to create a clean inheritance model and minimize problems when code is upgraded:

- Each class must have a single public construction method unless the class is abstract. If no initialization is required, use a static construct method. Otherwise, use a static **new** method (the default constructor for the class should be protected).
- Each class should have at least one static **construct** method method.
- Each class should have at least one static **new** method.
- Each class should have a **new** method (the default constructor). This method should be **protected**.

- Create accessor methods to get and set class variables.
- Create **init** methods to carry out any specialized initialization tasks that should be carried out after instantiation.

Create other objects in a constructor

A class constructor can instantiate other objects in addition to creating an instance of the class. For example, the following code declares a **Rectangle** class that uses two **Point** objects to define its bounds. In this case, the **Point** class has a constructor that has two **real** parameters.

```
class Point
{
    // Instance variables that are public. In practice, you would probably make this protected or private
    // and create accessor methods.
    public real x = 0.0;
    public real y = 0.0;

    // Constructor to initialize to a specific or default value
    void new(real _x = 10, real _y = 10)
    {
        x = _x;
        y = _y;
    }
}

class Rectangle
{
    public Point lowerLeft;
    public Point upperRight;

    void new(real _topLeftX = 0.0, real _topLeftY = 0.0, real _bottomRightX = 1.0, real _bottomRightY = 1.0)
    {
        lowerLeft  = new Point(_topLeftX, _topLeftY);
        upperRight = new Point(_bottomRightX, _bottomRightY);
    }

}

// This code creates two instances of the Rectangle class.
Rectangle defaultRectangle = new Rectangle();
info(any2Str(defaultRectangle.lowerLeft.x));
info(any2Str(defaultRectangle.lowerLeft.y));
// Output is "0.0" and "0.0".

Rectangle customRectangle = new Rectangle(1.0, 1.0, 2.0, 2.0);
info(any2Str(customRectangle.lowerLeft.x));
info(any2Str(customRectangle.lowerLeft.y));
// Output is "1.0" and "1.0".
```

Create an instance of an object

The constructor, **new**, returns a new instance of the class. The following code example creates two instances of the Point class.

```
// Declare a variable to refer to a Point instance.
Point myPoint;

// Create an instance of the Point class.
myPoint = new Point();

// Declare and instantiate a Point instance.
Point ap = new Point();
```

Destructors

You use a *destructor* to explicitly destroy a class instance. Instances are automatically destroyed when there are no references to them. However, you can destroy objects explicitly in the following ways:

- Use the **finalize** method.
- Set the reference variable to **null**.

Use the finalize method

Use the **finalize** method to explicitly destroy an object. There are no implicit calls to the **finalize** method. You must call the method to run the statements in it. In the **finalize** method, you should also put any clean-up code that is required. For example, if your class uses a dynamic-link library (DLL) module, you can use the **finalize** method to release the DLL when you no longer require it. Use the **finalize** method carefully. It will destroy an object even if there are references to it.

The following example shows the basic structure for a call to the **finalize** method.

```
// From any method in a class.
if (condition)
{
    // Removes object from memory.
    this.finalize();
}
```

Set reference variable to null

Set the reference variable to **null** to terminate an object. This approach destroys an object only if no other variables point to that object. You should verify that other code isn't using the variable. The following example creates an reference variable and then sets it to **null**.

```
Point myPoint = new Point();
myPoint = null;
```

Methods

Instance methods

Instance methods are embedded in each instance that is created from the class. You must instantiate the object before you can use the method. The following code shows how to define an instance method and call it from an instance.

```
class Square
{

    int side = 0;

    void new(int _side = 1) {
        side = _side;
    }

    int getArea() {
        return side * side;
    }

}

// This code creates an instance of Square and calls getArea.
Square square = new Square(15);
int area = square.getArea();
info(int2Str(area));
// Output is "225".
```

Static methods

Static methods, which are also known as *class methods*, belong to a class and are created by using the keyword **static**. You don't have to instantiate an object before you use static methods. Static methods are often used to work with data that is stored in tables. Member variables can't be used in a static method.

You use the following syntax to call static methods.

```
ClassName::methodName();
```

If you convert an instance method to a static method, you must restart the client. Otherwise, the compiler doesn't detect the change. After you've converted an instance method to a static method, you can no longer call the method from the instance of the class. Instead, you must call the method from the class itself. For more information about static methods, see X++ static classes.

main methods

A **main** method is a class method that is run directly from a menu option. The method should only create an instance of the object and then call the required member methods. The **_args** parameter lets you transfer data to the method.

```
static void main (Args _args)
{
    // Your code here.
}
```

Declaration of methods

Method declarations consist of a header and a body. The method header declares the method's name and return type), the method modifiers, and parameters. (The return type might be **void**.) The method body consists of variable declarations, method declarations, and statements.

Return type

A return type is required for each method. If a method doesn't return anything, use the **void** keyword as the return type.

The following example shows two methods. One method has a return type, but the other method doesn't have a return type.

```
void methodNameNoReturnValue()
{
    // Your code here.
}

// If a method returns something, you must specify the return type and include a return statement.
int methodNameIntegerReturnValue()
{
    return 1;
}
```

Syntax

Method declaration = *Heading Body* Heading = **[** *Modifiers* **]** *ReturnType MethodName* **(** *ParameterList* **)**

Modifiers = **[client] [server] [edit | display | public | protected | private]** [**static | abstract | final]**

ReturnType = *Datatype* **| void | anytype**

MethodName = *Identifier*

ParameterList = **[** *Parameter* **{ ,** *Parameter* **}]**

Parameter = *Datatype Variableidentifier* **[** = *Expression* **]**

Body = **{ [** *VariableDeclarations* **] [** *EmbeddedFunctionDeclarations* **] [** *Statements* **] }**

EmbeddedFunctionDeclaration = *Heading* **{[** *VariableDeclarations* **] [** *Statements* **]}**

If you use the **anytype** return type, the method can return any data type.

Example of a method that doesn't have a return type

```
void update ()
{
    // Variable declared and initialized
    CustTable this_Orig = this.orig();

    // First statement in body (begin transaction)
    ttsBegin;
    this.setNameAlias();
    // Calls super's implementation of update
    super();
    this.setAccountOnVend(this_Orig);
    if (this_Orig.custGroup != this.custGroup)
        ForecastSales::setCustGroupId(
            this.accountNum,
            this_Orig.custGroup,
            this.custGroup);
    // Commits transaction
    ttsCommit;
}
```

Example of a method that has parameters

In the following example, the **checkAccountBlocked** method returns a Boolean value and acts on the **amountCur** parameter.

```
boolean checkAccountBlocked(AmountCur amountCur)
{
    if (this.blocked == CustVendorBlocked::All
        ||(this.blocked == CustVendorBlocked::Invoice
        && amountCur > 0 ))
    return checkFailed(strFmt("@SYS7987",this.accountNum));
    return true;
}
```

Method modifiers

Several modifiers can be applied to method declarations. Some of the modifiers can be combined (for example, **final static**). Here are the method modifier keywords:

- **abstract**: The method is declared but isn't implemented in a parent class. The method must be overridden in subclasses. If you try to create an object from a subclass where one or more abstract methods that belong to the parent class haven't been overridden, you receive a compiler error.

  Classes can also be abstract. Sometimes, a class should not be instantiated even though it represents an abstract concept. Only subclasses should be instantiated. Base classes of this type can be declared as **abstract**. For example, you want to model the concept of an account. Accounts are abstract, because only derived classes (ledger accounts and so on) exist in the real world. This examples describes a clear case where you should declare the **Account** class as **abstract**.

- **display**: The method's return value should be shown on a page or a report. The value can't be modified on the page or report. Typically, the return value is a calculated value, such as a sum.

- **edit**: The method's return type should be used to provide information for a field that is used on a page. The value in the field can be modified.

- **final**: The method can't be overridden in any class that derives from its class.

- **public**: Methods that are declared as **public** can be accessed anywhere that the class is accessible, and they can be overridden by subclasses. Methods that have no access modifier are implicitly public.

- **protected**: Methods that are declared as **protected** can be called only from methods in the class and in subclasses that extend the class where the method is declared.

- **private**: Methods that are declared as **private** can be called only from methods in the class where the private method is declared.

- **static**: The method is a class method and doesn't act on an instance. Static methods can't refer to instance variables. They aren't invoked on an instance of the class. Instead, they are invoked by using the class name (for example, **MyClass::aStaticProcedure()**).

Methods that have modifiers

The following examples show only the method headers.

```
// A method that cannot be overridden
final int dontAlterMe()

// A static method
static void noChange()

// A display method that returns an integer
display int value()
```

Method access control

You use the accessor keywords **public**, **protected**, and **private** to control whether the methods in other classes can call the methods on your class. The accessor keywords on methods also interact with the rules for class inheritance. Here are the accessor keywords that you use with methods:

- **public**: Methods that are declared as **public** can be called from anywhere that the class is accessible. In addition, a public method can be overridden by a subclass, unless the method is declared as **final**.
- **protected**: Methods that are declared as **protected** can be called only from the following methods:
  - Methods in the class.
  - Methods in a subclass of the class that contains the protected method. Methods that are protected can be overridden in subclasses.
- **private**: Methods that are declared as **private** can be called only from methods in the class where the private method is declared. No private method can be overridden in a subclass. By default, when you create a new method, the **private** accessor keyword appears in the code editor. For maximum security, **private** is the most conservative default accessor keyword.

Static and instance methods

The accessor keywords on methods never restrict calls between two methods that are in the same class, regardless of which method is static or non-static. In a static method, calls to the **new** constructor method are valid even if the **new** constructor method is decorated with the **private** modifier. The syntax for these calls requires that the **new** keyword be used. The code in a static method must construct an instance object of its own class before it can call any instance methods on the class.

Increasing access during overrides

When a method is overridden in a subclass, the overriding method must be at least as accessible as the overridden method. For example, the following compiler rules apply when a protected method is overridden in a subclass:

- A public method in a superclass can be overridden only by a public method in the subclass.
- In a subclass, a public or protected method can override a protected method of the superclass.
- In a subclass, a private method can't override a protected method of the superclass.

Optional parameters

Parameters can be initialized in the method declaration. In this case, the parameter becomes an *optional parameter*. If no value is supplied in the method call, the default value is used. All required parameters must be listed before the first optional parameter. The following examples show how to create and call a method that has optional parameters. The example of the **AddThreeInts** method shows that you can't skip default parameters when you call a method.

Examples of optional parameters

The following code example shows a class with a default parameter.

```
// This is an example of a function being used as the default.
class Person
{
    date birthDate;

    // The constructor that takes a date type as a parameter.
    // That value is assigned to the field member birthDate.
    void new(date _date)
    {
        birthDate = _date;
    }

    // The CalculateAgeAsOfDate method references the birthDate field and has an
    // optional parameter. In this example, the default value is the
    // return value of a function.
    public real CalculateAgeAsOfDate(date _calcToDate =
DateTimeUtil::getToday(DateTimeUtil::getUserPreferredTimeZone()) )
    {
        return (_calcToDate - birthDate) / 365;
    }

    public static void callPerson()
    {

        Person person = new Person(13\5\2010);

        // Optional parameter's default is used.
        Info(strFmt('Age in years today is %1 years',
                real2int(person.CalculateAgeAsOfDate())));

        // January 2, 2044  is the parameter value for _date.
        Info(strFmt('Age in years on %1 is %2 years',
                2\1\2044,
                real2int(person.CalculateAgeAsOfDate(2\1\2044))));
    }

}
```

This is an example of how you cannot skip to a second optional parameter. The **AddThreeInts** method has two optional parameters. The **callAdditions** method calls the **AddThreeInts** method. The commented out code tries to override only the **_i3** default value, but the compiler requires that all prior optional parameters also be overridden in the call.

```
class Additions
{
    public static int AddThreeInts(int _i1, int _i2 = 2,int _i3 = 3)
    {
        return _i1 + _i2 + _i3;
    }

    public static void callAdditions()
    {
        // The next statement does not compile, because it skips the _i2 parameter.
        // info(int2Str(Additions::AddThreeInts(1, , 99)));

        // You must specify both optional parameters.
        info(int2Str(Additions::AddThreeInts(1, 2, 99)));
    }

}
```

Accessor methods

Class variables are protected by default. By hiding details of the internal implementation of a class, you can change the implementation of the class later without breaking any code that uses that class. To access the data from reference variables, you must create accessor methods. The following example defines a **Point** class that uses accessor methods to access the variables **x** and **y**.

```
class Point
{
    // Instance variables
    real x;
    real y;

    // Constructor to initialize to a specific or default value
    void new(real _x = 10, real _y = 10)
    {
        x = _x;
        y = _y;
    }

    // Accessor methods
    void setX(real _x)
    {
        x = _x;
    }

    void setY(real _y)
    {
        y = _y;
    }

    real getX()
    {
        return x;
    }

    real getY()
    {
        return y;
    }
}
```

These method declarations show how the **Point** class provides access to its variables from the outside world. Other objects can manipulate the instance variables of **Point** objects by using the accessor methods.

```
Point myPoint = new Point();
// Set the x variable using the accessor method.
myPoint.setX(4.0);
// Get the x variable using the accessor method.
info(any2Str(myPoint.getX()));
```

Parameters

All methods have their own *scope*. A method can take one or more parameters. Within the scope of the method, these parameters are treated as local variables and are initialized with a value from the parameter in the method call. All parameters are passed by value, which means that you can't change the value of the original variable. You can change only the local variable in the method. This local variable is a copy of the original variable.

Scope of variables in methods

A scope defines the area in which an item can be accessed. Variables that are defined in a class are available to the methods within that class. Variables in methods can be accessed only within the current block.

Local functions

You can declare functions inside a method. These are called local functions. While possible, it is not a best practice. Instead, you should add private methods to the class.

- The declarations of local functions must physically precede any non-declaration statements in the method.
- You can declare more than one local function in your method. However, all local functions must be declared in an uninterrupted series, and the set must be terminated by one semicolon (;).
- Code that is inside the local function can access variables that are declared in the method that contains the local function.
- Code that is outside the local function can't access variables that are declared in the local function.
- A local function can be called only by code in the same method where the local function is declared.
- A local function should never call itself. Such recursion can prevent successful compilation.

The following example shows valid declarations of two local functions, **localFunctionA** and **localFunctionB**. Calls to the local functions occur after the function declarations in the example, as is required.

```
static void StaticFunction()
{
    int number = 654;

    void localFunctionA(int _iNum)  // The local function.
    {
        str innerString = "String in localFunctionA";
        str output = strFmt("localFunctionA: %1 , %2 , %3", _iNum, innerString, number);
        info(output);
    }

    void localFunctionB()
    {
        info("Printing from inside localFunctionB.");
    }

    localFunctionA(55);
    localFunctionB();
    // Next info statement would fail to compile,
    // because innerString is restricted to the
    // scope of the local function in which it is declared.
    // print innerString;
}

// When called, the output is:
// localFunctionA: 55 , String in localFunctionA , 654
// Printing from inside localFunctionB.
```

The this keyword

The **this** keyword is a reference to the instance of the class or table where the **this** keyword is used. The **this** reference is never required, but it can clarify your code and enhances the behavior of IntelliSense in the code editor. All calls to instance methods must be qualified by either the **this** reference or a variable. The **this** reference can be used to qualify the following information:

- The names of other instance (non-static) methods in the same class where the **this** reference is used. Here is an example: `boolColorChanged = this.colorItOrange();`
- The names of methods that are inherited by the **this** object.
- The names of fields on the table that contains the method that the **this** keyword is used in.

The **this** reference can't be used in the following ways:

- It can't qualify the names of member variables that are declared in the **classDeclaration** code.
- It can't be used in a static method.
- It can't qualify the names of static methods of the class or table.

Call stack limitation

The depth of the call stack is limited to 100.

X++ inheritance

2/18/2021 • 3 minutes to read • Edit Online

This topic describes inheritance in X++, including how to create a subclass and override a method.

Creating a subclass

Subclasses are classes that extend or inherit from other classes. A class can extend only one other class. Multiple inheritance isn't supported. If you extend a class, the subclass inherits all the methods and variables in the parent class (the *superclass*). Subclasses let you reuse existing code for a more specific purpose. Therefore, they help save you time during design, development, and testing. To customize the behavior of a superclass, override the methods in a subclass. A superclass is often known as a *base class*, and a subclass is often known as a *derived class*.

Subclass example

The following example first creates a class that is named **Point**. It then extends the **Point** class to create a new class that is named **ThreePoint**.

```
class Point
{
    // Instance fields.
    real x;
    real y;

    // Constructor to initialize fields x and y.
    void new(real _x, real _y)
    {
        x = _x;
        y = _y;
    }
}

class ThreePoint extends Point
{
    // Additional instance fields z. Fields x and y are inherited.
    real z;

    // Constructor is overridden to initialize z.
    void new(real _x, real _y, real _z)
    {
        // Initialize the fields.
        super(_x, _y);
        z = _z;
    }
}
```

Preventing class inheritance

You can prevent classes from being inherited by using the **final** modifier.

```
public final class Attribute
{
    int objectField;
}
```

Overriding a method

The methods in a class are inherited by any class that extends the class. To change the functionality of an inherited method, you create a method in the subclass, and then give that method the same name and parameters as the method in the superclass. This process is known as *overriding* the method. In the following example, **ColorAttribute** is a subclass of **Attribute** and therefore inherits the **methodAttr** method. However, because **ColorAttribute** defines a method that has the same name and the same number of arguments, the method in the superclass is overridden.

When you instantiate the subclass, you can assign the reference to either a variable of the superclass type or the subclass type. Regardless of the type of the variable, the overridden method is called.

In the following code example, the subclass overrides the **write** method. Two variables, both of type **Point** are created. One is assigned a **Point** object, the other is assigned a **ThreePoint** object. When the **write** method is called on the **ThreePoint** object, the **ThreePoint** version of the method is called.

```
class Point
{
    // Instance fields.
    real x;
    real y;

    // Constructor to initialize fields x and y.
    void new(real _x, real _y)
    {
        x = _x;
        y = _y;
    }

    void write()
    {
        info("(" + any2Str(x) + ", " + any2Str(y) + ")");
    }
}

class ThreePoint extends Point
{
    // Additional instance fields z. Fields x and y are inherited.
    real z;

    // Constructor is overridden to initialize z.
    void new(real _x, real _y, real _z)
    {
        // Initialize the fields.
        super(_x, _y);
        z = _z;
    }

    void write()
    {
        info("(" + any2Str(x) + ", " + any2Str(y) + ", " + any2Str(z) + ")");
    }

}

// Code that creates Point objects and calls the write method.
Point point2 = new Point(1.0, 2.0);
Point point3 = new ThreePoint(3.0, 4.0, 5.0);

point2.write();
// Output is "(1.0, 2.0)".

point3.write();
// Output is "(3.0, 4.0, 5.0)".
```

Preventing method overrides

Static methods can't be overridden, because they exist per class. To protect other sensitive methods, or core methods, from being overridden, use the **final** modifier. In the following example, because **methodAtt** is declared as **final**, it can't be overridden in any class that extends **Attribute**. You should not specify **new** or **finalize** methods as **final**.

The following example shows how to use the **final** keyword.

```
public class Attribute
{
    int objectVariable;

    final void methodAtt()
    {
        //Some statements
    }
}
```

Overriding vs. overloading

Overriding occurs when the superclass's implementation of a method is changed by the subclass's implementation of that method, but the signatures of both methods are the same.

By contrast, *overloading* occurs when more than one method has the same name, but the methods have different signatures (return types, parameter lists, or both). X++ supports overriding, but it doesn't support overloading.

X++ static classes

2/18/2021 • 3 minutes to read • Edit Online

This topic describes static class members in X++. In general, static methods are intended for these cases:

- The method has no reason to access the member variables that are declared in the class.
- The method has no reason to call any instance (non-static) methods of the class.

You declare static class members by using the **static** keyword. The **static** keyword instructs the system to create only one instance of the method, regardless of the number of instances of the class there are. This one instance is used throughout your session.

Static methods

This section describes a scenario where a software key type is used to help prevent piracy. Each instance of a software key can have its own unique value. Because all software keys must conform to the rules of software key design, the logic that tests for software key conformance is the same for all software keys. Therefore, the method that contains the conformance validation logic should be static.

Here is an example of a method that is declared by using the **static** keyword.

```
public class SoftwareKey
{
    static public boolean validateSoftwareKey(str _softwareKeyString)
    {
        // Your code here.
        return false;
    }
}
```

In the following example, you don't have to construct an instance of the **SoftwareKey** class before you call a static method on the class. When you want to call the static **validateSoftwareKey** method, the syntax starts with the name of the class that contains the method. A pair of colons (::) is used to connect the class name to the static method name.

```
boolean yourBool = SoftwareKey::validateSoftwareKey(yourSoftwareKeyString);
```

Static fields

Static fields are variables that are declared by using the **static** keyword. Conceptually, they apply to the class, not to instances of the class.

Static constructors

A static constructor is guaranteed to run before any static or instance calls are made to the class. The execution of the static constructor is relative to the user's session. The static constructor has the following syntax.

```
static void TypeNew()
```

You never explicitly call the static constructor. The compiler will generate code to make sure that the constructor is called exactly one time before any other method on the class. A static constructor is used to initialize any static data or perform a particular action that must be performed only one time. No parameters can be provided for

the static constructor, and it must be marked as **static**.

The following code example shows how to create a singleton instance by using a static constructor.

```
public class Singleton
{
    private static Singleton instance;

    private void new()
    {
    }

    static void TypeNew()
    {
        instance = new Singleton();
    }

    public static Singleton Instance()
    {
        return Singleton::instance;
    }
}
```

The singleton guarantees that only one instance of the class will ever be called. The following example shows how to instantiate the singleton.

```
Singleton i = Singleton::Instance();
```

Static methods

Static methods, which are also known as *class methods*, belong to a class and are created by using the keyword **static**. You don't have to instantiate an object before you use static methods. Static methods are often used to work with data that is stored in tables. Member variables can't be used in a static method. You use the following syntax to call static methods.

```
ClassName::methodName();
```

Static and instance methods

The accessor keywords on methods never restrict calls between two methods that are in the same class, regardless of which method is static or non-static. In a static method, calls to the **new** constructor method are valid even if the **new** constructor method is decorated with the **private** modifier. The syntax for these calls requires that the **new** keyword be used. The code in a static method must construct an instance object of its own class before it can call any instance methods on the class.

X++ interfaces

2/18/2021 • 2 minutes to read • Edit Online

An *interface* specifies a set of public instance methods. An interface defines and enforces similarities between unrelated classes without having to derive one class from the other.

All interfaces are public, even if you don't explicitly add the **public** keyword in front of the **interface** keyword in interface declaration. The methods on an interface are also public. Explicit inclusion of the keyword **public** is optional.

To create an interface, follow these steps.

1. In Server Explorer, right-click the project, and then click **Add**.
2. In the **New Item** dialog box, select **Interface**, and then enter a name for the interface.
3. Click **Add**.

When you add the **implements** keyword on a class declaration, the class must declare and define the methods that are specified by the interface. A class declaration can implement multiple interfaces. List the interfaces after the single occurrence of the **implements** keyword, and separate the interface names by using commas.

All interface methods that a class implements must be explicitly declared as **public**. A class that implements an interface must also be declared as **public**. An interface can extend another interface by using the **extends** keyword, however, an interface can't extend more than one interface.

It is customary to preface the name of an interface with `I`.

Interface example

In the following code example, the **Automobile** class implements the **IDrivable** interface. The **is** keyword tests whether a class implements an interface.

```
interface IDrivable
{
    int getSpeed()
    {
    }

    void setSpeed(int newSpeed)
    {
    }
}

class Automobile implements IDrivable
{
    int speed;

    public int getSpeed()
    {
        return speed;
    }

    public void setSpeed(int newSpeed)
    {
        speed = newSpeed;
    }
}

class UseAnAutomobile
{
    void DriveAutomobile()
    {
        IDrivable drivable;
        Automobile myAutomobile = new Automobile();
        str temp;

        myAutomobile = new Automobile();

        if (myAutomobile is IDrivable)
        {
            drivable = myAutomobile;
            drivable.setSpeed(42);
            temp = int2str(drivable.getSpeed());
        }
        else
        {
            temp = "Instance is not an IDrivable.";
        }

        info(temp);
    }
}
```

X++ class library

2/18/2021 • 8 minutes to read • Edit Online

This topic describes the library of classes in X++.

There are two kinds of classes: *application classes* and *system classes*.

- **Application classes** – These classes are implemented in X++. They are available in the **Code > Classes** node in Application Explorer.
- **System classes** – These classes are sometimes known as *kernel classes*. They are listed under the **System Documentation > Classes** node in Application Explorer. The source code for these classes isn't available. For a list of the system classes, see API, class, and table reference.

Typical structure of an application class

The following code block types are standard for application classes:

- **class and variable declarations**: The class declaration contains modifiers, such as **public**, **private**, and **extends**.
- **variable declarations**: These are the field members for objects that are constructed from the class. When you type the keyword **this** on a class instance variable, IntelliSense can show a list of the members.
- **new** method: This method creates an instance of the class. The constructor can be called only by using the **new** keyword. Derived classes can call the **new** method of their constructor by calling the **super** method reference. For more information, see X++ inheritance.
- **finalize** method: This method finalizes an instance of the class. This method is the destructor method. However, it's a destructor by convention only. The system doesn't automatically call the **finalize** method during garbage collection.

Additional methods for a class have the following types:

- Instance methods
- Static methods
- Main methods

Methods can be created on many kinds of items. Here are some examples:

- Classes
- Maps
- Views
- Data Sets
- Forms
- Queries

Substituting application classes for system classes

You should use the *substitute application classes* instead of the system classes that they extend.

In Application Explorer, under **System Documentation > Classes**, several kernel or system classes have names that begin with a lowercase *x*. These classes are known as *x-system classes*. Examples of these system classes are **xApplication** and **xVersionControl**. Some of these classes are extended by application classes. For example, the **Application** class extends the **xApplication** system class.

The classes that derive from x-system classes are known as *substitute application classes*. In Application Explorer, under the **Classes** node, the icon next to the substitute application classes differs from the standard icon.

x-system classes

Some of the substitute application classes are associated with a special global variable that represents an instance of the class. For example, the **appl** variable references a pre-instantiated object from the **Application** class. The advantage of the **appl** variable is that the system maintains the object throughout the scope of your session. Your code would be less efficient if it repeatedly used the **new Application()** syntax to obtain an instance of the **Application** class. You should not use the **xApplication** system class. Instead, use the **Application** substitute application class.

You can reference the static members of the **Application** class by using the following standard syntax: **Application::checkForNewBatchJobs()**. However, to reference the instance members of the **Application** class, you should use that class's **appl** variable, if it exists. This pattern applies to most of the x-system classes. The **Session** substitute application class is one exception, because there is no special global variable for **Session**.

The following table lists the x-system classes that have a corresponding substitute application class. The special global variables are also shown for those classes that have one.

APPLICATION CLASS	X-SYSTEM CLASS	GLOBAL VARIABLE
Args	xArgs	Not applicable
Application	xApplication	**appl**
ClassFactory	xClassFactory	**classFactory**
Company	xCompany	**appl.company**
Global	xGlobal	Not applicable
Info	xInfo	**Infolog**
MenuFunction	xMenuFunction	Not applicable
Session	xSession	Not applicable
VersionControl	xVersionControl	**versionControl**

Example of x-system classes

The following example shows the syntax for using several special variables that reference instances of the substitute application classes.

```
TreeNode treeNode;
Args     args;
FormRun  formRun;

// appl variable
info(appl.buildNo());

// company variable
appl.company().reloadRights();

// infolog variable
treeNode = infolog.findNode("\\forms\\custTable");
info(treeNode.AOTgetProperty("Name"));
// Output is "CustTable".

// classFactory variable
args = new Args(formstr(Batch));
formRun = classFactory.formRunClass(args);
formRun.init();
formRun.run();
formRun.detach();
info("Method is ending. This is a message in the Infolog.");
// Output is "Method is ending. This is a message in the Infolog."
```

Batch processing classes

You implement classes by using the batch processing system, and by extending the **RunBase** and **RunBaseBatch** classes. To remove the **Recurrence** button from the **Batch processing** dialog box, you use the **Args::parmEnum** method. We recommend that you designate a class to run as a server-bound batch method. Server-bound batch methods are more secure than batch methods that aren't server-bound for the following reasons:

- The method is run by using the permissions of the user who submitted the method.
- The method can use only specific **Info** and **Global** class methods to interact with the client that is processing it. This restriction limits interaction with the client.

Enable a class to run as a server-bound batch method

1. Create a class that extends the **RunBaseBatch** class.
2. Override the **RunBaseBatch.runsImpersonated** method to return a value of **true**, as shown in the following example.

   ```
   public boolean runsImpersonated()
   {
       return true;
   }
   ```

3. Confirm that the class calls only the following **Info** and **Global** class methods:

   - add
   - Info.copy
   - Info.cut
   - Info.import
   - Info.export
   - Info.line
   - Info.num
   - Global::error

- Global::info
- Global::warning

The **Info.line** and **Info.num** methods are inherited from the **xInfo** class.

Removing the Recurrence button from the batch processing dialog box

When you implement a class by using the batch processing system, you can remove the **Recurrence** button by calling the **Args.parmEnum** method and passing the **NoYes::Yes** system enumeration value. The **NoYes** system enumeration determines whether the **Recurrence** button is removed from the dialog box. The default value is **NoYes::No**.

In the following example, the **InventTransferMultiShip** class is implemented. The **BatchDialog::main** method creates the **Batch processing** dialog box.

```
static void noRecurrenceButton(Args _args)
{
    Args a;
    InventTransferMultiShip inventTransferMultiShip;
    a = new Args();
    inventTransferMultiShip = InventTransferMultiShip::construct();
    a.caller(inventTransferMultiShip);
    a.parmEnum(NoYes::Yes);
    BatchDialog::main(a);
}
```

Image manipulation classes

Two system classes let you to manipulate graphics and icons: **Image** and **Imagelist**.

- **Image** – This class lets you load, save, and manipulate individual images. For example, you can capture a screen and save it as an image, crop or rotate an image, or manipulate the color depth.
- **Imagelist** – This class lets you work with a set of images that have common properties, such as the size and transparency color. You can view the image lists that are used in the **ImageListAppl** application classes.

Query object model

The query object model contains classes that are used to define and run a query. The query objects are used to define the query data source, the fields that are returned, record ranges, and relations to child data sources. The query classes are more visible when you create a dynamic query in code, but they are also used behind the scenes when you create a static query in Application Explorer.

The following table describes the classes in the query object model.

SYSTEM CLASS	DESCRIPTION
QueryRun	This class runs the query and fetches the data.
Query	This class holds some properties, and has one or more related data sources. It's the top level of the query definition.
QueryBuildDataSource	This class defines access to a single data source in the query. If there is more than one data source at the same level in a query, separate SQL statements are produced and are run sequentially. If one data source is a child of another data source, a join is created between the two data sources.

SYSTEM CLASS	DESCRIPTION
QueryBuildFieldList	This class defines the fields that are returned from the database. By default, the field list is dynamic, and all fields are returned from the data source table, map, or view. Each data source has only one **QueryBuildFieldList** object. This object contains information about all selected fields. You can specify aggregate functions, such as **SUM**, **COUNT**, and **AVG**, on the field list object.
QueryBuildRange	This class defines a subset of records that is returned, based on a single field. A range is translated into a **WHERE** clause in the query SQL statement. If more than one field is used to limit the query (**WHERE** clause), the data source will contain more than one range.
QueryBuildDynalink	This class contains information about a relation (limitation) to an external record. When the query is run, this information is converted to additional entries in the **WHERE** clause of the query SQL statement. This class can exist only on the parent data source of a query. Forms use the function when two data sources are synchronized. The child data source will then contain one or more DLLs to the parent data source. The function is used even if the two data sources are put in two different forms but are still synchronized.
QueryBuildLink	This class specifies the relation between the two data sources in the join. This class can exist only on a child data source.

You can also use the SysDa API to query data.

System classes overview

The source for system classes isn't available. A system class can have the following characteristics:

- Static methods (or class methods)
- Dynamic methods
- Properties – These properties are member functions that are used to set properties. An example is **LeftMargin**.

You can't override system class methods. It isn't our intention that you will use the system classes to design your application objects from scratch. Instead, use them to extend or modify the default functionality in Application Explorer. For example, you can dynamically add extra information to an existing report. Alternatively, you can change the options that are available on a page, based on the user's selection on a previous page.

Collection classes

The *collection classes* let you create lists, sets, structs, maps, and arrays.

Application object classes

These system classes hold functions that are activated whenever you use Application Explorer to create your application. For example, the system uses the **FormDesign** class when you define the layout of your form in the **Designs** node in Application Explorer. These classes also let you to create and modify application objects.

Integration classes

The integration with the environment is typically implemented by classes. Here are some examples of the classes in this category:

- **COM** – The call of methods on COM objects.
- **DLL** – The call of Microsoft Windows DLL functions.
- **IO** – Read and write external files.
- **ODBCConnection** – An Open Database Connectivity (ODBC) interface to a foreign database.

X++ event terminology and keywords

2/18/2021 • 2 minutes to read • Edit Online

This topic describes event terminology and keywords in X++.

You can use the event design pattern to make your code more modular and reusable. The term *event* is a metaphor that explains how delegates are used. When something important occurs during a program run, other modules might have to process the occurrence. These important occurrences are known as *events*. When an event occurs, the program tells its notifier for the event that the notifier must send notifications about the event. A notification must be sent to all the event handlers that are subscribers of the notifier. When the program tells its notifier to send the notifications, we call that process *raising* an event.

The following table shows the terms that are used to describe the event metaphor.

TERM	DESCRIPTION
Event	An important occurrence in a program module where additional modules must process the occurrence.
Notifier	The program element that sends information about the event to all the event handlers that are subscribed to the notifier.
Subscriber	The program functions or methods that are subscribed to an event notifier.
Event handler	The methods that subscribe to an event notifier. Only the appropriate kind of methods can be event handlers.

Keywords that are used for programming that uses delegates

The following table shows the keywords that describe the use of delegates.

KEYWORD OR TERM	CODE	DESCRIPTION
delegate	`delegate myDelegate(str information) {}`	The code shows what the delegate looks like in the code editor. Because the return type is always **void**, it isn't mentioned in the syntax. No code is allowed inside the braces ({}).
eventHandler	`myClassInstance.myDelegate += eventHandler(otherClass.myInstanceMethod);`	Although the syntax of the **eventHandler** keyword might give the impression that **eventHandler** is an X++ function, it isn't a function. The **eventHandler** keyword tells the compiler that a method is being subscribed to a delegate.
Subscribe or add a method to a delegate	`myClassInstance.myDelegate += eventHandler(OtherClass::aStaticMethod);`	In the code, the static method **OtherClass::aStaticMethod** becomes subscribed to the delegate.

KEYWORD OR TERM	CODE	DESCRIPTION
Call a delegate	`myClassInstance.myDelegate("Hello");`	This call to the delegate prompts the delegate to call each method that is subscribed to the delegate. The subscribed methods are called in the same order in which they were added to the delegate. One subscribed method must be completed before the delegate calls the next method.

Example

The two classes in the following code example demonstrate how to define an event, subscribe to an event, and raise an event. The **PointWithEvent** class defines a delegate, **moved**. The **move** method calls the **moved** delegate, thereby notifing any objects that have subscribed to the event. The **PointKeeper** class defines the **writeMove** method and assigns it as the event handler for the **moved** delegate of the **Point** instance created in the **createAndMove** method.

```
class PointWithEvent
{
    // Instance fields.
    real x;
    real y;

    // Constructor to initialize fields x and y.
    void new(real _x, real _y)
    {
        x = _x;
        y = _y;
    }

    void move(real x_offset, real y_offset)
    {
        x += x_offset;
        y += y_offset;
        this.moved(abs(x_offset) + abs(y_offset));
    }

    delegate void moved(real distance)
    {
    }

}

class PointKeeper
{

    public void createAndMove()
    {
        PointWithEvent point = new PointWithEvent(1.0, 2.0);

        point.moved += eventhandler(this.writeMove);

        point.move(4.0, 5.0);
        // Output is "9.0".
    }

    public void writeMove(real distance)
    {
        info(any2Str(distance));
    }

}
```

X++ data selection and manipulation overview

2/18/2021 • 2 minutes to read • Edit Online

You can use SQL statements, either interactively or in source code, to retrieve and modify data that is stored in the database. You can use the **select** statement and API methods for these tasks:

- Select data: Select the data to view or modify.
  - **select statement** – Fetch records.
- Insert data: Add one or more new records to a table.
  - **insert and doInsert methods** – Insert one record at a time.
  - **insert_recordset, RecordInsertList.insertDatabase, and RecordSortedList.insertDatabase methods** – Insert multiple records at the same time.
- Update data: Modify the data in existing table records.
  - **update and doUpdate methods** – Update one record at a time.
  - **update_recordset statement** – Update multiple records at the same time.
- Delete data: Remove existing records from a table.
  - **delete and doDelete methods** – Delete one record at a time.
  - **delete_from statement** – Delete multiple records at the same time.

Here are some other statements that you will use in data access:

- while select statement
- select expression
- next statement

Transactional integrity helps prevent data corruption and improve scalability.

The Conversion of operations from set-based to record-by-record topic provides information about how you can use the record set–based statements and methods more efficiently.

You can also use the SysDa classes to retrieve and modify data. The extensible SysDa API provides almost all the data access possibilities that are available in X++.

The **executeQueryWithParameters** API can help mitigate a SQL injection attack.

Select statement

2/18/2021 • 18 minutes to read • Edit Online

The **select** statement fetches or manipulates data from the database.

- All **select** statements use a table variable to fetch records. This variable must be declared before a **select** statement can be run.
- The **select** statement fetches only one record, or field. To fetch or traverse multiple records, you can use the **next** statement or the **while select** statement.
  - The **next** statement fetches the next record in the table. If no **select** statement precedes the **next** statement, an error occurs. If you use a **next** statement, don't use the **firstOnly** find option.
  - It's more appropriate to use a **while select** statement to traverse multiple records.
- The results of a **select** statement are returned in a table buffer variable.
- If you use a field list in the **select** statement, only those fields are available in the table variable.

Select example

The following example fetches all the columns in the first row of the CustTable table and prints the value in the **AccountNum** column of that row.

```
CustTable custTable;
select * from custTable;
info("AccountNum: " + custTable.AccountNum);
```

For more examples of data selection, see Select data.

Insert example

The following example inserts a new record into the CustTable table. The **AccountNum** column of the new record is set to **2000**, and the **CustGroup** column is set to **1**. Other fields in the record will be blank.

```
ttsBegin;
    CustTable custTable;
    select forUpdate custTable;
    custTable.AccountNum = '2000';
    custTable.CustGroup = '1';
    custTable.insert();
ttsCommit;
```

For more examples of data insertion, see Insert data.

Update example

The following example selects the CustTable table for update. Only records where the value of the **AccountNum** field equals **2000** are updated. Because there is no call to **next**, and this example doesn't use a **select while** statement, only one record is updated. The value of the **CreditMax** field is changed to **5000**.

```
ttsBegin;
    CustTable custTable;
    select forUpdate custTable
        where custTable.AccountNum == '2000';
    custTable.CreditMax = 5000;
    custTable.update();
ttsCommit;
```

For more examples of data updates, see Update data.

Delete example

In the following example, all records in the CustTable table where the **AccountNum** field equals **2000** are deleted from the database. One record is deleted at a time.

```
ttsBegin;
    CustTable custTable;
    while select forUpdate CustTable
        where custTable.AccountNum == '2000'
    {
        custTable.delete();
    }
ttsCommit;
```

For more examples of data deletion, see Delete data.

Syntax of the select statement

The following symbols are used in the syntax:

- **[]** – Brackets enclose an optional element.
- **{}** – Braces enclose an element that can be included zero or more times.
- **+** – A plus sign indicates an element that can be included one or more times.
- **|** – A bar indicates options.

SYMBOL		EXPRESSION
SelectStatement	=	**select** *Parameters*
Parameters	=	{ *FindOption* } [*FieldList* **from**] *TableBufferVariable* [*IndexClause*] [*Options*] [*WhereClause*] [*JoinClause*]
FindOption	=	**crossCompany** [: *ContainerVariable*] | **reverse** | **firstFast** | *FirstOption* | **forUpdate** | **noFetch** | *ForceOption* | **forceSelectOrder** | **forceNestedLoop** | *LockOption* | **repeatableRead** | **validTimeState**
FirstOption	=	**firstOnly** | **firstOnly10** | **firstOnly100** | **firstOnly1000**
LockOption	=	**optimisticLock** | **pessimisticLock**

SYMBOL		EXPRESSION
ForceOption	=	**forcePlaceholders** | **forceLiterals**
FieldList	=	{ *Field* } | *****
Field	=	*Aggregate* **(** *FieldIdentifier* **)** | *FieldIdentifier*
Aggregate	=	**sum** | **avg** | **minof** | **maxof** | **count**
Options	=	*OrderClause* | *IndexClause*
OrderClause	=	[*OrderBy* [*GroupBy*]] | [*GroupBy* [*OrderBy*]]
OrderBy	=	**order** [**by**] *FieldOrder* {, *FieldOrder* }
GroupBy	=	**group** [**by**] *FieldOrder* {, *FieldOrder* }
FieldOrder	=	*FieldIdentifier* [**asc** | **desc**]
IndexClause	=	**index** *IndexName* | **index hint** *IndexName*
WhereClause	=	**where** *Expression InClause*
InClause	=	**in** *List*
JoinClause	=	[**exists** | **notexists** | **outer**] **join** *Parameters*
ContainerVariable	=	A container.
Expression	=	An expression.
TableBufferVariable	=	The variable name for the results.
FieldIdentifier	=	The name of a field in the table.
IndexName	=	The name of an index for a table.
List	=	An array of values.

Aggregate functions

The aggregate functions perform calculations on a single field over a group of records.

- The result is returned in the field that you perform the aggregate function over.
- The fields in the results are the aggregate values and the fields in the **group by** clause.
- You can count, average, or sum only integer and real fields.
- In cases where the **sum** function will return **null**, no rows are returned.

Differences between X++ and SQL

In industry-standard SQL, a database query can contain aggregate functions. Examples include **count(RecID)** and **sum(columnA)**. When an aggregate function is used, but no rows match the **where** clause, a row must be returned to hold the result of the aggregates. The row that is returned shows the value **0** (zero) for the **count** function and **null** for the **sum** function. X++ doesn't support the concept of **null** values for the database. Therefore, in cases where the **sum** function will return **null**, no row is returned to the user. Additionally, every data type has a specific value that is treated as a **null** value in some circumstances.

Grouping and ordering the query results

A query can have multiple **group by** clauses, but the fields can be qualified by a table name in only one **group by** clause. We recommend that you use table name qualifiers. The **order by** clause follows the same syntax patterns as **group by**. Both clauses, if they are provided, must appear after the **join** (or **from**) clause, and both must appear before any **where** clause that exists on the same **join** clause. We recommend that all **group by**, **order by**, and **where** clauses appear immediately after the last **join** clause. The following example shows a **group by** clause where a field is qualified by a table name.

```
CustTable custTable;
CustGroup custGroup;
struct groupSummary = new struct("int CustomerCount; str CustGroup");

while select count(CreditMax) from custTable
    join custGroup
    order by custGroup.Name
    group by custGroup.CustGroup
    where custTable.CustGroup == custGroup.CustGroup
        && custGroup.Name like "*Days*"
{

    groupSummary.value("CustomerCount", custTable.CreditMax);
    groupSummary.value("CustGroup", custGroup.CustGroup);
    info(groupSummary.toString());
}

// Example output:
// (CustomerCount:1; CustGroup:"1")
// (CustomerCount:3; CustGroup:"2")
```

Join tables

The following example shows how an inner join can be performed as part of a **select** statement. The example also shows an **order by** clause where each field is qualified by a table name. Therefore, you can use just one **order by** clause to control how the retrieved records are sorted.

```
CustTable custTable;
CustGroup custGroup;
struct output = new struct("int AccountNum; str CustGroup");

while select AccountNum from custTable
    join Name from custGroup
    order by custGroup.Name, custTable.AccountNum
    where custTable.CustGroup == custGroup.CustGroup
{
    info(custGroup.Name + ': ' + custTable.AccountNum);
}

// Example output:
// Days1: 6000
// Days1: 6001
// Days2: 5000
```

Using where, order by, and index hint together in a query

You use the **order by** keyword in **select** statements to order the data that is returned. Use the **index hint** keyword to specify the index that should be used in the query, and to sort the selected records in the manner that is defined by the index. Indexes optimize the selection of records. To select records in a specific order, combine the **index hint** keyword with an **order by** expression. If you want the output to be sorted in reverse order, use the **reverse** keyword. If a table index has been disabled (that is, if the index's **Enabled** property is set to **No**), the **select** statement that references the index is still valid. However, the database can't use the index as a hint to sort the data, because the index doesn't exist in the database. The following table shows how to use the **index hint** and **order by** keywords in **select** statements.

TASK	SELECT STATEMENT
Select records when the order isn't significant.	select .. where ...
Select records when the order is significant.	select .. order by ... where ...
Select records, and force a specific index to be used.	select .. index hint ... where ...
Select records when the order is significant, and force a specific index to be used.	select .. index hint ... order by ... where ...

The following example shows how to select transactions from the SalesTable table, based on a range of customers and due dates.

```
SalesTable salesTable;
select salesTable
    index hint CustIdx
    order by CustAccount
    where
        salesTable.CustAccount >= '3000'
        && salesTable.CustAccount <= '4000'
        && salesTable.FixedDueDate >= 12\12\2004
        && salesTable.FixedDueDate <= 05\05\2009;
```

asc keyword

The **asc** keyword is an option on the **order by** or **group by** clause. It specifies an ascending sort order. If neither **asc** nor **desc** is specified, the sort is ascending.

```
CustTable custTable;
select * from custTable
    order by Value asc;
```

avg keyword

The **avg** keyword returns the average of the fields.

```
CustTable custTable;
select avg(Value) from custTable;
info(int642Str(custTable.Value));
```

count keyword

The **count** keyword returns the number of records.

```
CustTable custTable;
int64 iCountRows;
select count(RecID) from custTable;
iCountRows = custTable.RecID;
info('Rows: ' + int642Str(iCountRows));
```

crossCompany keyword

The **crossCompany** keyword returns data for all companies that the user is authorized to read from. You can add a container to reduce the number of companies that are involved. The following example returns data for companies that the user is authorized to read from. Results are limited to the **dat** and **dmo** companies.

```
CustTable custTable;
container conCompanies = ['dat','dmo'];
select crossCompany :conCompanies
    * from custTable;
```

desc keyword

The **desc** keyword is an option on the **order by** or **group by** clause. It specifies a descending sort order. If neither **asc** nor **desc** is specified, the sort is ascending.

```
CustTable custTable;
select * from custTable
    order by Value desc;
```

exists keyword

The **exists** keyword is a method that returns a Boolean value and a **join** clause.

```
CtrTable ctrTable;
CustTable custTable;
while select AccountNum, Value from custTable
    order by AccountNum
    exists join * from ctrTable
    where (ctrTable.AccountNum == custTable.AccountNum)
{
}
```

firstFast keyword

The **firstFast** keyword is a priority hint. The first row appears more quickly, but the total return time for this option might be slower. The **firstFast** hint is automatically issued from all pages.

The following code example quickly returns the first row.

```
CustTable custTable;
select firstFast custTable
    order by AccountNum;
```

firstOnly, firstOnly10, firstOnly100, and firstOnly1000 keywords

The **firstOnly** keywords speed up the fetch by returning a limited number of rows. When you include **firstOnly** in your query, the runtime returns a table buffer. When you omit **firstOnly**, the runtime allocates an object that can iterate over records. From a performance perspective, you should use **firstOnly** only when your intent is to fetch the first record.

KEYWORD	DESCRIPTION
firstOnly	Return only the first row.
firstOnly10	Return 10 rows.
firstOnly100	Return 100 rows.
firstOnly1000	Return 1,000 rows.

The following code example returns only the first row of the results.

```
CustTable custTable;
select firstOnly custTable
    index hint AccountIdx
    where custTable.AccountNum == '5000';
```

forceLiterals keyword

The **forceLiterals** keyword instructs the kernel to reveal the actual values that are used in **where** clauses to the Microsoft SQL Server database at the time of optimization. The **forceLiterals** and **forcePlaceholders** keywords are mutually exclusive. For more information, see the forcePlaceholders keyword section.

WARNING

You should not use the **forceLiterals** keyword in **select** statements, because it could expose code to an SQL injection security threat.

forceNestedLoop keyword

The **forceNestedLoop** keyword forces the SQL Server database to use a nested-loop algorithm to process a particular SQL statement that contains a join algorithm. Therefore, a record from the first table is fetched before any records from the second table are fetched. Typically, other join algorithms, such as hash joins and merge joins, are considered. This keyword is often combined with the **forceSelectOrder** keyword.

```
CustGroup custGroup;
CustTable custTable;

while select forceNestedLoop custGroup
    join custTable
    where custGroup.CustGroup == custTable.CustGroup
{
    Info(custTable.CustGroup);
}
```

forcePlaceholders keyword

The **forcePlaceholders** keyword instructs the kernel **not** to reveal the actual values that are used in **where** clauses to the SQL Server database at the time of optimization. By default, this behavior is used in all statements that aren't **join** statements. The advantage of using this keyword is that the kernel can reuse the access plan for similar statements that have other search values. The disadvantage is that, although the access plan is computed, the fact that data distribution might be uneven isn't considered. The access plan is an on-average access plan. The **forcePlaceholders** and **forceLiterals** keywords are mutually exclusive.

The following example iterates through the **CustGroup** table that is joined with the **CustTable** table.

```
CustGroup custGroup;
CustTable custTable;

while select forcePlaceholders custGroup
    join custTable
    where custGroup.CustGroup == custTable.CustGroup
{
    Info(custTable.CustGroup);
}
```

forceSelectOrder keyword

The **forceSelectOrder** keyword forces the SQL Server database to access the tables in a join in the specified order. If two tables are joined, the first table in the statement is always accessed first. This keyword is often combined with the **forceNestedLoop** keyword.

The following example joins the CustGroup and CustTable tables on the **CustGroup** field.

```
CustGroup custGroup;
CustTable custTable;

while select forceSelectOrder custGroup
    join custTable
    where custGroup.CustGroup == custTable.CustGroup
{
    Info(custTable.CustGroup);
}
```

forUpdate keyword

The **forUpdate** keyword selects records for update only. Depending on the underlying database, the records might be locked for other users. The following example selects the **CreditMax** column in the CustTable table for update, for the record where the **AccountNum** value is **2000**.

```
ttsBegin;
    CustTable custTable;
    select forUpdate custTable
        where custTable.AccountNum == '2000';
    custTable.CreditMax = 5000;
    custTable.update();
ttsCommit;
```

group by keyword

The **group by** keyword instructs the database to group selected records by fields.

```
CustTable custTable;
while select sum(CreditMax) from custTable
    group by CustGroup
{
    info(custTable.CustGroup + ' ' + int642Str(custTable.CreditMax));
}
```

in keyword

The **in** keyword filters rows where a value is contained in a list.

If you don't use the **in** keyword, the code that you write will resemble the following example.

```
// This code doesn't use the in keyword.
private CostAmountStdAdjustment calcCostAmountStdAdjustment()
{
    InventSettlement inventSettlement;

    select sum(CostAmountAdjustment) from inventSettlement
        where inventSettlement.TransRecId == this.RecId
            && inventSettlement.Cancelled == NoYes::No
            && (inventSettlement.OperationsPosting == LedgerpostingType::purchStdProfit
                || inventSettlement.OperationsPosting == LedgerpostingType::purchStdLoss
                || inventSettlement.OperationsPosting == LedgerpostingType::InventStdProfit
                || inventSettlement.OperationsPosting == LedgerpostingType::InventStdLoss);

    return inventSettlement.CostAmountAdjustment;
}
```

If you use the **in** keyword, the code that you write will resemble the following example.

```
// This code uses the in keyword.
private CostAmountStdAdjustment calcCostAmountStdAdjustment()
{
    InventSettlement inventSettlement;
    container ledgerPostingTypes = this.ledgerPostingTypesForCostAmountStdAdjustmentCalculation();

    select sum(CostAmountAdjustment) from inventSettlement
        where inventSettlement.TransRecId == this.RecId
            && inventSettlement.Cancelled == NoYes::No
            && inventSettlement.OperationsPosting in ledgerPostingTypes;

    return inventSettlement.CostAmountAdjustment;
}

protected container ledgerPostingTypesForCostAmountStdAdjustmentCalculation()
{
return [
    LedgerPostingType::purchStdProfit,
    LedgerPostingType::PurchStdLoss,
    LedgerPostingType::InventStdProfit,
    LedgerPostingType::InventStdLoss
];
}
```

index keyword

The **index** keyword instructs the database to sort the selected records as specified by the index.

```
CustTable custTable;
while select AccountNum, Value from custTable
    index AccountIdx
{
    Info(custTable.AccountNum +  ": " + int642Str(custTable.Value));
}
```

index hint keyword

The **index hint** keyword gives the database a hint to use a specific index to sort the selected records as specified in the index. The database can ignore the hint. An incorrect index hint can greatly affect performance. Index hints should be applied only to SQL statements that don't have dynamic **where** clauses or **order by** clauses, and where the effect of the hint can be verified.

Before you can use **index hint** in queries, you must call **allowIndexHint(true)** on the table. The default behavior for **index hint** is **false**, and the hint is ignored.

> **WARNING**
> You should use **index hint** sparingly and with caution, and only when you can be sure that it improves performance. The **index hint** keyword and API let you pass the correct hints when they are required. If you're ever in doubt, avoid using **index hint**.

In the following example, the **AccountIdx** index is used to sort the records in the query on the CustTable table.

```
str _accountNum = '111';
CustTable custTable;
custTable.allowIndexHint(true);

while select forUpdate custTable
    index hint AccountIdx
    where custTable.AccountNum == _accountNum
{
}
```

join keyword

The **join** keyword is used to join tables on a column that is shared by both tables. The join criteria are specified in a **where** clause, because there is no **on** keyword, such as is found in SQL. This keyword reduces the number of SQL statements that are required if you want to loop through a table and update transactions in a related table. For example, you process 500 records in a table and want to update related records in another table. If you use a nested **while select**, there will be 501 trips to the database. However, if you use a **join**, there will be just one trip to the database.

```
CustTable custTable;
CustGroup custGroup;
int totalCredit;

while select custGroup
    join custTable
    where custGroup.CustGroup == custTable.CustGroup
{
    totalCredit += custTable.CreditMax;
}
}
```

maxof keyword

The **maxof** keyword returns the maximum of the fields.

```
CustTable custTable;
select maxof(CreditMax) from custTable;
info(int642Str(custTable.Value));
```

minof keyword

The **minof** keyword returns the minimum of the fields.

```
CustTable custTable;
select minof(CreditMax) from custTable;
info(int642Str(custTable.Value));
```

noFetch keyword

The **noFetch** keyword indicates that no records should be fetched now. Typically, this keyword is used when the result of the **select** statement is passed on to another application object, such as a query that performs the actual fetch.

The following example creates a query variable but doesn't fetch the records.

```
CustTable custTable;
select noFetch custTable
    order by AccountNum;
```

notExists keyword

The **notExists** keyword is selected only if there are no posts.

```
CustTable custTable;
CtrTable ctrTable;

while select AccountNum, Value from custTable
    order by AccountNum
    notExists join * from ctrTable
    where (ctrTable.AccountNum == custTable.AccountNum)
{
}
```

optimisticLock keyword

The **optimisticLock** keyword forces a statement to run by using optimistic concurrency control, even if a different value is set on the table.

```
CustTable custTable;
select optimisticLock custTable
    where custTable.AccountNum > '1000';
```

order by keyword

The **order by** keyword instructs the database to sort the selected records by the fields in the **order by** list. The keyword **by** is optional.

```
CustTable custTable;
select * from custTable
    order by accountNum desc
    where custTable.AccountNum > '100';
info("AccountNum: " + custTable.AccountNum);
```

The following example prints the highest **AccountNum** value in the CustTable table.

```
CustTable custTable;
select reverse custTable
    order by accountNum;
info("AccountNum: " + custTable.AccountNum);
```

outer keyword

The **outer** keyword returns all rows from the table that is named first, even rows that have no match in the table that is named second. This join is a left outer join. Default values are substituted for any data that could not be obtained from a matching row in the other joined table.

There is no **left** keyword, and there is no right outer join.

For an inner join, the behavior if you filter on an **on** clause is the same as the behavior if you filter on the **where**

clause.

```
CustTable custTable;
CustGroup custGroupTable;

while select CustGroup from custGroupTable
    order by CustGroup
    outer join * from custGroupTable
    where custTable.CustGroup == custGroupTable.CustGroup
{
    Info(custTable.CustGroup + ', ' + custGroupTable.Name);
}
```

The following example is based on two tables. The field types and example data are included. There is a one-to-many relationship between the SalesOrder parent table and the SalesOrderLine child table. For each row in the SalesOrder table, there are 0 (zero) or more rows in the SalesOrderLine table. There are two rows in the SalesOrder table.

SALESORDERID (INTEGER, PRIMARY KEY)	DATEADDED (DATE)
1	2010-01-01
2	2010-02-02

The SalesOrderLine table contains a foreign key field that is named **SalesOrderID**. This field references the primary key column of the SalesOrder table. A **SalesOrderID** value of **2** doesn't occur in the data for the SalesOrderLine table.

SALESORDERLINEID (STRING, PRIMARY KEY)	QUANTITY (INTEGER)	SALESORDERID (INTEGER, FOREIGN KEY)
AA	32	1
BB	67	1
CC	66	1

The following code has a **select** statement that reads the two tables. The **select** statement includes a left **outer join** clause. Both the join criteria and the data filter are on the **where** clause. The output from the code is also shown. The second record in the output has a **SalesOrderID** value of **2**. However, that value isn't present in the SalesOrderLine table. Therefore, some of the fields in the second record have default values: **0** for an integer and a zero-length string for a string.

```
SalesOrder recSalesOrder;
SalesOrderLine recSalesOrderLine;
struct struct4 = new struct
    ("int SalesOrderID;"
    + "date DateAdded;"
    + "str SalesOrderLineID;"
    + "int Quantity"
    );
while select *
    from
        recSalesOrder
        outer join recSalesOrderLine
    where
        recSalesOrder.SalesOrderID == recSalesOrderLine.SalesOrderID
        && recSalesOrderLine.Quantity == 66
{
    struct4.value("SalesOrderID", recSalesOrder.SalesOrderID);
    struct4.value("DateAdded", recSalesOrder.DateAdded);
    struct4.value("SalesOrderLineID", recSalesOrderLine.SalesOrderLineID);
    struct4.value("Quantity", recSalesOrderLine.Quantity);
    info(struct4.toString());
}

// Example output:
// (SalesOrderID:1; DateAdded:2010/1/1; SalesOrderLineID:"CC"; Quantity:66)
// (SalesOrderID:2; DateAdded:2010/2/2; SalesOrderLineID:""; Quantity:0)
```

pessimisticLock keyword

The **pessimisticLock** keyword forces a statement to run by using pessimistic concurrency control, even if a different value is set on the table.

```
CustTable custTable;
select pessimisticLock custTable
    where custTable.AccountNum > '1000';
```

repeatableRead keyword

This **repeatableRead** keyword specifies that the current transaction must be completed before other transactions can modify data that has been read by logic inside the current transaction. An explicit transaction is completed at either **ttsAbort** or the outermost **ttsCommit**. For a standalone **select** statement, the transaction duration is the duration of the **select** command. However, the database sometimes enforces the equivalent of **repeatableRead** in individual **select** statements, even if this keyword doesn't appear in your code. (The behavior depends on the method that the database uses to determine whether it should scan the tables.) For more information, see the documentation for the underlying relational database product.

reverse keyword

The **reverse** keyword returns records in reverse order.

```
CustTable custTable;
select reverse custTable
    order by AccountNum;
```

sum keyword

The **sum** keyword returns the sum of the fields. It can be used to sum all accounts, order lines, and so on.

```
CustTable custTable;
select sum(CreditMax) from custTable;
info(int642Str(custTable.Value));
```

validTimeState keyword

The **validTimeState** keyword selects rows from a table where the **ValidTimeStateFieldType** property is set to a value other than **None**.

```
CustPackingSlipTransHistory history;
utcDateTime dateFrom, dateTo = DateTimeUtil::utcNow();
anytype recid = -1;
select
    validTimeState(dateFrom, dateTo)
    *
    from history;
recid = history.RecId;
info('RecId:' + int642Str(recid));
```

where keyword

The **where** keyword filters rows from a table where the expression is **true**.

The following example finds a customer that has an **AccountNum** value that is more than 100.

```
CustTable custTable;
select * from custTable
    where custTable.AccountNum > '100';
info("AccountNum: " + custTable.AccountNum);
```

The following examples prints the lowest **AccountNum** value that is more than 100.

```
CustTable custTable;
select * from custTable
    order by accountNum
    where custTable.AccountNum > '100';
info("AccountNum: " + custTable.AccountNum);
```

The following example prints the highest **AccountNum** value that is more than 100.

```
CustTable custTable;
select * from custTable
    order by accountNum desc
    where custTable.accountNum > "100";
info("AccountNum: " + custTable.AccountNum);
```

Select data

2/18/2021 • 2 minutes to read • Edit Online

The **select** statement fetches or manipulates data from the database.

- All **select** statements use a table variable to fetch records. This variable must be declared before a **select** statement can be run.
- The **select** statement fetches only one record, or field. To fetch or traverse multiple records, you can use the **next** statement or the **while select** statement.
  - The **next** statement fetches the next record in the table. If no **select** statement precedes the **next** statement, an error occurs. If you use a **next** statement, don't use the **firstOnly** find option.
  - It's more appropriate to use a **while select** statement to traverse multiple records.
- The results of a **select** statement are returned in a table buffer variable.
- If you use a field list in the **select** statement, only those fields are available in the table variable.

The following example fetches all the columns in the first row of the CustTable table and prints the value in the **AccountNum** column of that row.

```
CustTable custTable;
select * from custTable;
info("AccountNum: " + custTable.AccountNum);
```

The following example prints the value in the **AccountNum** column of each row in the CustTable table.

```
CustTable custTable;
while select * from custTable
{
    info("AccountNum: " + custTable.AccountNum);
}
```

The following example prints the value in the **AccountNum** column of the first two rows that are returned by the **select** statement.

```
CustTable custTable;
select * from custTable;
info("AccountNum: " + custTable.AccountNum);

next custTable;
info("AccountNum: " + custTable.AccountNum);
```

For more examples, see Select statement.

Insert data

2/18/2021 • 7 minutes to read • Edit Online

You can use SQL statements, either interactively or in source code, to insert one or more rows into tables that are stored in the database.

- **insert method** – Insert one row at a time.
- **doInsert method** – Insert one row at a time.
- **insert_recordset statement** – Copy multiple records directly from one or more tables into another table in one database trip.
- **RecordInsertList.insertDatabase** – Insert multiple rows at the same time in one database trip. Use this construct when you don't have to sort the data.
- **RecordSortedList.insertDatabase** – Insert multiple rows at the same time in one database trip. Use this construct when you want a subset of data from a specific table, and you want that data to be sorted in an order that doesn't currently exist as an index.

RecordSortedList, **RecordInsertList**, and **insert_recordset** let you insert multiple records. By using these methods, you reduce communication between the application and the database. Therefore, you help increase performance. In some situations, record set–based operations can fall back to record-by-record operations. For more information, see Conversion of operations from set-based to record-by-record.

insert method

The **insert** method inserts one record at a time. It generates values for the **RecId** field and system fields, and then inserts the contents of the buffer (that is, the column values) into the database.

- Don't use a **select** statement on the table variable before you call the **insert** method.
- The **insert** method doesn't handle all the key field requirements and table dependencies. You must write code to handle them.

Here is how the **insert** method works:

- Only the specified columns of the rows that have been selected by the query are inserted into the named table.
- The columns of the table that is copied from and the columns of the table that is copied to must be type-compatible.
- If the columns of both tables match in type and order, the column list can be omitted from the **insert** clause.

The following example inserts a new record into the CustGroup table. The **CustGroup** column of the new record is set to **41**. Other fields in the record will be blank.

```
CustGroup custGroup;
ttsBegin;
    custGroup.CustGroup = '41';
    custGroup.insert();
ttsCommit;
```

To override the behavior of the **insert** method, use the **doInsert** method.

doInsert method

The **doInsert** method generates values for the **RecId** field and other system fields, and then inserts the contents of the buffer into the database. Use this method when the **insert** method on the table must be bypassed.

> **WARNING**
> A call to **doInsert** skips all logic, including database event handlers (for example **oninserting** and **oninserted**), chain-of-command **onInsert()**, and the **insert()** call itself. It's generally considered bad practice to use **doInsert**, and we don't recommend that you use it.

insert_recordset statement

The **insert_recordset** statement copies data directly from one or more source tables into one destination table in one server trip. It's faster to use **insert_recordset** than an array insert (**RecordInsertList.insertDatabase** or **RecordSortedList.insertDatabase**). However, array inserts are more flexible if you want to handle the data before you insert it. Although **insert_recordset** is a record set–based operator that performs operations on multiple records at a time, it can fall back to record-by-record operations in many situations. For more information, see Conversion of operations from set-based to record-by-record.

In the following syntax for the **insert_recordset** statement, brackets ([]) indicate optional elements of the statement.

insert_recordset *DestinationTable* **(** *ListOfFields* **)**

select *ListOfFields1* **from** *SourceTable* **[where** *WhereClause* **]**

[join *ListOfFields2* **from** *JoinedSourceTable* **[where** *JoinedWhereClause* **]]**

- *ListOfFields* in the destination table must match the list of fields in the source tables. Data is transferred in the order in which it appears in the list of fields. Fields in the destination table that aren't present in the list of fields are assigned **0** (zero) values, as in other areas. System fields, such as **RecId**, are assigned transparently by the kernel in the destination table.
- *WhereClause* and *JoinedWhereClause* are described in the *WhereClause* clause in the **select** statement.

insert_recordset: Inserting data from another table

In this example, the **Value** column in the NameValuePair table is summed for each **Name** value. The results of the aggregation are stored in the ValueSumByName table.

```
ValueSumByName valueSumName;
NameValuePair nameValuePair;

insert_recordset valueSumName (Name, ValueSum)
    select Name, sum(Value)
    from nameValuePair
    group by Name;
```

insert_recordset: Inserting data from variables

The following example shows that the **insert_recordset** statement can insert variable data.

- Include the **firstonly** keyword to insert only one new record. If you omit **firstonly**, a record is inserted for each record in the CustTable table.
- Literals, such as **128** or **"this literal string"**, can't be used in the query as a source of data that is inserted.
- The columns in the source table don't have to correspond to the target table.

In this example, one new record is inserted into the NameValuePair table. This record has an **Id** value of **1**, a

Name value of **Name1**, and a **Value** value of **1**.

```
NameValuePair nameValuePair;
CustTable custTable;

int id_var = 1;
str name_var = 'Name1';
int value_var = 1;

insert_recordset nameValuePair (Id, Name, Value)
select firstonly id_var, name_var, value_var from custTable;
```

insert_recordset: Inserting data by using a join

The following example shows a join of three tables on an **insert_recordset** statement that has a subselect. It also shows a **while select** statement that has a similar join. A variable is used to supply the inserted value for one column. The **str** variable must be declared, and it must have a length that is less than or equal to the maximum length of the corresponding database field.

In this example, there is an **insert_recordset** statement for the tabEmplProj5 table. One of the target fields is named **Description**, and its data comes from the local **sDescriptionVariable** variable. The **insert_recordset** statement succeeds even when the configuration key for the **Description** field is turned off. The system ignores both the **Description** field and the **sDescriptionVariable** variable. Therefore, this code provides an example of *configuration key automation*. Configuration key automation occurs when the system can automatically adjust the behavior of an **insert_recordset** statement that inserts data into fields that the configuration key is turned off for.

```
static void InsertJoin42Job(Args _args)
{
    GmTabDepartment tabDept2;
    GmTabEmployee tabEmpl3;
    GmTabProject tabProj4;
    GmTabEmployeeProject tabEmplProj5;
    str 64 sDescriptionVariable = "From variable.";
    DELETE_FROM tabEmplProj5;
    INSERT_RECORDSET tabEmplProj5
        (
        Description
        , EmployeeRecId
        , ProjectRecId
        )
    Select
        sDescriptionVariable
        , RecId
    from
        tabEmpl3
        join
            tabDept2
            where tabEmpl3 .DepartmentGuid == tabDept2 .DepartmentGuid
        join RecId
            from tabProj4
            where tabDept2 .DepartmentGuid == tabProj4 .DepartmentGuid
    info(int642str(tabEmplProj5 .rowCount())
        + " ==Number of rows inserted.");
    WHILE SELECT *
        from
            tabEmplProj5
            join tabEmpl3
                where tabEmplProj5 .EmployeeRecId == tabEmpl3 .RecId
            join tabProj4
                where tabEmplProj5 .ProjectRecId == tabProj4 .RecId
    {
        info(
            tabEmpl3 .EmployeeName
            + "  --works on--  "
            + tabProj4 .ProjectName
            + " (" + tabEmplProj5 .Description + ")."
            );
    }

/*****************  Actual Infolog output
Message (01:05:41 pm)
4 ==Number of rows inserted.
Alice  --works on--  Project ZZZ (From variable.).
Alice  --works on--  Project YY (From variable.).
Beth  --works on--  Project ZZZ (From variable.).
Beth  --works on--  Project YY (From variable.).
****************/
}
```

Handling DuplicateKeyException exceptions

The following example shows how you can catch a **DuplicateKeyException** exception in the context of an explicit transaction. The exception is thrown when a call to **xRecord.insert** fails because the key value already exists. In the **catch** block, your code can either take corrective action or log the error for later analysis. Your code can then continue without losing all the pending work of the transaction. You can't catch a **DuplicateKeyException** exception that is caused by a set-based operation such as **insert_recordset**.

This example depends on two tables: SourceTable and DestinationTable. Each table has one mandatory integer field. The fields are named **SourceKeyField** and **DestinationKeyField**, respectively. A unique index is defined

on each key field. The SourceTable table must have at least one record in it.

```
static void JobDuplicKeyException44Job(Args _args)
{
    SourceTable sourceTable; // Must have at least one record.
    DestinationTable destinationTable;
    int countTries = 0;
    int numberAdjust = 0;
    int newKey;
    int inote;
    container notes;

    // Empty the destination table.
    delete_from destinationTable;

    // Copy all the records from SourceTable to DestinationTable
    insert_recordset destinationTable (destinationKeyField)
        select SourceKeyField from sourceTable order by SourceKeyField asc;

    // Copy the records from SourceTable to DestinationTable, one at a time.
    // This immediately throws a DuplicateKeyException.
    ttsBegin;
    try
    {
        countTries++;
        notes += strFmt("Inside the try block, try count is %1.", countTries);
        while select * from sourceTable order by SourceKeyField asc
        {
            destinationTable.clear();
            newKey = sourceTable.SourceKeyField + numberAdjust;
            destinationTable.DestinationKeyField = newKey;
            notes += strFmt("%1 is the key to be tried." , newKey);
            destinationTable.insert();
            notes += "Success: .insert()";
        }
        ttsCommit;
    }
    catch (Exception::DuplicateKeyException, destinationTable) // Table is optional.
    {
        notes += "Inside the catch block.";
        notes += 'Error: ' + infolog.text().strReplace('\n', '');
        if (countTries <= 1)
        {
            notes += "Will issue retry.";
            numberAdjust = 1;
            retry; // Erases Infolog.
        }
        else
        {
            notes += "Aborting the transaction.";
            ttsAbort;
        }
    }

    for (inote = 1; inote <= conLen(notes); inote++)
    {
        info(conPeek(notes, inote));
    }
}

/* Output
    ---- Inside the try block, try count is 1.
    ---- 11 is the key to be tried.
    ---- Inside the catch block.
    Cannot create a record in DestinationTable (DestinationTable).
    The record already exists.
    ---- Will issue retry.
    ---- Inside the try block, try count is 2.
```

```
    ---- 12 is the key to be tried.
    ---- .insert() successful.
*/
```

The survey will take about seven minutes. No personal data is collected (privacy statement).

Update data

2/18/2021 • 3 minutes to read • Edit Online

You can use SQL statements, either interactively or in source code, to update one or more rows in a table that is stored in the database.

- **update method** – Update the current record with the contents of the buffer. Also update the appropriate system fields.
- **doUpdate method** – Update one row at a time.
- **update_recordset statement** – Update multiple records in one database trip. By using the **update_recordset** statement, you reduce communication between the application and the database. Therefore, you help increase performance. In some situations, record set–based operations can fall back to record-by-record operations. For more information, see Conversion of operations from set-based to record-by-record.

update method

The **update** method updates the current record with the contents of the buffer. It also updates the appropriate system fields. The optional **where** clause specifies a condition that the **update** method tests as it processes each row of the table. Only those rows that test **true** against the condition are updated with the new values.

The following example selects the CustTable table for update. Only records where the value of the **AccountNum** field equals **4000** are updated. Because there is no call to **next**, and this example doesn't use a **select while** statement, only one record is updated. The value of the **CreditMax** field is changed to **5000**.

```
CustTable custTable;
ttsBegin;
    select forUpdate custTable
        where custTable.AccountNum == '4000';
    custTable.CreditMax = 5000;
    custTable.update();
ttsCommit;
```

doUpdate method

To override the behavior of the **update** method, use the **doUpdate** method. The **doUpdate** method updates the current record with the contents of the buffer. It also updates the appropriate system fields. You should use the **doUpdate** method when the **update** method on the table must be bypassed. The syntax for a **doUpdate** table method is **void doUpdate()**.

WARNING

A call to **doUpdate** skips all logic, including database event handlers (for example **onUpdating** and **onUpdated**), chain-of-command **onUpdate()**, and the **update()** call itself. It's generally considered bad practice to use **doUpdate**, and we don't recommend that you use it.

```
CustTable custTable;
ttsBegin;
select forUpdate custTable
    where custTable.CreditMax == 3000;
if (custTable)
{
    custTable.CreditMax += 1000;
    custTable.doUpdate();
}
ttsCommit;
```

update_recordset statement

The **update_recordset** operator is a record set–based operator that updates multiple records in one trip to the server. Therefore, the power of Microsoft SQL Server can help improve the performance of some tasks. The **update_recordset** statement resembles **delete_from** in X++ and **update set** in SQL. It doesn't retrieve each record separately by fetching, changing, and updating. Instead, it works on an SQL-style record set on the database server side. If the **update** method is overridden, the implementation falls back to a classic looping construction, where one record at a time is updated. (This behavior resembles the behavior of **delete_from** for deletions.) Therefore, the construction works on temporary tables and whole table–cached tables by using the looping construction.

The following example updates the CustTable table and increments the value in the **CreditMax** column by **1000** for records where the **CreditMax** value is more than **0** (zero).

```
CustTable custTable;
ttsBegin;
update_recordset custTable
    setting CreditMax = custTable.CreditMax + 1000
    where custTable.CreditMax > 0;
ttsCommit;
```

The following example updates multiple columns.

```
CustTable custTable;
ttsBegin;
update_recordset custTable
    setting
        CreditMax = custTable.CreditMax + 1000,
        AccountStatement = CustAccountStatement::Always
    where custTable.CreditMax > 0;
ttsCommit;
```

The following example shows that the **update_recordset** statement supports joins of several tables. Data from the joined tables can be used to assign values to fields in the table that is being updated.

```
TableEmployee tabEmpl;
TableDepartment tabDept;
TableProject tabProj;
update_recordset tabEmpl
    setting
        currentStatusDescription = tabDept.DeptName + ", " + tabProj .ProjName
join tabDept
    where tabDept.DeptId == tabEmpl.DeptId
join tabProj
    where tabProj.ProjId == tabEmpl .ProjId;
```

The survey will take about seven minutes. No personal data is collected (privacy statement).

Delete data

2/18/2021 • 5 minutes to read • Edit Online

You can use SQL statements, either interactively or in source code, to delete one or more rows from tables that are stored in the database.

- **delete method** – Delete one row at a time.
- **doDelete method** – Delete one row at a time.
- **delete_from statement** – Delete multiple rows at the same time. By using the **delete_from** statement, you reduce communication between the application and the database. Therefore, you help increase performance. In some situations, this set-based operation can fall back to a record-by-record operation. For more information, see Conversion of operations from set-based to record-by-record.

delete method

The **delete** method deletes the current record from the database. To use this method, use a **where** clause to specify the rows to delete. One record at a time is then removed from the specified table.

The **delete** method can be overridden. For example, you might want to add extra validation before records are deleted. If you override the **delete** method, you can run the original (base) version of the **delete** method by calling the **doDelete** method. Therefore, a call to the **doDelete** method is equivalent to a call to **super()** in the **delete** method.

In the following example, all records in the NameValuePair table that satisfy the **where** clause (that is, all records where the value of the **Name** field equals **Name1**) are deleted from the database. One record is deleted at a time.

```
ttsBegin;
    NameValuePair nameValuePair;

    while select forUpdate nameValuePair
        where nameValuePair.Name == 'Name1'
    {
        nameValuePair.delete();
    }
ttsCommit;
```

The following example deletes records from the LedgerJournalTrans table and updates the associated number sequence.

```
int counter = 0;
str _journalNum = '';
str _voucher = '';
LedgerJournalTrans ledgerJournalTrans;
LedgerJournalTable ledgerJournalTable;

ttsBegin;
    while select forUpdate ledgerJournalTrans
        index hint NumVoucherIdx
        where ledgerJournalTrans.journalNum == _journalNum
            && ledgerJournalTrans.voucher == _voucher
    {
        ledgerJournalTrans.doDelete();
        counter++;
    }

    if (counter && ledgerJournalTable.journalType != LedgerJournalType::Periodic)
    {
        NumberSeq::release(ledgerJournalTable.voucherSeries, _voucher);
    }
ttsCommit;
```

doDelete method

Like the **delete** table method, the **doDelete** table method deletes the current record from the database. Use the **doDelete** method if the **delete** table method has been overridden, and you want to run the original (base) version of that method instead of the overridden version. Therefore, a call to the **doDelete** method is equivalent to a call to **super()** in the **delete** method.

> **WARNING**
> A call to **doDelete** skips all logic, including database event handlers (for example, **onDeleting** and **onDeleted**), chain-of-command **onDelete()**, and the **delete()** call itself. It's generally considered bad practice to use **doDelete**, and we don't recommend that you use it.

delete_from statement

The **delete_from** operator is a record set–based operator that removes multiple records at the same time. This approach can be more efficient and faster than an approach that uses the **delete** method in a loop to delete one record at a time. If you've overridden the **delete** method, the system interprets the **delete_from** statement into code that calls the **delete** method one time for each row that is deleted.

The following example deletes all records in the NameValuePair table where the value in the **Name** column is **Name1**.

```
NameValuePair nameValuePair;
delete_from nameValuePair where nameValuePair.Name == 'Name1';
```

In contrast to the previous example, the following example is inefficient, because it issues a separate SQL **delete** call to the database server for each record. The **delete** method never deletes more than one record per call.

```
// Example of inefficient code.
MyWidgetTable tabWidget; // extends xRecord.
ttsBegin;
    while select forUpdate tabWidget
        where tabWidget .quantity <= 100
    {
        tabWidget.delete();
    }
ttsCommit;
```

A delete operation that has an inner join

Inner joins aren't supported on the **delete_from** statement. Therefore, you can't use the unmodified **join** keyword on the **delete_from** statement. However, you can logically perform an inner join by using other techniques.

The following example shows the recommended way to use the **delete_from** method and inner joins. This example is relatively efficient. It issues a separate **delete_from** statement for each loop iteration. However, each **delete_from** statement can delete multiple records (a subset of all the records that the job deletes).

```
MyWidgetTable tabWidget; // extends xRecord.
ttsBegin;
while select from tabGalaxy
    where tabGalaxy .isTrusted == 0
{
    delete_from tabWidget
        where tabWidget .GalaxyRecId == tabGalaxy .RecId;
}
ttsCommit;
```

A delete operation that uses the notexists join keyword

You can use the **notexists join** keyword pair in a **delete_from** statement. The **delete_from** statements in the following example are efficient. The **notexists join** clause enables the **delete_from** statement to delete a specific set of rows. In this example, the **delete_from** statement removes all parent-order header rows that there are no child-order line rows for. You can also use the **exists join** clause on the **delete_from** statement.

```
static void DeleteFromNotexists3bJob(Args _args)
{
    GmTabOrderHeader tabOHeader;
    GmTabOrderLine tabOLine;
    AddressState tabAddressState;
    str 127 sOH_Info;
    str 127 sOL_Data;
    int64 i64OHRecId;
    delete_from tabOLine;
    delete_from tabOHeader;
    // Inserts into parent table.
    sOH_Info = "Albert needs tires.";
    insert_recordset tabOHeader
        (OH_Info)
        select firstOnly sOH_Info from tabAddressState;
    sOH_Info = "Benson wants plastic.";
    insert_recordset tabOHeader
        (OH_Info)
        select firstOnly sOH_Info from tabAddressState;
    // Obtain a OrderHeader RecId,
    // use it to insert one child row.
    sOL_Data = "4 re-treads.";
    while select firstOnly tabOHeader
        order by OH_Info
        where tabOHeader .OH_Info like "A*"
    {
```

```
    {
        i64OHRecId = tabOHeader .RecId;
        insert_recordset tabOLine
            (OL_Data ,OrderHeaderRecId)
            select firstOnly
                sOL_Data ,i64OHRecId
                from tabAddressState;
        break;
    }
    // Before the delete notexists.
    // Display all parent, and then all child rows.
    while select tabOHeader
        order by OH_Info
    {
        info(strFmt("Before: OHeader:  OH_Info==%1 , RecId==%2"
            ,tabOHeader .OH_Info ,tabOHeader .RecId));
    }
    while select tabOLine
        order by OL_Data
    {
        info(strFmt("Before: OLine:  OL_Data==%1 , OrderHeaderRecId==%2"
            ,tabOLine .OL_Data ,tabOLine .OrderHeaderRecId));
    }
    // Delete_From NotExists Join, to remove from the
    // parent table all order headers without children.
    delete_from tabOHeader
        notexists join tabOLine
            where tabOHeader .RecId ==
                tabOLine .OrderHeaderRecId;
    info(strFmt("%1 is the number of childless OHeader records deleted."
        ,tabOHeader.rowCount()));
    // After the delete notexists.
    // Display all parent, and then all child rows.
    info("- - - - - - - - - - - - - - -");
    while select tabOHeader
        order by OH_Info
    {
        info(strFmt("After: OHeader:  OH_Info==%1 , RecId==%2"
            ,tabOHeader .OH_Info ,tabOHeader .RecId));
    }
    while select tabOLine
        order by OL_Data
    {
        info(strFmt("After: OLine:  OL_Data==%1 , OrderHeaderRecId==%2"
            ,tabOLine .OL_Data ,tabOLine .OrderHeaderRecId));
    }

While select statement

2/18/2021 • 2 minutes to read • Edit Online

A **while select** statement is used to handle data. It's the most widely used form of the **select** statement. The **while select** statement loops over many records that meet specific criteria, and can run a statement on each record. The syntax of a **while select** statement resembles the syntax of a **select** statement, but the statement is preceded by **while select** instead of **select**.

- Typically, when you use the **while select** statement for data manipulation, you use it in a transaction to ensure data integrity.
- The results of the **while select** statement are returned in a table buffer variable.
- If you use a field list in the **select** statement, only those fields are available in the table variable.
- If you use aggregate functions, such as **sum** or **count**, the results are returned in the fields that you perform the **sum** or **count** over. You can count, average, or sum only integer and real fields.
- The **select** statement itself is run only one time, immediately before the first iteration of the statements in the loop.
- Any Boolean expressions that are added to the **while select** statement (for example, **iCounter < 1**) are tested only one time. This behavior differs from the behavior of the **while** statement in languages such as C++ and C#. For example, the following loop can have more than one iteration.

```
int iCounter = 0;
BankAccountTable xrecBAT;

while select * from xrecBAT
    where iCounter < 1
{
    iCounter++;
    info(strFmt("%1 , %2", iCounter, xrecBAT.AccountID));
}
```

The following example prints the **AccountNum** and **SalesGroup** values of every customer in the CustTable table whose account number is within a specified range.

```
CustTable custTable;

while select custTable
    order by custTable.AccountNum
    where  custTable.AccountNum >= '4010' && custTable.AccountNum <= '4100'
{
    info(strFmt("%1 , %2", custTable.AccountNum, custTable.SalesGroup));
}
```

Write select statements as expressions

2/18/2021 • 2 minutes to read • Edit Online

You can use a **select** statement as an expression. This type of **select** statement is known as an *expression **select** statement*.

- You can't use a table buffer variable in an expression **select** statement.
- The name of the table must be used in the **from** clause.
- The **join** keyword isn't supported.
- The table name can't be used to qualify a field name in the **order by** clause.
- In a **where** clause, the table name must be used as a qualifier of the field.
- You can mention only one table in an expression **select** statement. Therefore, subselects aren't supported as a workaround for the unsupported **join** keyword.
- The only column that can be filled with data is the column that is named before the **from** clause in the **select** clause.
- After the closing parenthesis, the name of a column is used to reference the data value.

The following expression returns the value in the **AccountNum** column of the first row in the CustTable table (if a row exists).

```
str accountNum = (select AccountNum from CustTable order by AccountNum desc).AccountNum;
info('Max AccountNum: ' + accountNum);
```

Here is a simpler way to achieve the same result as the previous example.

```
str accountNum = (select maxof(AccountNum) from CustTable).AccountNum;
info('Max AccountNum: ' + accountNum);
```

The following example returns the maximum **RecId** value of customers that aren't blocked. Here, the **maxof** aggregate function is used, and the **RecId** field is mentioned in the function. The field that is mentioned in the aggregate function must match the field name that is used to reference the data value after the closing parenthesis. Otherwise, empty data is returned.

```
int64 nRecId = (select maxof(RecId) from CustTable
            where CustTable.Blocked == CustVendorBlocked::No).RecId;
info("Max RecId: " + int642Str(nRecId));
```

In the following example, the **RecId** field is used to reference a data value that isn't a **RecId** value. The **count** aggregate function doesn't return a **RecId** value. It's a typical practice to use the **RecId** field with the **count** function.

```
int64 nRecId = (select count(RecId) from CustTable
            where CustTable.Blocked == CustVendorBlocked::No).RecId;
info('Count of unblocked customers: ' + int642Str(nRecId));
```

select statements on fields

You can use a **select** statement in a lookup on a field. After a **select** statement that fetches a record in a table,

you can enter **.fieldName** to reference a field in the table. These **select** statements must be used in expressions. A *normal **select** statement* differs from a *field **select** statement* in the following way:

- The field **select** statement operates directly on a table.
- The normal **select** statement operates on a table buffer variable.

The following examples shows how to access fields from a select statement.

```
print((select CustTable order by AccountStatement).AccountStatement);

if ((select custTable where CustTable.AccountNum == '3000').CreditMax < 5000)
{
    info('This customer has a credit maximum less than $5000.');
}
```

X++ transactional integrity

2/18/2021 • 2 minutes to read • Edit Online

This topic describes transactional integrity in the X++ language.

If you don't take steps to ensure the integrity of transactions, data corruption can occur. At the very least, you might experience poor scalability with respect to concurrent users on the system. Two internal checking features help ensure the integrity of transactions: the **forUpdate** check and the **ttsLevel** check.

- A **forUpdate** check helps ensure that a record can be updated or deleted only if it has first been selected for update. You can select a record for update by using either the **forUpdate** keyword in the **select** statement or the **selectForUpdate** method on the table.
- A **ttsLevel** check helps ensure that a record can be updated or deleted only in the same transaction scope where it was selected for update.

The following statements are used to help ensure integrity:

- **ttsBegin** – This statement marks the beginning of a transaction. It helps ensure data integrity and also helps ensure that all updates that are done until the transaction ends (through **ttsCommit** or **ttsAbort**) are consistent.
- **ttsCommit** – This statement marks the successful end of a transaction. It ends and commits a transaction. The Finance and Operations app ensures that a transaction that has been committed will be performed according to intentions.
- **ttsAbort** – This statement lets you explicitly discard all changes in the current transaction. In this case, the database is rolled back to the original state, where nothing has been changed. Typically, you use this statement if you've detected that the user wants to break the current job. The **ttsAbort** statement helps ensure that the database is consistent.

Usually, it's a better idea to use exception handling instead of **ttsAbort**. The **throw** statement automatically aborts the current transaction. As the following example shows, statements between **ttsBegin** and **ttsCommit** can include one or more transaction blocks. In these cases, nothing is committed until a successful exit from the final **ttsCommit** statement occurs.

```
ttsBegin;
    // Some statements.
    ttsBegin;
        // More statements.
    ttsCommit;
ttsCommit;
```

The following example selects a set of records and updates the **CustGroup** field. This code will throw an exception if the **select** statement doesn't return any records.

```
Custtable custTable;
ttsBegin;
    select forUpdate custTable where custTable.AccountNum == '5000';
    custTable.CustGroup = '1';
    custTable.update();
ttsCommit;
```

Example of code that is rejected by the forUpdate check

In this example, the first failure occurs because the **forUpdate** keyword is missing.

```
ttsBegin;
    select myTable; // Rejected by the forUpdate check.
    mytable.myField = 'xyz';
    myTable.update();
ttsCommit;
```

Example of code that is rejected by the ttsLevel check

In this example, the failure occurs because the transaction scope of the update differs from the transaction scope where the record was selected for update in **ttsCommit**.

```
ttsBegin;
    select forUpdate * from myTable;
    myTable.myField = 'xyz';
ttsCommit;

ttsBegin;
    myTable.update(); // Rejected by the ttsLevel check.
ttsCommit;
```

Conversion of operations from set-based to record-by-record

2/18/2021 • 2 minutes to read • Edit Online

You can use the following statements and methods to help improve performance by reducing communication between the application and the database:

- delete_from
- update_recordset
- insert_recordset
- RecordSortedList.insertDatabase
- RecordInsertList.insertDatabase

In some situations, these record set–based operations can be converted to slower record-by-record operations. The following table identifies these situations.

SITUATION	DELETE_FROM	UPDATE_RECORDSET	INSERT_RECORDSET	RECORDSORTEDLIST, RECORDINSERTLIST	USED TO OVERRIDE
Non-SQL tables	Yes	Yes	Yes	Yes	Not applicable
Delete actions	Yes	No	No	No	**skipDeleteActions**
The database log is enabled.	Yes	Yes	Yes	No	**skipDatabaseLog**
Overridden method	Yes	Yes	Yes	Yes	**skipDataMethods**
Alerts are set up for the table.	Yes	Yes	Yes	No	**skipEvents**
The **ValidTimeStateFieldType** property on a table is set to a value other than **None**.	Yes	Yes	Yes	Yes	Not applicable

You can use the **skip*** settings that are shown in the "Used to override" column to explicitly skip or ignore one or more factors that adversely affect performance. If one of the previously mentioned SQL operations is downgraded to a record-by-record operation, all the **skip*** settings are ignored. In the following example code, the **insert** method on the myTable table is run, even though it's explicitly stated that this method should be skipped if a container or memo field is defined for myTable.

```
public void tutorialRecordInsertList()
{
    MyTable myTable;
    RecordInsertList insertList = new RecordInsertList(
        myTable.TableId,
        True);
    int i;
    for ( i = 1; i <=  100; i++ )
    {
        myTable.value = i;
        insertList.add(myTable);
    }
    insertList.insertDatabase();
}
```

Access data by using the SysDa classes

2/18/2021 • 5 minutes to read • Edit Online

This topic explains how to create extensible queries by using the SysDa application programming interface (API).

The extensible SysDa API provides almost all the data access possibilities that are available in X++. In fact, the APIs are wrappers around the code that the X++ compiler would generate. Therefore, use of the SysDa classes carries no overhead, unlike use of the **QueryRun** object, for example. Additionally, the check that the X++ compiler does on data access statements is your responsibility. For example, you create a **where** clause that compares a globally unique identifier (GUID) to an integer. The X++ compiler would diagnose this clause as an error.

The SysDa APIs include an extensive set of APIs for creating custom queries. However, there is a smaller set of types that drives the primary query activities:

- Select: **SysDaQueryObject**, **SysDaSearchObject**, and **SysDaSearchStatement**
- Update: **SysDaUpdateObject** and **SysDaUpdateStatement**
- Insert: **SysDaInsertObject** and **SysDaInsertStatement**
- Delete: **SysDaQueryObject**, **SysDaDeleteObject**, and **SysDaDeleteStatement**

The following sections provide examples of each type of query and the customizations that it supports. The examples use a table that is named TestTable. This table has two fields: a string field that is named **stringField** and an integer field that is named **intField**.

Select query

To run a **select** query, follow these steps.

1. Create and configure a **SysDaQueryObject** object that specifies the table instance that will contain the designated records.
2. Create a **SysDaSearchObject** object, and pass the **SysDaQueryObject** object to the constructor.
3. Iterate over the results of the query by passing the **SysDaSearchObject** object to the **SysDaSearchStatement.next()** method.

The following example finds all rows in TestTable where **intField** <= **5**.

```
// t is the table buffer that will hold the result.
TestTable t;

// Create the query.
var qe = new SysDaQueryObject(t);

// Add clauses to the query. First the projection.
var s = qe.projection()
    .add(fieldStr(TestTable, intField))
    .add(fieldStr(TestTable, stringField));

// At this point the query is:
// intField, stringField FROM TestTable

// Add a where clause to include rows where intField is <= 5.
qe.WhereClause(new SysDaLessThanOrEqualsExpression(
    new SysDaFieldExpression(t, fieldStr(TestTable, intField)),
    new SysDaValueExpression(5)));

// Now the query is:
// intField, stringField FROM TestTable WHERE (TestTable.intField<= 5)

// Order the results by intField.
qe.OrderByClause().addDescending(fieldStr(TestTable, intField));

// Now the query is:
// intField, stringField FROM TestTable ORDER BY intField DESC WHERE (TestTable.intField<= 5)

var so = new SysDaSearchObject(qe);
var ss = new SysDaSearchStatement();

// Enumerate the designated values by using ss.
while (ss.next(so))
{
    info(t.stringField);
}
```

Update statement

To run an **update** statement, follow these steps.

1. Create and configure a **SysDaUpdateObject** object.
2. Update data by passing the **SysDaUpdateObject** object to the **SysDaUpdateStatement.execute()** object. Because updates modify the data in the database, you must wrap the call to **execute** in **ttsbegin** and **ttscommit** statements.

The following example updates **stringField** to **"fifty"** for all rows where **intField** = **50**.

```
TestTable t;

// Create an update query to find rows where intField = 50.
var uo = new SysDaUpdateObject(t);

// Set stringField to "fifty".
uo.settingClause()
    .add(fieldStr(TestTable, stringField), new SysDaValueExpression("fifty"));

// At this point the update statement is:
// UPDATE_RECORDSET TestTable SETTING stringField=fifty

uo.whereClause(new SysDaEqualsExpression(
    new SysDaFieldExpression(t, fieldStr(TestTable, intField)),
    new SysDaValueExpression(50)));

// Now the update statement is:
// UPDATE_RECORDSET TestTable SETTING stringField=fifty WHERE (TestTable.intField == 50)

// Update the rows.
ttsbegin;
    new SysDaUpdateStatement().execute(uo);
ttscommit;

// Verify the results of the update query.
TestTable t1;
select intField, stringField from t1 where t1.intField == 50;
info("Updated value is: " + t1.stringField);
// Output is: "Updated value is: fifty".
```

Insert statement

To run an **insert** statement, follow these steps.

1. Create and configure a **SysDaInsertObject** object to specify which fields are updated during the insertion.
2. Create and configure a **SysDaQueryObject** object that specifies the source of the rows to insert. The order of the fields in **SysDaQueryObject.projection()** must match the order of the fields in **SysDaInsertObject.fields()**.
3. Assign the **SysDaQueryObject** object to the **SysDaInsertObject** object.
4. Insert the new row by passing the **SysDaInsertObject** object to the **SysDaInsertStatement.executeQuery()** method.

The following example inserts rows where **intField** = **40** and **stringField** = **"en-us"** into TestTable.

```
TestTable t;

// Specify the fields in the new row.
var insertObject = new SysDaInsertObject(t);
insertObject.fields()
    .add(fieldStr(TestTable, stringField))
    .add(fieldStr(TestTable, intField));

// At this point the insert statement is:
// INSERT_RECORDSET TestTable(stringField, intField) SELECT

// Retrieve the data to insert from the LanguageTable by using a query.
LanguageTable source;
var qe = new SysDaQueryObject(source);

var s1 = qe.projection()
    .Add(fieldStr(LanguageTable, LanguageId))
    .AddValue(40);

// The query statement is:
// LanguageId, 40 FROM LanguageTable

qe.WhereClause(new SysDaEqualsExpression(
        new SysDaFieldExpression(source, fieldStr(LanguageTable, LanguageId)),
        new SysDaValueExpression("en-us")));

// Now the query is:
// LanguageId, 40 FROM LanguageTable WHERE (LanguageTable.LanguageId == en-us)

// Assign the query to the insert statement.
insertObject.query(qe);

// The insert statement is now:
// INSERT_RECORDSET TestTable(stringField, intField) SELECT LanguageId, 40 FROM LanguageTable WHERE
(LanguageTable.LanguageId == en-us)

var insertStmt = new SysDaInsertStatement();
ttsbegin;
    insertStmt.executeQuery(insertObject);
ttscommit;

// Verify the results of the insert query.
TestTable t1;
select * from t1 where t1.stringField == "en-us";
info(any2Str(t1.intField) + ":" + t1.stringField);
// The output is "40:en-us".
```

Delete statement

To run a **delete** statement, follow these steps.

1. Create and configure a **SysDaQueryObject** object to specify which rows to delete.
2. Create a **SysDaDeleteObject** object, and pass the **SysDaQueryObject** object to the constructor.
3. Delete the rows by passing the **SysDaDeleteObject** object to the **SysDaDeleteStatement.executeQuery()** method.

The following example deletes rows where **intField** is an even number.

```
TestTable t;

// Build the query that specifies which rows to delete.
var qe = new SysDaQueryObject(t);

var s = qe.projection()
    .add(fieldStr(TestTable, intField));

// At this point the query is:
// intField FROM TestTable

// Delete rows where intField is even.
qe.WhereClause(new SysDaEqualsExpression(
    new SysDaModExpression(
    new SysDaFieldExpression(t, fieldStr(TestTable, intField)),
    new SysDaValueExpression(2)),
    new SysDaValueExpression(0)));

// Now the query is:
// intField FROM TestTable WHERE ((TestTable.intField MOD 2) == 0)

var ds = new SysDaDeleteStatement();
var delobj = new SysDaDeleteObject(qe);

// The deletion statement, from the SysDaDeleteObject, is:
// DELETE_FROM intField FROM TestTable WHERE ((TestTable.intField MOD 2) == 0)

ttsbegin;
    ds.executeQuery(delobj);
ttscommit;

info("Number of rows after deletion: " + any2Str(t.RowCount()));
```

Clauses

SysDa queries support several clauses:

- **whereClause** – The **where** clause is constructed from objects that inherit from **SysDaQueryExpression**. Examples are **SysDaEqualsExpression**, **SysDaNotEqualsExpression**, and **SysDaLessThanExpression**. You can find the full list by filtering in Application Explorer.
- **orderByClause**
- **groupByClause**
- **joinClause** with **joinClauseKind**
- **joinedQuery**
- **settingClause**

Troubleshooting

You can use the **toString()** method on **SysDaQueryObject**, **SysDaUpdateObject**, **SysDaInsertObject**, and **SysDaQueryObject** objects to view the statement that you're building.

Mitigate a SQL injection attack

2/18/2021 • 4 minutes to read • Edit Online

IMPORTANT

Some or all of the functionality noted in this topic is available as part of a preview release. The content and the functionality are subject to change. For more information about preview releases, see Service update availability.

An SQL injection attack occurs when malicious data values are passed to Microsoft SQL Server in a query string. Those values can cause lots of damage in a database. SQL injection can occur if you aren't careful about how you use a query to pass data that comes from an uncontrolled source, such as user input, to SQL Server. SQL injection isn't usually an issue in Finance and Operations apps, because the built-in data access statements in X++ prevent it. However, if you use Direct-SQL, SQL injection can occur when raw SQL code is passed to the server.

A new API will help mitigate these attacks. The API is available starting with platform updates for version 10.0.17 of Finance and Operations apps (April 2021).

The issue

Consider a scenario where a developer writes the following code to look up the first name of customers, based on their last name.

```
public str GetFirstName(str name)
{
    str sqlStatementText = "SELECT TOP(1) firstName FROM Customer WHERE customer.Name = '" + name + "'";

    // Create a connection to the SQL Server
    var connection = new Connection();

    // Create a statement and submit the sql statement to the server:
    Statement statement = connection.createStatement();
    var results= statement.executeQuery(sqlStatementText);

    // Get the first record:
    results.next();
    statement.close();

    // Harvest the results.
    return results.getString(1);
}
```

Additionally, there is either a page where users can enter customer names in a string field, or a service endpoint that enables names to come into the server.

In this scenario, everything works well if users enter valid names such as "Jones." However, a malicious user might enter the following string as a name.

```
'; drop table Customer --
```

In this case, here is the final query that the server runs.

```
SELECT TOP(1) firstName FROM Customer WHERE customer.Name = ''; drop table Customer --'
```

The first quotation mark in the given string just ends the string literal that should contain the name that the user is looking for. Then another SQL statement is run because of the semicolon (;), which is a statement terminator token. This second statement irretrievably deletes the **Customer** table and all the data in it. Finally, the commenting characters (--) ensure that the single quotation mark at the end doesn't cause syntax errors. Therefore, the string is valid Transact SQL (T-SQL).

SQL injection occurs because the connection to SQL Server doesn't impose any restrictions that prevent it from performing operations that create or delete tables, views, and stored procedures at runtime. Therefore, organizations must rely on the assumption that developers are reasonable people who know what they are doing.

The solution

SQL Server mitigates the threat by using *statement parameters*. Statement parameters never use literals that are subject to textual changes to the resulting string. Instead, they provide named parameters, the actual content of which is provided contextually. For this release, Microsoft has added a new API that lets you use parameters instead of building SQL strings in code.

The following example shows what the code from the previous example looks like after these changes are incorporated.

```
public str GetFirstName(str name)
{
    str sqlStatementText = "SELECT TOP(1) firstName FROM Customer WHERE customer.Name = @Name";

    // Create a connection to the SQL Server
    var connection = new Connection();

    // Submit the sql statement to the server:
    Statement statement = connection.createStatement();

    // Create a mapping from parameter names onto values
    Map paramMap = SqlParams::create();
    paramMap.add('Name', name);

    // Execute the query, providing both the query
    // and the parameters.
    var results= statement.executeQueryWithParameters(sqlStatementText, paramMap);

    // Capture the results:
    results.next();
    statement.close();

    return results.getString(1);
}
```

The updated example uses the new **executeQueryWithParameters** API instead of the old API that didn't take parameters. The code builds the map that contains the mapping from parameter names to parameter values. In this case, **Name** will be the value of **@Name** in SQL. The incoming **name** value can be anything.

A related method on the **Statement** type is used to run statements that return integer values instead of rows. Typically, the integer value indicates the number of rows that are affected. The following example uses the X++ data statements with the **executeQueryWithParameters** API.

```
public void InsertWithStrParameter()
{
    var connection = new Connection();
    Statement statement = connection.createStatement();

    connection.ttsbegin();

    str sql = @"
        UPDATE Wages
        SET Wages.Wage = Wages.Wage * @percent
        WHERE Wages.Level = @Level";

    Map paramMap = SqlParams::create();
    paramMap.add('percent', 1.1);        // 10 percent increase
    paramMap.add('Level', 'Manager');    // Management increase

    int cnt = statement.executeUpdateWithParameters(sql, paramMap);
    statement.close();

    connection.ttscommit();
}
```

Conclusion

As Microsoft introduces the new methods, we are also marking the existing methods (that is, the methods without the parameters) as obsolete. The usual deprecation periods apply. Therefore, you can update your code to take advantage of the new protection that the parameters provide.

Although the new **executeQueryWithParameters** API helps you protect your customers from disasters, you aren't required to use it. You can still do string concatenations and provide an empty parameter set. However, in this case, you don't gain the advantages that the parameters provide. We hope that you will take this opportunity to eliminate any dangerous usage that you have in your code.

Macros in X++

2/18/2021 • 25 minutes to read • Edit Online

This topic describes how to create and use macros in X++.

Precompiler directives are processed before the code is compiled. The directives declare and handle macros and their values. The directives are removed by the precompiler so that the X++ compiler never encounters them. The X++ compiler only sees the sequence of characters written into the X++ code by the directives.

#define and #if directives

All precompiler directives and symbols begin with the # character. A macro can be defined at any point in the code. The variable can have a value that is a sequence of characters, but it is not required to have a value. The **#define** directive tells the precompiler to create the macro variable, including an optional value. The **#if** directive tests whether the variable is defined, and optionally, whether it has a specific value. The X++ precompiler directives, the macro names that they define, and the **#if** directive value tests are all case-insensitive. However, it is a best practice to begin macro names with an uppercase letter.

Code example

In the following code sample, a macro named **MyMacro** is defined. It is not given a value in the **#define.MyMacro** definition line. Therefore it behaves as if the value is a zero-length sequence of characters. The **#if.MyMacro** statement tests whether **MyMacro** is defined. Because **MyMacro** is defined, the lines of code before the first **#endif** are included in the X++ code at the test location. Near the end of the example there is an **#ifnot.MyMacro** test. Because **MyMacro** is defined, that test is false and no lines are written into the X++ code. After the precompile phase ends for this method, the **MyMacro** definition goes out of scope and is no longer known to the system.

```
static void SimpleDefineIfJob(Args _args)
{
    str sTest = "Initial value.";

    #define.MyMacro // MyMacro is now defined.
    #if.MyMacro
        sTest = "Yes, MyMacro is defined.";
        info(sTest);
    #endif
    // Notice the non-code sentence line causes no X++ compiler error,
    // because the X++ compiler never sees it.
    #ifnot.MyMacro
        The X++ compiler would reject this sentence.
        sTest = "No, MyMacro is not defined.";
        info(sTest);
    #endif
/********** Actual output
Message (03:46:20 pm)
Yes, MyMacro is defined.
**********/
}
```

Precompile and Compile Error Messages

When you are developing code that contains macros, you must understand whether an error message is generated during the precompile or the compile phase. The two key words to look for are:

- Lexical – This indicates a precompile error.
- Syntax – This indicates a compile error.

The following code example has a lexical error caused by the first closing parenthesis, which marks the end of the directive. Therefore the precompiler is confused by the last two characters, """;)".

```
#define.MyMacro1(info("Hello");)
```

The following code example has a syntax error caused by using the non-existent **++++** operator. The X++ compiler encounters this operator after **#MyMacro2** is replaced by the macro value. The macro definition is correct even though its value is not accepted X++ syntax.

```
#define.MyMacro2(++++iTest;)
#MyMacro2
```

#undef directive

You can use the **#undef** directive to remove a macro definition that exists from a previous **#define**. After a macro name has been created by **#define** and then removed by **#undef,** the macro can be created again by another **#define**. **#undef** has no effect on macros that are created by the **#localmacro** directive. In the following code sample, the macro **MyMacro** is undefined by using the #undef directive. The #undef occurs between the two #if tests for its existence. The output shows only the first #if test was true.

```
static void UndefMacroJob(Args _args)
{
    #define.MyMacro
    #if.MyMacro
        info("Macro is defined (1)");
    #endif
    #undef.MyMacro // Removes the macro.
    #if.MyMacro
        info("Macro is defined (2)");
    #endif
/************* Actual output
Message (10:19:15 am)
Macro is defined (1)
*************/
}
```

Use a Macro Value

You can define a macro name to have a value. A macro value is a sequence of characters. A macro value is not a string (or **str**) in the formal sense of a data type. You assign a value to a macro by appending the value enclosed in parentheses at the end of a #define directive. You can use the macro symbol where you want the value to occur in the X++ code. A macro symbol is the name of the macro with the # character added as a prefix. The following code sample shows a macro symbol **#MyMacro**. The symbol is replaced by the value of the macro.

```
static void MacroWithIntValueJob(Args _args)
{
    int iTest = 8;
    ;
    #define.MyMacro(32)
    // This next #define, which has no value for the macro name,
    // would not disrupt the value 32 set by the previous #define.
    //#define.MyMacro
    // This next #define, which has a different value than 32,
    // would overwrite the value 32 set by the previous #define.
    //#define.MyMacro(444)
    iTest = #MyMacro;
    info(int2str(iTest));
/**********  Actual output
Message (04:33:49 pm)
32
**********/
}
```

Test a Macro Value

You can test a macro to see whether it has a value. You can also test to see whether its value is equal to a specific sequence of characters. These tests enable you to conditionally include lines of code in your X++ program. There is no way you can test whether a defined macro has a value. You can only test whether a specific value matches the value of a macro. As a best practice, any macro name that you define should always have a value, or it should never have a value. When you alternate between these modes, your code becomes difficult to understand. For macros that have a value, you can vary the value when you see fit. In the following code sample, two **#if** tests are run to determine whether the macro **MyIntMacro** exists. The **#if.MyIntMacro()** test is true. This syntax behaves the same as **#if.MyIntMacro**.

```
static void TestMacroValue6Job(Args _args)
{
    #define.MyIntMacro(66)
    // #if tests.
    #if.MyIntMacro()
        info("A: " + int2str(#MyIntMacro));
    #endif
    #if.MyIntMacro(66)
        info("B: " + int2str(#MyIntMacro));
    #endif
    // #ifNOT tests.
    #ifNOT.MyIntMacro(7777)
        info("C: " + int2str(#MyIntMacro));
    #endif
    #ifNOT.No_Such_Macro_Name(66)
        info("D: " + int2str(#MyIntMacro));
    #endif
/****************  Actual output
Message (11:24:47 am)
A: 66
B: 66
C: 66
D: 66
****************/
}
```

The following code sample shows the **#if.DebugMacro(heavy)** directive that tests the value of the **DebugMacro** macro. If the value is the five character sequence **heavy**, then the test is true.

```
static void TestMacroSpecificValue8Job(Args _args)
{
    ;
    // Uncomment either one of these defines, or neither.
    //#define.DebugMacro(light) // This line for: light debugging.
    #define.DebugMacro(heavy) // This line for: heavy debugging.
    #if.DebugMacro
        info("Starting the job.");
    #endif
    #if.DebugMacro(heavy)
        info("UTC == "
            + DateTimeUtil ::toStr
                (DateTimeUtil::utcNow()
                )
            );
    #endif
    // Do something useful here.
/**********  Actual output
Message (01:58:12 pm)
Starting the job.
UTC == 2007-12-05T21:58:12
**********/
}
```

#defInc and #defDec directives

#defInc and **#defDec** are the only directives that interpret the value of a macro and they apply only to macros that have a value that can be converted to the formal **int** type. The value can only contain numerals. The only non-numeric character allowed is a leading negative sign (-). The integer value is treated as an X++ **int**, not as an **int64**. For macro names that are used by the **#defInc** directive, it is important that the **#define** directive that creates the macro not reside in a class declaration. The behavior of **#defInc** in these cases is unpredictable. Instead, such macros should be defined in only a method. We recommend that the **#defInc** and **#defDec** directives only be used for macros that have an integer value. The precompiler follows special rules for **#defInc** when the macro value is not an integer, or when the value is unusual or extreme. The following table lists the values that **#defInc** converts to zero (0) and then increments. When a value is converted to 0 by **#defInc,** the original value cannot be recovered, not even by **#defDec.**

MACRO VALUE	BEHAVIOR
(+55)	The positive sign (+) prefix makes the precompiler treat this as a non-numeric string. The precompiler treats all non-numeric strings as 0 when it handles a **#defInc** (or **#defDec)** directive.
("3")	Integers enclosed in quotation marks are treated as 0. The quotation marks are discarded, and these changes persist.
( )	A string of spaces is treated as 0, and then incremented.
()	A zero-length string is treated as 0, and then incremented, when the value is enclosed in parentheses, as in **#define.MyMac().**
(Random string.)	Any non-numeric string of characters is treated as 0, and then incremented.

MACRO VALUE	BEHAVIOR
(0x12)	Hexadecimal numbers are treated as non-numeric strings. Therefore they are converted to 0, and then incremented.
(-44)	Negative numbers are acceptable, including integers without the negative sign (-).
(2147483647)	The maximum positive **int** value is changed to the minimum negative **int** value by #defInc.
(999888777666555)	Any large number, beyond the capacity of **int** and **int64**. This is treated as the maximum positive **int** value.
(5.8)	Real numbers are truncated by #defDec (and #defInc). Subsequent symbol substitution shows that the truncation persists.
	When no value and no parentheses are provided for the directive #define.MyValuelessMacro, the precompiler rejects use of the directive #defInc.MyValuelessMacro.

Code example

In the following code sample, the initial value of the macro **CounterMacroA** is a string that can be converted into an integer. The sample shows how the **#defInc** and **#defDec** directives can be used for this macro name.

```
static void SimpleDefINCJob(Args _args)
{
    ;
    #define.CounterMacroA(1)
    #defInc.CounterMacroA
    info("mg11: # CounterMacroA == " + int2str(#CounterMacroA));
    #if.CounterMacroA(2)
        info("mg12: # if confirms CounterMacroA == 2");
    #endif
    #defDec.CounterMacroA
    info("mg23: # CounterMacroA == " + int2str(#CounterMacroA));
    #if.CounterMacroA(1)
        info("mg24: # if confirms CounterMacroA == 1");
    #endif
/**************  Actual Infolog output
Message (12:47:57 pm)
mg11: # CounterMacroA == 2
mg12: # if confirms CounterMacroA == 2
mg23: # CounterMacroA == 1
mg24: # if confirms CounterMacroA == 1
**************/
}
```

#globaldefine directive

The **#globaldefine** directive is similar to the **#define** directive. The difference is that **#define** directives generally take precedence over **#globalmacro** directives. This is true regardless of which directive occurs first in the X++ code. A **#globaldefine** never overwrites a **#define** directive that has both a macro name and a value. A **#globaldefine** can overwrite another **#globaldefine. **A **#define** directive that has only a name does not overwrite a #globalmacro that has both a name and a value. It is recommended that you use **#define,** and that you do not use **#globaldefine.** Use of **#globaldefine** can create uncertainty that makes code difficult to maintain. The exact semantics of **#globaldefine** cannot be achieved through **#if** test directives. By using **#if**

tests you can avoid overwriting a **#define** and a **#globaldefine.** But **#if** tests cannot distinguish between **#define** and **#globaldefine** macros. The following code sample is the closest you can come to achieving the **#globaldefine** semantic with other directives such as **#if.**

```
static void IfNotDefineNestGlobalJob (Args _args)
{
    ;
    #undef.MaybeMac
    #ifnot.MaybeMac
    #define.MaybeMac(4444) // Works.
    #endif
    #if.MaybeMac
        info(int2str(#MaybeMac));
    #endif
/**********************  Actual Infolog output
Message (07:43:32 pm)
4444
**********************/
}
```

Code example

The following code sample shows a difference in the behavior of **#define** and **#globaldefine**. Following the code sample is a table explaining the conclusions from the output. The primary test case in the code sample is labeled **12**.

```
static void InteractDefineGlobalJob(Args _args)
{
    ;
    // Pairs of #define - #globaldefine directives (same macro names).
    #define.11_DEFINEvalue_GLOBALnoval("11__DEFINE.")
    #globaldefine.11_DEFINEvalue_GLOBALnoval
    #define.12_DEFINEnoval_GLOBALvalue
    #globaldefine.12_DEFINEnoval_GLOBALvalue("12_GLOBAL.")
    #define.13_DEFINEvalue_GLOBALvalue("13__DEFINE.")
    #globaldefine.13_DEFINEvalue_GLOBALvalue("13_GLOBAL.")
    // Pairs of #globaldefine - #define directives.
    #globaldefine.27_GLOBALvalue_DEFINEnoval("27_GLOBAL.")
    #define.27_GLOBALvalue_DEFINEnoval
    #globaldefine.28_GLOBALnoval_DEFINEvalue
    #define.28_GLOBALnoval_DEFINEvalue("28__DEFINE.")
    #globaldefine.29_GLOBALvalue_DEFINEvalue("29_GLOBAL.")
    #define.29_GLOBALvalue_DEFINEvalue("29__DEFINE.")
    // Pairs of same directive types.
    #define.50_DEFINEvalue_DEFINEnoval("50__DEFINE 1.")
    #define.50_DEFINEvalue_DEFINEnoval
    #globaldefine.64_GLOBALvalue_GLOBALnoval("64_GLOBAL 1.")
    #globaldefine.64_GLOBALvalue_GLOBALnoval
    #globaldefine.65_GLOBALnoval_GLOBALvalue
    #globaldefine.65_GLOBALnoval_GLOBALvalue("65_GLOBAL 2.")
    #globaldefine.66_GLOBALvalue_GLOBALvalue("66_GLOBAL 1.")
    #globaldefine.66_GLOBALvalue_GLOBALvalue("66_GLOBAL 2.")
    // Infolog outputs.
    info(#11_DEFINEvalue_GLOBALnoval);
    info(#12_DEFINEnoval_GLOBALvalue);
    info(#13_DEFINEvalue_GLOBALvalue);
    info(#27_GLOBALvalue_DEFINEnoval);
    info(#28_GLOBALnoval_DEFINEvalue);
    info(#29_GLOBALvalue_DEFINEvalue);
    info(#50_DEFINEvalue_DEFINEnoval);
    info(#64_GLOBALvalue_GLOBALnoval);
    info(#65_GLOBALnoval_GLOBALvalue);
    info(#66_GLOBALvalue_GLOBALvalue);
/*****************************  Actual Infolog output

has both a name and a value. The same is true between a pair of #define directives. This resembles test case
12.
65_GLOBAL 2. Shows that a #globaldefine that has both a name and a value overwrites a previous
#globaldefine.
66_GLOBAL 2. Shows that a #globaldefine that has both a name and a value overwrites a previous
#globaldefine.
*****************************/
}
```

Macro parameters

You can define macro values to include parameter symbols. The first parameter symbol is %1, the second is %2, and so on. You pass values for the parameters when you reference the macro symbol name for expansion.

Macro parameter values are character sequences of no formal type, and they are comma delimited. There is no way to pass in a comma as part of a parameter value. The number of parameters passed can be less than, greater than, or equal to the number of parameters that the macro value is designed to receive. The system tolerates mismatches in the number of parameters passed. If fewer parameters are passed than the macro expects, each omitted parameter is treated as a zero-length sequence of characters. In the following code sample, **MyMacro** is defined to have a value that contains parameters. Macro substitution symbols are given with parameter values in parentheses.

```
static void MacroParameterSubstitutionJob(Args _args)
{
    ;
    #define.MyMacro("One == [%1] ,  Two == [%2]")
    // Make parameter substitutions:
    info("AA: " + #MyMacro(Apple));
    info("BB: " + #MyMacro(Apple,Banana));
    info("CC: " + #MyMacro(Apple, Banana, cranberry));
    info("DD: " + #MyMacro(,Apple,Banana));
    info("EE: " + #MyMacro());
    info("FF: " + #MyMacro);
/************  Actual Infolog output
Message (03:22:07 pm)
AA: One == [Apple] ,  Two == []
BB: One == [Apple] ,  Two == [Banana]
CC: One == [Apple] ,  Two == [ Banana]
DD: One == [] ,  Two == [Apple]
EE: One == [] ,  Two == []
FF: One == [] ,  Two == []
************/
}
```

#localmacro and #globalmacro directives

The **#localmacro** directive is a good choice when you want a macro to have a value that is several lines long, or when your macro value contains a closing parenthesis. The **#localmacro** directive is a good choice when you want your macro value to be lines of X++ or SQL code. The **#localmacro** directive can be written as **#macro.** However, **#localmacro** is the recommended term. Both macros have the same behavior. By using the **#if** directive, you can test whether a macro name is declared with the **#define** directive. However, you cannot test whether the macro name is declared with the **#localmacro** directive. Only macros declared by using the **#define** directive are affected by the **#undef** directive. In a **#define** directive, you can specify a name that is already in scope as a **#localmacro.** The effect is to discard the **#localmacro** and create a **#define** macro. This also applies to the opposite sequence, which means that a **#localmacro** can redefine a **#define.** A **#localmacro** (that has both a macro name and a value) always overrides a previous **#localmacro** that has the same name. However, you cannot always be sure whether the override occurs when you use **#globalmacro.** For this reason we recommend that you do not use **#globalmacro. **This same problem occurs with **#globaldefine.** The main difference between a **#define** macro and a **#localmacro** macro is in how their syntax is terminated. The terminators are as follows:

- **#define** – is terminated by– **)**
- **#localmacro** – is terminated by– **#endmacro**

#localmacro is a better choice for macros with multiple line values. Multiple line values are typically lines of X++ or SQL code. X++ and SQL contain lots of parentheses, and these would prematurely terminate a #define. Both **#define** and **#localmacro** can be declared and terminated on either a single line or on subsequent lines. In practice, the **#define** is terminated on the same line that it is declared on. In practice, the **#localmacro** is terminated on a subsequent line. Where both macro names and values are supplied, the **#globalmacro** directive cannot override the #define directive. Also, the **#globaldefine** directive cannot override the **#localmacro** directive.

Code examples

The following code sample shows how to use the **#localmacro** directive. It demonstrates that the **#undef** directive does not affect **#localmacro** macros. It also shows that #if tests cannot determine whether a **#localmacro** macro has been defined.

```
static void LocalMacroJob(Args _args)
{
    ;
    #localmacro.LMacReportLog
        print("%1  --LM, print.");
        info("%1  --LM, Infolog.");
    #endmacro
    #LMacReportLog(g11: Hello World )
    #if.LMacReportLog
        info("The # IF LMacReportLog is true");
    #endif
    #undef.LMacReportLog
    #LMacReportLog(g22: Greetings World)
    #localmacro.LMacReportLog
    #endmacro // No lines for value before this end.
    #LMacReportLog(g33: Bye Bye) // Not present in the output.
/*************  Actual Infolog output
Message (03:10:17 pm)
g11: Hello World   --LM, Infolog.
g22: Greetings World  --LM, Infolog.
*************/
}
```

The following X++ code sample shows that **#localmacro** overrides a **#globalmacro** of the same macro name, but that **#globalmacro** does not override **#localmacro**.

```
static void GlobalMacroNotOverrideJob(Args _args)
{
    ;
    //---------  LGMa ,  L then G  ---------
    #localmacro.LGMa
        info("LGMa: Loc 11");
    #endmacro
    #globalmacro.LGMa
        info("LGMa: Glob 12");
    #endmacro
    #LGMa
    //---------  LGMb ,  G then L  ---------
    #globalmacro.LGMb
        info("LGMb: Glob 24");
    #endmacro
    #localmacro.LGMb
        info("LGMb: Loc 25");
    #endmacro
    #LGMb
/****************  Actual Infolog output
Message (06:39:42 am)
LGMa: Loc 11
LGMb: Loc 25
***************/
}
```

Nesting Macro Symbols

You can nest precompiler definition directives inside an outer definition directive. The main definition directives are **#define** and **#localmacro. **The cases for which this topic provides code samples are as follows:

- Transitive substitution: A **#define** macro can have the symbol for another macro as its value. Transitive substitution of the symbol occurs in X++ code.
- No transitive substitution: An **#if** directive test of a macro value does not perform substitutions.
- Macro within a macro: A #define directive can be given inside a **#localmacro** directive, or a **#localmacro** can be inside a **#define**.

Transitive Substitution

In the following code sample, the value of the first **#define** variable includes a symbol (#D) of the second **#define** variable. This works even though the expansion symbol #D occurs before macro **D** is defined.

```
static void NestMacroJobA1(Args _args)
{
    ;
    #define.Cd("Cd +: # D == " + #D)
    // If not commented out, this next code line would cause the
    // error message "The macro does not exist.", because
    // #D in the value of #Cd cannot be expanded before it is defined.
    //info(#Cd);
    #define.D("D")
    info(#Cd);
/************  Actual Infolog output
Message (10:42:13 am)
Cd +: # D == D
************/
}
```

No transitive substitution

The following code sample tries to determine whether two macro variables have the same value, without specifying what that value might be. The output shows that this determination cannot made..

```
static void NestMacroJobA2(Args _args)
{
    ;
    #define.A1(5)
    #define.A2(5)
    info("Status: A1==" + int2Str(#A1) + " , A2==" + int2Str(#A2));
    #if.A1(#A2)
        info("Yes, symbol substitution does work on # IF test.  Unexpected.");
    #endif
    #ifNOT.A1(#A2)
        info("No, symbol substitution does not work on # IF test.");
    #endif
/************  Actual Infolog output
Message (11:27:38 am)
Status: A1==5 , A2==5
No, symbol substitution does not work on # IF test.
************/
}
```

The following code sample shows that the #defInc directive does not lead to transitive substitution of symbol values. For more information about the #defInc directive, see How to: Use the #defInc and #defDec Directives. After the #defInc.E2 directive, the subsequent output value for #E2 shows the value for **E2** is converted to zero (0) by #defInc.E2 before it is incremented to one (1). Before the conversion, the value of **E2** was the three characters #E2. The output for test case **36** shows the value has been converted to 1.

```
static void NestMacroJobA4(Args _args)
{
    ;
    #define.E1(5)
    #define.E2(#E1)
    info("11:  # E1 == " + int2Str(#E1));
    info("12:  # E2 == " + int2Str(#E2));
    #defInc.E1
    info(" -------");
    info("23: After Inc.E1,  # E1 == " + int2Str(#E1));
    info("24: After Inc.E1,  # E2 == " + int2Str(#E2));
    #defInc.E2
    info(" -------");
    info("35: After Inc.E2,  # E1 == " + int2Str(#E1));
    info("36: After Inc.E2,  # E2 == " + int2Str(#E2));
/************  Actual Infolog output
Message (02:39:41 pm)
11:  # E1 == 5
12:  # E2 == 5
-------
23: After Inc.E1,  # E1 == 6
24: After Inc.E1,  # E2 == 6
-------
35: After Inc.E2,  # E1 == 6
36: After Inc.E2,  # E2 == 1
************/
}
```

Macro within a macro

A **#define** directive can be given inside a **#localmacro** directive, and a **#localmacro** can be inside a #define. This is shown in the following code sample.

```
static void NestMacroJobB5(Args _args)
{
    int iTest = 31;
    ;
    //-------------  J  ---------------
    #localmacro.LocMacOuterJL
        #define.DefinInnerJD(5)
    #endmacro
    #LocMacOuterJL
    info("J: Directive nesting works if 5 appears: # DefinInnerJD == "
            + int2Str(#DefinInnerJD));
    //-------------  K  ---------------
    #define.DefinOuterKD(#localmacro.LocMacInnerKL ++iTest; #endmacro)
    ++iTest; // Result is 32.
    #DefinOuterKD
    #LocMacInnerKL
    info("K: Directive nesting works if 33 appears: iTest == "
            + int2Str(iTest));
/**************  Actual Infolog output
Message (11:21:02 am)
J: Directive nesting works if 5 appears: # DefinInnerJD == 5
K: Directive nesting works if 33 appears: iTest == 33
**************/
}
```

#macrolib directive

In the Application Explorer under the Macros node, there are many library nodes that contain sets of macro directives. Both **#define** and **#localmacro** often appear in the contents of these macro libraries. You can use the **#macrolib.MyAOTMacroLibrary** to include the contents of a macro library in your X++ code. The **#if** and

#undef directives do not apply to **#macrolib** names. However, they do apply to **#define** directives that are the contents of a **#macrolib** macro. The directive **#macrolib.MyAOTMacroLibrary** can also be written as **#MyAOTMacroLibrary.** The **#macrolib** prefix is recommended because it is never ambiguous to a person who later reads the code.

Create a macro library

To create a macro library:

1. In **Solution Explorer,** right-click on the project, select **Add** and then **New item.**
2. In the **Add New Item** dialog, select Installed and then **AX Artifacts** in the left pane.
3. In the middle pane, select **Macro.**
4. Enter a name and click **Add.** Save the macro file and refresh the Application Explorer to find your macro library.

Code examples

There is a macro library that is named **Event.** This macro library contains the directive **#define.DefaultEventPollFrequency(15)**. The following code sample shows that the **#macrolib.Event** directive makes the macro **#DefaultEventPollFrequency** available.

```
static void SystemProvidedMacroLibraryJob(Args _args)
{
    ;
    #macrolib.Event // Contains: #define.DefaultEventPollFrequency(15)
    info("# DefaultEventPollFrequency == "
            + int2str(#DefaultEventPollFrequency));
/***************  Actual Infolog output
Message (06:31:26 pm)
# DefaultEventPollFrequency == 15
***************/
}
```

The following code example shows what happens when you write a **#define** for a name that is already the name of a node in the macro library. For this example, there is a node named **MacLib23,** and its contents are one **#define** as follows:

```
#define.DefinInMacLib23("_This is inside AOT macrolib MacLib23.")
```

After a #macrolib directive is issued for **MacLib23**, **#define** and **#undef** directives have no effect on the **#macrolib** macro (see output _BB). However, a **#define** in the contents of a **#macrolib** macro can be overwritten by a subsequent #define or **#undef** in the code (see output _DD).

```
static void PrecedenceMacrolibDefineJob(Args _args)
{
    ;
    #define.MacLib23("_11:  Plain #define value for MacLib23, same name as the AOT macrolib macro.")
    info("_AA: " + #MacLib23);
    #macrolib.MacLib23
    info("_BB: " + #DefinInMacLib23); // Defined inside the macrolib macro.
    info("_CC: " + #MacLib23); // Output shows plain #define, not the macrolib macro contents.
    #define.DefinInMacLib23("_33:  Plain #define in the job code, overwrite of same macro name defined
inside the macrolib macro.")
    info("_DD: " + #DefinInMacLib23);
/**************************  Actual Infolog output
Message (10:53:13 am)
_AA: 11:  Plain #define value for MacLib23, same name as the AOT macrolib macro.
_BB: This is inside AOT macrolib MacLib23.
_CC: 11:  Plain #define value for MacLib23, same name as the AOT macrolib macro.
_DD: 33:  Plain #define in the job code, overwrite of same macro name defined inside the macrolib macro.
**************************/
}
```

#linenumber Directive

You can use the #linenumber directive during your development and debugging of code. It is replaced by the physical line number in the code file.

Code example

The following X++ code sample shows the behavior of the **#linenumber** directive.

```
static void LinenumberPhysicalJob(Args _args)
{
    ;
    #define.Debug(light)
    #if.Debug
        info("Physical Line 8: # linenumber == "
            + int2Str(#linenumber));
    #endif
/******************  Actual Infolog output
Message (08:55:26 pm)
Physical Line 8: # linenumber == 8
******************/
}
```

Range (scope) of macros

The range in which a macro can be referenced depends on where the macro is defined. In a class, macros that are defined in the parent class can be referenced, but macros defined in a child class cannot be referenced. When the precompiler handles a child class, the precompiler first traces the inheritance chain to the most ascendant class. The precompiler processes all the directives from the class declaration part of the ascendant class. It stores all the macros and their values in its internal tables. The precompiler handles the next class in the inheritance chain the same way. The result of the directives in each class declaration are applied to the internal tables that are already populated from directives that were found earlier in the inheritance chain. When the precompiler reaches the target child class, it again handles the class declaration part. However, it next handles each method in a series of separate operations. The precompiler updates its internal tables in a way that the state of the tables can be restored as they were before processing of the current method began. After the first method is handled, the internal tables are restored before the next method is handled.

The Method is All Contents of the Node

In this context, a method is defined as the contents of a method node in the Application Object Tree (AOT). In the

AOT, you can expand the Classes node, expand a class node, right-click a method node, and then select Edit. Then you can add a line for #define.MyMacro("abc") before the method declaration. The precompiler treats this #define directive as part of the method, even though the #define occurs outside the {} block of the method.

Class Inheritance and Macro Reference Range

The following code example demonstrates the range of macro referencing in class inheritance scenarios. The primary line to notice in the method's output is the line labeled ClassC_h. It shows that a macro defined in a grandparent class can be referenced in a method of the grandchild class. Another important line in the output is labeled ClassA_k. This line shows that a macro defined in a method is not available in other methods. ClassA is the base class and it defines several macros in its class declaration. Its descendant classes reference these macros. The base class also defines a macro inside one of its methods. A second method in this class determines the macro is defined out of range and cannot be referenced in the second method. The **#undef.MacroRange333** in the method **UseOtherMethodMacro** affects the availability of macro **MacroRange333** in the rest of that method. Descendant classes can still reference **MacroRange333**. ClassB extends ClassA and it undefines the macro **MacroRangeA** that is defined in its parent class. This makes the macro unavailable to any class that extends the present class. The present class also redefines the macro **MacroRangeB** that is defined in its parent class. This changes the value of the macro (from positive to negative). ClassC extends ClassB and it uses **#ifnot** to demonstrate that it cannot access the **MacroRangeA** macro that the base class, ClassInheritanceOfMacrosCBase1, defines. The reason is that the mid-level class undefined the macro. This class also demonstrates that it can access the macro **MacroRange333** that ClassInheritanceOfMacrosCBase1 class defines. TestClass contains a method that calls the demonstration methods and displays the results.

```
class ClassA
{
    // Unless disturbed by other directives, these macros can
    // be referenced by method in this class in child classes.
    #define.MacroRangeA
    #define.MacroRangeB(22)
    #define.MacroRange333(333)

    static void UseMacros()
    {
        //  This method shows that a macro that is defined
        // in the class declaration is in range in every
        // method in that class.
        // This method also contains a define for macro
        // MacroDefInMethodD, and tests outside this
        // method determine the macro is not in range.
        ;
        info("ClassA: #MacroRangeB == " + int2str(#MacroRangeB));
        #define.MacroDefInMethodD // Cannot be referenced in other methods.
    }

    static void UseOtherMethodMacro()
    {
        // This method shows that the macro MacroDefInMethodD
        // that was defined in another method in this class
        // cannot be referenced in this method.
        // This method contains an #undef of MacroRange333,
        // yet descendant classes can still reference this macro.
        #ifnot.MacroDefInMethodD
        info("ClassA_k: This means MacroDefInMethodD is in not range here.");
        #endif
        #undef.MacroRange333
    }
}

class ClassB extends ClassA
{
    // This class declaration makes the macro MacroRangeA
```

```
    // This class declaration makes the macro MacroRangeA
    // unavailable to methods in this class and child classes.
    // This class declaration also redefines MacroRangeB for
    // this class and child classes.
    #undef.MacroRangeA // Makes unavailable to child classes.
    #define.MacroRangeB(-22)
    // Redefining with a different value.
    static void UseMacros()
    {
        // This method shows that the value for #MacroRangeB comes
        // from its redefinition in this class, instead of from
        // the definition in the parent class.

        info("ClassB_c: #MacroRangeB == " + int2str(#MacroRangeB)
            + " (Is now negative due to later redefinition.)");
    }
}

class ClassC extends ClassB
{
    static void UseMacros()
    {
        //   This method shows that the #undef in the parent
        // class overwrites the #define in the grandparent class.
        //   This method also shows that a macro defined in the
        // grandparent class is in range in methods on this class.
        ;
        #ifnot.MacroRangeA
        info("ClassC_f: MacroRangeA is no longer defined, due to #undef in ClassB.");
        #endif
        info("ClassC_h: #MacroRange333 == " + int2str(#MacroRange333)
            + " (Defined in ClassA.)");
    }
}

class TestClass
{
    static void JobClassesCC(Args _args)
    {
        ;
        ClassA ::UseMacros();
        ClassA ::UseOtherMethodMacro();
        ClassB ::UseMacros();
        ClassC ::UseMacros();
        /***************  Actual output
        Message (08:10:59 am)
        ClassA_a: #MacroRangeB == 22
        ClassA_k: This means MacroDefInMethodD is not in range here.
        ClassB_c: #MacroRangeB == -22 (Is now negative due to later redefinition.)
        ClassC_f: MacroRangeA is no longer defined, due to #undef in child class ClassB.
        ClassC_h: #MacroRange333 == 333 (Defined in ClassA.)
        ***************/
    }
}
```

X++ attribute classes

2/18/2021 • 4 minutes to read • Edit Online

This topic describes the use of attributes in X++.

An attribute is a non-abstract class that extends (inherits from) the **SysAttribute** class. Attributes represent or store metadata about types and methods. An attribute can be attached to a class, an interface, or a method of a class, interface, or table.

Creating an attribute class

An attribute class can extend the **SysAttribute** class directly, or it can extend any descendant of the **SysAttribute** class. The **SysAttribute** class cannot be used as an attribute because it is declared **abstract**. The following example shows the declaration and design of an ordinary attribute class that you could create.

```
public class PracticeAttribute extends SysAttribute
{
    // Fields in the classDeclaration.
    StartEnd startEndEnum;
    str reason;
    // Constructor.
    public void new(StartEnd _startEndEnum, str _reason)
    {
        startEndEnum  = _startEndEnum;
        reason = _reason;
    }
    // Other methods can go here.
}
```

Decorating a class with an attribute

The following example shows a class and a method that are decorated with the **PracticeAttribute** given in the previous example. If the constructor of the attribute takes no parameters, the parentheses for the parameters are optional. The attribute decoration could be `[AnotherAttribute]` without parentheses.

```
[PracticeAttribute(StartEnd::End, "Use the RegularClass class at the end.")]
public class RegularClass
{
    [PracticeAttribute(Startend::Start, "Use the rehearse method at the start.")]
    public int rehearse()
    {
        // Logic goes here.
    }
    // More fields and methods belong here.
}
```

Attribute constructors

You can enable your attribute class to store tailored metadata each time it is used to decorate a class, by having its constructor take parameters. The parameters for the constructor must be literals of the primitive types, such as **int**, **enum**, or **str**. The compiler does not construct an instance of the attribute class. It stores the name of the attribute class, plus the literal values for its constructor. Therefore, if the logic in an attribute constructor would throw an exception, the exception would not be found by decorating a class with the attribute. The exception would be found later when a process looks at a class to see the attribute it is decorated with. That is when the attribute is constructed.

Naming conventions

All attribute classes have the suffix **Attribute** in their name. The **Attribute** suffix is the name convention that we recommend, but it is not a system requirement. You can determine whether a class **extends** directly from **SysAttribute** by selecting the class in the **Application Explorer** and reviewing the **Extends** property in the **Properties** window.

SysObsoleteAttribute

The system provides several attributes, including the **SysObsoleteAttribute** class. One use of the **SysObsoleteAttribute** class is to notify the compiler that the compile should fail if a particular method is called in the source code. The compiler rejects the compile, and displays the specific message that is stored in this use of the attribute. The **SysObsoleteAttribute** class can also be used to notify the compiler to issue warning messages instead of errors.

SysObsoleteAttribute code example

```
[SysObsoleteAttribute("The Automobile class might have faster performance.", false)]
class Bicycle
{
    // Members of the Bicycle class go here.
}
```

Metadata reflection

You use reflection to find the attribute metadata that is attached to a class. The classes to use for attribute reflection are as follows:

- **DictClass** class – For classes and interfaces.
- **DictMethod** class – For methods on classes, interfaces, or tables.

On the previous reflection classes, the methods for reflecting on attribute metadata are as follows:

- **getAllAttributes** method
- **getAttribute** method
- **getAttributedClasses** method
- **getAttributes** method

> **NOTE**
>
> There is no mechanism for listing all methods or classes that are adorned with a particular attribute from X++ code. However, because the X++ compiler records this information in the cross reference database, the information can be mined from there.

Metadata reflection code example

You use the **DictMethod** class to find the metadata value of an attribute that is decoration on a method. The following code example uses the **SysEntryPointAttribute** class as the attribute. It accepts your parameter values for the method name, and for the name of the class that contains the method. The **parmChecked** method is particular to the **SysEntryPointAttribute** class, and it is not inherited from its base class **SysAttribute**. Each attribute class can have its own method name for its metadata.

```
static public int MetadataOfSysEntryPointAttributeOnMethod
        (
        str _sNameOfClass,
        str _sNameOfMethod
        )
{
    // Return Values:
    // 0 == Has the attribute, its metadata value is false;
    // 1 == Has the attribute, its metadata value is true;
    // 2 == The method lacks the SysEntryPointAttribute.
    int nReturnValue = -1,
        nClassId;
    boolean boolParmChecked;
    DictMethod dm;
    Object attributeAsObject;
    SysEntryPointAttribute sepAttribute;
    Global::info("Starting AttributeReflection"
        + " ::MetadataOfSysEntryPointAttributeOnMethod ....");
    Global::info(strFmt
        ("Parameters are: _sNameOfClass = %1 ,  _sNameOfMethod = %2 .",
        _sNameOfClass, _sNameOfMethod)
        );
    nClassId = Global::className2Id(_sNameOfClass);
    dm = new DictMethod
        (UtilElementType::ClassInstanceMethod,
        nClassId,
        _sNameOfMethod
        );
    attributeAsObject = dm.getAttribute("SysEntryPointAttribute");
    if (attributeAsObject is SysEntryPointAttribute)
    {
        sepAttribute = attributeAsObject as SysEntryPointAttribute;
        boolParmChecked = sepAttribute.parmChecked();
        if (boolParmChecked)
            nReturnValue = 1;
        else
            nReturnValue = 0;
        Global::info(
            strFmt("Return value is %1.",
                nReturnValue)
            );
    }
    else
    {
        nReturnValue = 2;
        Global::error("Object is not a SysEntryPointAttribute??");
    }
    return nReturnValue;
}
/*** Output displayed in the Infolog.
Message (05:03:22 pm)
Starting AttributeReflection ::MetadataOfSysEntryPointAttributeOnMethod ....
Parameters are: _sNameOfClass = CustCustomerService ,  _sNameOfMethod = create .
Return value is 1.
***/
/**************
// Simple AOT > Jobs job to run the method.
static void AttributeReflection33Job(Args _args)
{
    AttributeReflection::MetadataOfSysEntryPointAttributeOnMethod
        ("CustCustomerService", "create");
}
**************/
```

X++ and C# comparison

2/18/2021 • 62 minutes to read • Edit Online

This topic compares X++ and C# syntax and programming.

X++, C# Comparison: Hello World

This section compares the simplest X++ program to its counterpart in C#.

X++ to C# Comparisons

The following sections describe some basic similarities and differences between X++ and C#.

Similarities

The following X++ features are the same for C#:

- Single line (`//`) and multi-line (`/* */`) comments.
- `==` (equal) operator for determining whether two values are equal.
- `!=` (not equal to) operator for determining whether two values are not equivalent.
- `+` (plus sign) operator for string concatenation.

Differences

The following table lists X++ features that are different in C#.

FEATURE	X++	C#	COMMENTS
`if` and `else` conditional statements	The `if` statement accepts any type of expression that it can automatically convert to a Boolean. Common examples include an `int` for which 0 means false, or an object for which null means false.	The `if` statement requires a Boolean expression.	The syntax structure regarding curly braces and parentheses is exactly the same between X++ and C#.
Literal string	A literal string can be delimited by either of the following: • A pair of double quotation mark (") characters. • A pair of single quotation mark (') characters.	A literal string must be delimited by a pair of double quotation mark (") characters.	For X++, the double quotation mark characters are usually used to delimit strings. However, it is convenient delimit a string with single quotation mark characters when your string must contain a double quotation mark character.
char `type`	There is no `char` or character type in X++. You can declare a `str` of length one, but it is still a string: `str 1 myString = "a";`	There is a `char` in C#. You cannot pass a `char` as the parameter to a method that inputs a `string` parameter, although you can first explicitly convert the `char` to a `string`.	For more information about X++ data types, see Primitive Data Types.

FEATURE	X++	C#	COMMENTS

Output of messages	X++ delivers messages to the user in the Infolog window. Common methods include the following:
	• The **print** statement:
	• static methods on the `Global` class:
	  ◦ Global::info
	  ◦ Global::warning
	  ◦ Global::error
		For a command line program, messages can be delivered to the console. Common methods include the following:
		• `Console.Out.WriteLine`
		• `Console.Error.WriteLine`	

X++ and C++ Samples

This section contains two simple code samples. One sample is written in X++, and the other is in C#. Both samples achieve the same result. The following X++ features are demonstrated:

- `//` single line comment
- `/\*` `\*/` multi-line comment
- `if` statement
- `==` operator
- `!=` operator
- `+` operator to concatenate strings
- Global::info for message output, with and without the Global:: prefix
- Global::error for message output
- The use of single and double quotation characters (' and ") as string delimiters.

> **NOTE**
> The best practice is to use double quotation marks for any string that might be displayed to the user.

X++ Sample

This X++ code sample is in the form of a job. There is a node titled Jobs in the Application Object Tree (AOT). This sample can be added under the Jobs node, and then the job can be run.

```
static void JobRs001a_HelloWorld(Args _args)
{
    if (1 == 1)
    {
        // These two info() calls are identical to the X++ compiler.
        // The second form is the one typically used in X++.
        Global::info("Hello World, 1.");
        info('Hello World, 2.');
    }
    if (1 != 1)
    {
        error("This message will not appear.");
    }
    else
    {
        // These two methods are also from the Global class.
        // The + operator concatenates two strings.
        warning("This is like info, but is for warnings, 3.");
        error("This is like info, but is for errors, 4.");
    }
}
```

Output

Here is the output from the Infolog window: Message (09:49:48) Hello World, 1. Hello World, 2. This is like info, but is for warnings, 3. This is like info, but is for errors, 4.

C# Sample

The following C# program is a rewrite of the previous X++ program.

```
using System;
class Pgm_CSharp
{
    static void Main( string[] args )
    {
        new Pgm_CSharp().Rs001a_CSharp_HelloWorld();
    }
    void Rs001a_CSharp_HelloWorld()
    {
        if (1 == 1)
        {
            Console .Out .WriteLine("Hello World, Explicit .Out , 1.");
            Console .WriteLine("Hello World, Implicit default to .Out , 2.");
        }
        if (1 != 1)
        {
            Console .Error .WriteLine("This message will not appear.");
        }
        else
        {
            Console .Error .WriteLine(".Error is like .Out, but can be for warnings, 3.");
            Console .Error .WriteLine(".Error is like .Out, but is for errors, 4.");
        }
    }
}
```

Output

Here is the actual output to the C# console:

```
Hello World, Explicit .Out, 1.
Hello World, Implicit default to .Out, 2.
.Error is like .Out, but can be for warnings, 3.
.Error is like .Out, but is for errors, 4.
```

X++, C# Comparison: Loops

This section compares the loop features between X++ and C#.

Similarities

The following features are the same in X++ and C#:

- Declarations for variables of the int primitive data type. Declarations for other primitive types are almost the same, but the types might have different names.
- while statement for loops.
- break statement to exit a loop.
- continue statement to jump up to the top of a loop.
- <= (less than or equal) comparison operator.

Differences

The following table lists X++ features that are different in C#.

FEATURES	X++	C#	COMMENTS
The `for` statement.	The for statement is available for loops.	The C# `for` statement is slightly different from `for` in X++.	In C# you can declare the counter integer in the `for` statement. But in X++ the counter must be declared outside the `for` statement.

++ increment operator.	An ++ increment operator is available in X++. But an **int** variable that is decorated with ++ can only be used as a statement, not as an expression. For example, the following lines of X++ code would not compile:
	`int age=42;`
	`print age++;`
	However, the following lines of X++ code would compile:
	`int age=42;`
	`age++; print age;`
		The C# ++ operator is more flexible than in X++.	The following lines of code are the same in both languages:
			• ++ myInteger;
			• myInteger++;
			But the following lines of code have a different effect from each other, and are valid only in C#:
			• yourInt = ++myInt;
			• yourInt = myInt++;

modulo operator.	In X++ the modulo operator is mod.	In C# the modulo operator is %.	The symbols for the modulo operator are different, but their behavior is the same in both languages.
Temporarily suspend a console program that has already begun.	The `pause` statement.	In C#, a command line program can be paused by the following line of code: `Console.In.Read();`	In X++ you continue by clicking an OK button on a modal dialog box. In C# you continue by pressing any keyboard on the keyboard.

FEATURES	X++	C#	COMMENTS
Display a message.	In X++, the `print` statement displays a message in the Print window.	In C# a message can be displayed on the console by the following line of code: `Console.WriteLine();`	The X++ `print` function is used only when you test. An X++ program that uses `print` almost always uses the `pause` statement somewhere later in the code. For production X++ code, use the Global::info Method instead of `print`. The `strfmt` function is often used together with `info`. There is no reason to use `pause` after `info`.
Make a sound.	The beep function makes a sound that you can hear.	In C# a sound that you can hear is issued by the following line of code: `Console.Beep();`	The statements each produce a short tone.

Print and Global::info

The X++ code samples for loops use the `print` function to display results. In X++ you can use the `print` statement can display any primitive data type without having to call functions that convert it to a string first. This makes `print` useful in quick test situations. Generally the Global::info method is used more often than `print`. The `info` method can only display strings. Therefore the strfmt function is often used together with `info`. A limitation of `print` is that you cannot copy the contents of the Print window to the clipboard (such as with Ctrl+C). Global::info writes to the Infolog window which does support copy to the clipboard.

Example 1: The while Loop

The **while** keyword supports looping in both X++ and C#.

X++ Sample of while

```
static void JobRs002a_LoopsWhile(Args _args)
{
    int nLoops = 1;
    while (nLoops <= 88)
    {
        print nLoops;
        pause;
        // The X++ modulo operator is mod.
        if ((nLoops mod 4) == 0)
        {
            break;
        }
        ++ nLoops;
    }
    beep(); // Function.
    pause; // X++ keyword.
}
```

Output

The output in the X++ Print window is as follows:

```
1
2
3
4
```

C# Sample of while

```
using System;
public class Pgm_CSharp
{
    static void Main( string[] args )
    {
        new Pgm_CSharp().WhileLoops();
    }

    void WhileLoops()
    {
        int nLoops = 1;
        while (nLoops <= 88)
        {
            Console.Out.WriteLine(nLoops.ToString());
            Console.Out.WriteLine("(Press any key to resume.)");
            // Paused until user presses a key.
            Console.In.Read();
            if ((nLoops % 4) == 0) {
                break;
            }
            ++ nLoops;
        }
        Console.Beep();
        Console.In.Read();
    }
}
```

Output

The console output from the C# program is as follows:

```
1
(Press any key to resume.)
2
(Press any key to resume.)
3
(Press any key to resume.)
4
(Press any key to resume.)
```

Example 2: The for Loop

The **for** keyword supports looping in both X++ and C#.

X++ Sample of for

In X++ the counter variable cannot be declared as part of the **for** statement.

```
static void JobRs002a_LoopsWhileFor(Args _args)
{
    int ii; // The counter.
    for (ii=1; ii < 5; ii++)
    {
        print ii;
        pause;
        // You must click the OK button to proceed beyond a pause statement.
        // ii is always less than 99.
        if (ii < 99)
        {
            continue;
        }
        print "This message never appears.";
    }
    pause;
}
```

Output

The output in the X++ Print window is as follows:

```
1
2
3
4
```

C# Sample of for

```
using System;
public class Pgm_CSharp
{
    static void Main( string[] args )
    {
        new Pgm_CSharp().ForLoops();
    }
    void ForLoops()
    {
        int nLoops = 1, ii;
        for (ii = 1; ii < 5; ii++)
        {
            Console.Out.WriteLine(ii.ToString());
            Console.Out.WriteLine("(Press any key to resume.)");
            Console.In.Read();
            if (ii < 99)
            {
                continue;
            }
            Console.Out.WriteLine("This message never appears.");
        }
        Console.Out.WriteLine("(Press any key to resume.)");
        Console.In.Read();
    }
}
```

Output

The console output from the C# program is as follows:

```
1
(Press any key to resume.)
2
(Press any key to resume.)
3
(Press any key to resume.)
4
(Press any key to resume.)
(Press any key to resume.)
```

X++, C# Comparison: Switch

In both X++ and C#, the **switch** statement involves the keywords **case**, **break**, and **default**. The following table lists the differences in the **switch** statement between X++ and C#.

FEATURE	X++	C#	COMMENTS
`break;` at the end of each case block	In X++, when any **case** block matches the expression value on the **switch** clause, all other **case** and **default** blocks are executed until a `break;` statement is reached. No `break;` statement is ever required in an X++ **switch** statement, but `break;` statements are important in almost all practical situations.	In C#, a `break;` statement is always needed after the statements in a **case** or **default** block. If a **case** clause has no statements between itself and the next **case** clause, a `break;` statement is not required between the two **case** clauses.	We recommend against omitting the `break;` statement after any case **block**, because it can confuse the next programmer who edits the code.
`break;` at the end of the **default** block	In X++ there is no effect of adding a `break;` statement at the end of the **default** block.	In C# the compiler requires a `break;` statement at the end of the **default** block.	For more information, see Switch Statements.
Only constant values on a **case** block	In X++ you can specify either a literal value or a variable on a case block. For example, you can write case myInteger:.	In C# you must specify exactly one literal value on each **case** block, and no variables are allowed.	No comments.
Multiple values on one **case** block	In X++ you can specify multiple values on each case block. The values must be separated by a comma. For example, you can write `case 4,5,myInteger:`.	In C# you must specify exactly one value on each **case** block.	In X++ it is better to write multiple values on one **case** block than to omit the `break;` statement at the end of one or more case blocks.

Code Examples for switch

The following sections show comparable switch statements in X++ and C#.

X++ switch Example

The X++ switch example shows the following:

- `case iTemp:` and `case (93-90):` to show that **case** expressions are not limited to constants, as they are in C#.
- `//break;` to show that `break;` statements are not required in X++, although they are almost always

desirable.

- `case 2, (93-90), 5:` to show that multiple expressions can be listed on one **case** clause in X++.

```
static void GXppSwitchJob21(Args _args)  // X++ job in AOT &gt; Jobs.
{
    int iEnum = 3;
    int iTemp = 6;
    switch (iEnum)
    {
        case 1:
        case iTemp:  // 6
            info(strFmt("iEnum is one of these values: 1,6: %1", iEnum));
            break;
        case 2, (93-90), str2Int("5"):  // Equivalent to three 'case' clauses stacked, valid in X++.
            //case 2:
            //case (93-90):  // Value after each 'case' can be a constant, variable, or expression; in X++.
            //case str2Int("5"):
            info(strFmt("iEnum is one of these values: 2,3,5: %1", iEnum));
            //break;  // Not required in X++, but usually wanted.
        case 4:
            info(strFmt("iEnum is one of these values: 4: %1", iEnum));
            break;
        default:
            info(strFmt("iEnum is an unforeseen value: %1", iEnum));
            break;
            // None of these 'break' occurrences in this example are required for X++ compiler.
    }
    return;
}

/*** Copied from the Infolog:
Message (02:32:08 pm)
iEnum is one of these values: 2,3,5: 3
iEnum is one of these values: 4: 3
***
```

C# switch Example

The C# switch example shows the following:

- case 1: has a comment explaining that only constant expressions can be given on a **case** clause.
- `break;` statements occur after the last statement in each **case** block that has statements, as is required by C#.

```
using System;
namespace CSharpSwitch2
{
    class Program
    {
        static void Main(string[] args)  // C#
        {
            int iEnum = 3;
            switch (iEnum)
            {
                case 1:  // Value after each 'case' must be a constant.
                case 6:
                    Console.WriteLine("iEnum is one of these values: 1,6: " + iEnum.ToString());
                    break;
                //case 2,3,5:  // In C# this syntax is invalid, and multiple 'case' clauses are needed.
                case 2:
                case 3:
                case 5:
                    Console.WriteLine("iEnum is one of these values: 2,3,5: " + iEnum.ToString());
                    break;
                case 4:
                    Console.WriteLine("iEnum is one of these values: 4: " + iEnum.ToString());
                    break;
                default:
                    Console.WriteLine("iEnum is an unforeseen value: " + iEnum.ToString());
                    break;
                // All 'break' occurrences in this example are required for C# compiler.
            }
          return;
        }
    }
}
/*** Output copied from the console:
>> CSharpSwitch2.exe
iEnum is one of these values: 2,3,5: 3
>>
***/
```

X++, C# Comparison: String Case and Delimiters

This section compares the treatment of strings with mixed casing in X++ and C#. It also explains the string delimiters that are available in X++.

Similarities

The following X++ features are the same as in C#:

- The backslash (\) is the escape operator for string delimiters.
- The at sign (@) nullifies the escape effect of the backslash when the at sign is written immediately before the open quotation mark of a string.
- The plus sign (+) is the string concatenation operator.

Differences

X++ features that are different in C# are listed in the following table.

FEATURE	X++	C#	COMMENTS
`==` comparison operator	Insensitive: the `==` operator is insensitive to differences in string casing.	In C#, the `==` operator is sensitive to differences in string casing.	In X++ you can use the strCmp Function for case sensitive comparisons between strings.

FEATURE	X++	C#	COMMENTS
String delimiters	In X++ you can use either the single (') or double (`"`) quotation mark as the string delimiter. **Note:** Usually the best practice is to use double quotation marks for strings that might be displayed to the user. However, it is convenient to delimit a string with single quotation marks when a double quotation mark is one of the characters in the string.	In C# you must use the double quotation mark as the string delimiter. This refers to the type `System.String`.	In X++ and C# you have the option of embedding a delimiter in a literal string and escaping it with . In X++ you also have the alternative of embedding single quotation marks in a string that is delimited by double quotation marks (or the reverse), without having to use the escape.
Character delimiters	X++ has a string data type (`str`), but no character type.	In C# you must use the single quotation mark as the character delimiter. This refers to the type `System.Char`.	In the .NET Framework, a `System.String` of length one is a different data type than a `System.Char` character.

Example 1: Case Sensitivity of the == Operator

The `==` and != operators are case insensitive in X++, but are case sensitive in C#, as is illustrated by the following example.

X++	C#	COMMENTS
`"HELLO" == "hello"` True in X++.	`"HELLO" == "hello"` False in C#.	Different case comparisons between X++ and C#.

Example 2: The + String Concatenation Operator

The + and += operators are used to concatenate strings in both X++ and C#, as is shown by the examples in the following table.

X++	C#	COMMENTS

`myString1 = "Hello" + " world";`
Result is equality:
`myString1 == "Hello world"`
	(Same as for X++.)	In both X++ and C#, the behavior of the + operator depends on the data type of its operands. The operator concatenates strings, or adds numbers.

`mystring2 = "Hello";`
`myString2 += " world";`
Result is equality:
`myString2 == "Hello world"`
	(Same as for X++.)	In both X++ and C#, the following statements are equivalent:
		`a = a + b;`
		`a += b;`

Example 3: Embedding and Escaping String Delimiters

Either single or double quotation marks can be used to delimit strings in X++. The escape character (\) can be used to embed delimiters in a string. These are illustrated in the following table.

X++	C#	COMMENTS

`myString1 = "He said \"yes\".";`
Result:
`He said "yes".`
	(Same as for X++.)	The escape character enables you to embed string delimiters inside strings.

`myString2 = 'He said "yes".';`
Result:
`He said "yes".`
	C# syntax does not allow for single quotation marks to delimit strings.	For strings that may be seen by the user, it is considered a best practice to use the escape character instead of the single quotation marks as shown in the example.

`myString3 = "He said 'yes'.";`
Result:
`He said 'yes'.`
	(Same as for X++.)	In X++, the single quotation marks are not treated as delimiters unless the string starts with a single quotation mark delimiter. In C# the single quotation mark has no special meaning for strings, and it cannot be used to delimit strings. In C# the single quotation mark is the required delimiter for literals of type `System.Char`. X++ has no character data type.

`str myString4 = 'C';` Here the single quotation is a string delimiter.	`char myChar4 = 'C';` Here the single quotation mark is a `System.Char` delimiter, not a `System.String` delimiter.	X++ has no data type that corresponds to `System.Char` in the .NET Framework. An X++ string that is limited to a length of one is still a string, not a character data type.

Example 4: Single Escape Character

Examples that illustrate the single escape character in either the input or the output are shown in the following table.

X++	C#	COMMENTS

`myString1 = "Red\ shoe";`
Result:
`Red shoe`
	A literal string in C# cannot contain the two character sequence of escape followed by a space, such as "\ ". A compiler error occurs.	When the X++ compiler encounters the two character sequence of "\ ", it discards the single escape character.

`myString2 = "Red\\ shoe";`
Result:
`Red\ shoe`
	(Same as for X++.)	In a pair of escape characters, the first negates the special meaning of the second.

Comparison: Array Syntax

There are similarities and differences in the features and syntax for arrays in X++ versus C#.

Similarities

Overall there is much similarity in the syntax and treatment of arrays in X++ and C#. However there are many differences.

Differences

The following table lists areas in the [] syntax for arrays that are different for X++ and C#.

CATEGORY	X++	C#	COMMENTS

Declaration	An array is declared with square brackets appended to the variable name.	An array is declared with square brackets appended to the data type.	`int myInts[]; // X++`
			Note: An X++ array cannot be a parameter in a method.
			`int[] myInts; // C#`

Declaration	The array syntax supports only primitive data types, such as `int` and `str`. The syntax does not support classes or tables.	The array syntax supports primitive data types and classes.	In X++ you can use the `Array` Array for an array of objects.
Declaration	X++ is limited to single dimension arrays (myStrings[8]).	C# adds support for multi-dimensional arrays (myStrings[8,3]) and for jagged arrays (myStrings[8][3]).	In X++ you cannot have an array of arrays. However, there is advanced syntax for limiting the amount of active memory that a large array can consume, which looks like the multi-dimensional syntax in C#: int intArray[1024,16];. For more information, see Best Practice Performance Optimizations: Swapping Arrays to Disk.
Declaration	In X++ an array is a special construct but it is not an object.	In C# all arrays are objects regardless of syntax variations.	X++ does have an Array class, but its underlying mechanism differs from arrays created by using the [] syntax. In C# all arrays use the same underlying mechanism, regardless of whether [] syntax of the `System.Array` class is used in your code.
Length	In X++ the length of a static sized array is determined in the declaration syntax.	In C# the size of an array is determined when the array object is constructed.	When you use the [] declaration syntax in X++, no more preparation is needed before you assign values to the array. In C# you must declare and then construct the array before assigning to it.

Length	An X++ array can have a dynamic length that can be increased even after population has begun. This applies only when the array is declared without a number inside the []. Performance might be slowed if the length of the dynamic array is increased many times.	In C# the length of an array cannot be changed after the length is set.	In the following fragment of X++ code, only the `myInts` array is dynamic and can increase in size.
			`int myInts[];`
			`int myBools[5];`
			`myInts[2] = 12;`
			`myInts[3] = 13;`
			`myBools[6] = 26; //Error`

CATEGORY	X++	C#	COMMENTS
Length	You can get the length of some arrays by using the `dimOf` function.	C# arrays are objects that have a `Length` property.	No comments.
Indexing	Array indexing is 1 based.	Array indexing is 0 based.	mtIntArray[0] would cause an error in X++.
Constant	In X++ a constant value is best achieved by using the **#define** precompiler directive.	In C# you can decorate your variable declaration with the keyword **const**, to achieve a constant value.	X++ has no **const** keyword. C# cannot assign values to variables that are created by its #define precompiler directive.

X++ and C# Samples

The following code samples show how arrays of primitive data types are handled. The first sample is in X++, and the second sample is in C#. Both samples achieve the same results.

X++ Sample

```
static void JobRs005a_ArraySimple(Args _args)
{
    #define.macroArrayLength(3)
    // Static length.
    str sSports[#macroArrayLength];
    // Dynamic length, changeable during run time.
    int years[];
    int xx;
    Global::warning("-------- SPORTS --------");
    sSports[#macroArrayLength] = "Baseball";
    for (xx=1; xx <= #macroArrayLength; xx++)
    {
        info(int2str(xx) + " , [" + sSports[xx] + "]");
    }
    warning("-------- YEARS --------");
    years[ 4] = 2008;
    years[10] = 1930;
    for (xx=1; xx <= 10; xx++)
    {
        info(int2str(xx) + " , " + int2str(years[xx]));
    }
}
```

Output

The output to the Infolog is as follows:

```
Message (14:16:08)
-------- SPORTS --------
1 , []
2 , []
3 , [Baseball]
-------- YEARS --------
1 , 0
2 , 0
3 , 0
4 , 2008
5 , 0
6 , 0
7 , 0
8 , 0
9 , 0
10 , 1930
```

C# Sample

```
using System;
public class Pgm_CSharp
{
    static public void Main( string[] args )
    {
        new Pgm_CSharp().ArraySimple();
    }
    private void ArraySimple()
    {
        const int const_iMacroArrayLength = 3;
        // In C# the length is set at construction during run.
        string[] sSports;
        int[] years;
        int xx;
        Console.WriteLine("-------- SPORTS --------");
        sSports = new string[const_iMacroArrayLength];
        sSports[const_iMacroArrayLength - 1] = "Baseball";
        for (xx=0; xx < const_iMacroArrayLength; xx++)
        {
            Console.WriteLine(xx.ToString() + " , [" + sSports[xx] + "]");
        }
        Console.WriteLine("-------- YEARS --------");
        // In C# you must construct the array before assigning to it.
        years = new int[10];
        years[ 4] = 2008;
        years[10 - 1] = 1930;
        for (xx=0; xx < 10; xx++)
        {
            Console.WriteLine(xx.ToString() + " , [" + years[xx].ToString() + "]");
        }
    }
} // EOClass
```

Output

The output from the C# program to the command line console is as follows:

```
-------- SPORTS --------
0 , []
1 , []
2 , [Baseball]
-------- YEARS --------
0 , [0]
1 , [0]
2 , [0]
3 , [0]
4 , [2008]
5 , [0]
6 , [0]
7 , [0]
8 , [0]
9 , [1930]
```

Additional array-like X++ features

The **container** is a special data type that is available in X++. It can be considered as similar to an array, or similar to a `List` collection.

Comparison: Collections

In a Finance and Operations application, you can use the X++ `List` collection class. The .NET Framework that is used in C# has a similar class named `System.Collections.Generic.List`.

Comparing the Use of the List Classes

The following table compares methods on the X++ `List` class to the methods on `System.Collections.Generic.List` from the .NET Framework and C#.

FEATURE	X++	C#	COMMENTS
Declaration of collection	`List myList;`	`List<string> myList;`	The X++ declaration does not include the type of elements to be stored.
Declaration of iterator	`ListIterator iter` `ListEnumerator enumer;`	IEnumerator<string> iter;	In X++ the `ListIterator` object has methods that can `insert` and `delete` items from the `List`. The X++ `ListEnumerator` cannot modify the contents of the `List`. In X++ the `ListEnumerator` object is always created on the same tier as the `List`. This is not always true for `ListIterator`.
Obtaining an iterator	`new ListIterator (myList)` `myList.getEnumerator()`	`myList.GetEnumerator()`	In both X++ and C#, the List object has a getter method for an associated enumerator.

FEATURE	X++	C#	COMMENTS
Constructor	`new List(Types::String)`	`new List<string>()`	Information about the type of objects to be stored inside the `List` classes is given to the constructor in both X++ and C#.
Updating data	Enumerator – the enumerator becomes invalid if any items in the `List` are added or removed. Iterator – the iterator has methods that insert and delete items from the `List`. The iterator remains valid.	Enumerator – the enumerator becomes invalid if any items in the `List` are added or removed.	Enumerators become invalid after items are added or deleted from the `List`, in both X++ and C#.
Updating data	In X++ the `List` class has methods for adding items at the start or end of the list.	In C# the `List` class has methods for adding members at any position in the list. It also has methods for removing items from any position.	In X++ items can be removed from the `List` only by an iterator.

Example 1: Declaration of a List

Following are code examples in X++ and C# that declare `List` collections.

```
// X++
List listStrings ,list2 ,listMerged;
ListIterator literator;
```

```
// C#
using System;
using System.Collections.Generic;
List<string> listStrings ,list2 ,listMerged; IEnumerator<string> literator;
```

Example 2: Construction of a List

In both languages, the type of items that the collection stores must be specified at the time of construction. For class types, X++ can get no more specific than whether the type is a class (Types::Class). Following are code examples in X++ and C#.

```
// X++
listStrings = new List( Types::String );
```

```
// C#
listStrings = new List<string>;
```

Example 3: Add Items to a List

In both X++ and C#, the collection provides a method for appending an item to the end of the collection, and for inserting an item the start. In C# the collection provides a method for inserting at any point in the collection based on an index value. In X++ a collection iterator can insert an item at its current position. Following are code

examples in X++ and C#.

```
// X++
listStrings.addEnd ("StringBB.");
listStrings.addStart ("StringAA.");
// Iterator performs a midpoint insert at current position.
listIterator.insert ("dog");
```

```
// C#
listStrings.Add ("StringBB.");
listStrings.Insert (0 ,"StringAA.");
// Index 7 determines the insertion point.
listStrings.Insert (7 ,"dog");
```

Example 4: Iterate Through a List

Both X++ and C# have iterator classes that you can use to step through the items in a collection as shown in the following examples.

```
// X++
literator = new ListIterator (listStrings);
// Now the iterator points at the first item.

// The more method answers whether
// the iterator currently points
// at an item.
while (literator.more())
{
    info(any2str (literator.value()));
    literator.next();
}
```

```
// C#
literator = listStrings .GetEnumerator();
// Now enumerator points before the first item, not at the first item.

// The MoveNext method both advances the item pointer, and
// answers whether the pointer is pointing at an item.
while (literator.MoveNext())
{
    Console.WriteLine (literator.Current);
}
```

Example 4b: foreach in C#

In C# the `foreach` keyword is often used to simplify the task of iterating through a list. The following code example behaves the same as the previous C# example.

```
foreach (string currentString in listStrings)
{
    Console.WriteLine(currentString);
}
```

Example 5: Delete the Second Item

The following code examples delete the second item from the collection. In X++ this requires an iterator. In C# the collection itself provides the method for removing an item.

```
// X++
literator.begin();
literator.next();
literator.delete();
```

```
// C#
listStrings.RemoveAt(1);
```

Example 6: Combine Two Collections

The following code examples combine the contents of two collections into one.

```
// X++
listStrings = List::merge(listStrings ,listStr3);
// Or use the .appendList method:
listStrings.appendList (listStr3);
```

```
// C#
listStrings.InsertRange(listStrings.Count ,listStr3);
```

Comparison: Collections of keys with values

In a Finance and Operations application, you can use the `Map` collection class. The `Map` collection holds pairs of values, the key value plus a data value. This resembles the .NET Framework class named `System.Collections.Generic.Dictionary`.

Similarities

The following list describes similarities between X++ and C# regarding their collections that store key-value pairs:

- Both prevent duplicate keys.
- Both use an enumerator (or iterator) to loop through the items.
- Both key-value collection objects are constructed with designations of the types that are stored as key and value.
- Both can store class objects, and are not limited to storing primitives like **int**.

Differences

The following table describes differences between X++ and C# regarding their collections classes that store key-value pairs:

FEATURE	X++	C#	COMMENTS
Duplicate keys	In X++ the `Map` class prevents duplicate keys by implicitly treating your call to its `insert` method as an operation to update only the value associated with the key.	In C# the `Dictionary` class throws an exception when you try to add a duplicate key.	Duplicate keys are prevented in both languages, although by different techniques.

FEATURE	X++	C#	COMMENTS
Delete items	In X++ the `delete` method on an iterator object is used to remove an unwanted key-value pair from a `Map`.	In C# the `Dictionary` class has a `remove` method.	In both languages, an enumerator is made invalid if the collection item count is modified during the life of the enumerator.

Example 1: Declaration of a Key-Value Collection

In both languages, the type of items that the key-value collection stores must be specified. In X++ the type is specified at time of construction. In C# the type is specified at both the time of declaration and the time of construction. Following are code examples in X++ and C#.

```
// X++
Map mapKeyValue;
MapEnumerator enumer;
MapIterator mapIter;
```

```
// C#
Dictionary<int,string> dictKeyValue;
IEnumerator<SysCollGen.KeyValuePair<int,string>> enumer;
KeyValuePair<int,string> kvpCurrentKeyValuePair;
```

Example 2: Construction of the Collection

In both languages, the type of items that the key-value collection stores specified during construction. For class types, X++ can get no more specific than whether the type is a class (Types::Class). Following are code examples in X++ and C#.

```
// X++
mapKeyValue = new Map(Types::Integer, Types::String);
```

```
// C#
dictKeyValue = new Dictionary<int,string>();
```

Example 3: Add an Item to the Collection

There is almost no difference in how an item is added to a key-value collection in X++ and C# as shown in the following code examples.

```
// X++
mapKeyValue.insert(xx ,int2str(xx) + “_Value”);
```

```
// C#
dictKeyValue.Add(xx ,xx.ToString() + “_Value”);
```

Example 4: Iterate Through a Key-Value Collection

Enumerators are used to loop through the key-value collections in both X++ and C# as shown in the following code examples.

```
// X++
enumer = mapKeyValue.getEnumerator();
while (enumer.moveNext())
{
    iCurrentKey = enumer.currentKey();
    sCurrentValue = enumer.currentValue();
    // Display key and value here.
}
```

```
// C#
enumer = dictKeyValue.GetEnumerator();
while (enumer.MoveNext())
{
    kvpCurrentKeyValuePair = enumer.Current;
    // Display .Key and .Value properties=
    // of kvpCurrentKeyValuePair here.
}
```

Example 5: Update the Value Associated with a Key

The syntax is very different between the two languages for an update of the value associated to a given key. Following are code examples for the key 102.

```
// X++
mapKeyValue.insert(
    102 ,
    ".insert(), Re-inserted" + " key 102 with a different value.");
```

```
// C#
dictKeyValue[102] =
    "The semi-hidden .item property in C#, Updated the value for key 102.";
```

Example 6: Delete One Item

The syntax is very different between the two languages to delete one key-value pair from a collection, while iterating through the collection members. Code examples for the key 102 are shown below.

```
// X++
mapIter = new MapIterator(mapKeyValue);
//mapIter.begin();
while (mapIter.more())
{
    iCurrentKey = mapIter.key();
    if (104 == iCurrentKey)
    {
        // mapKeyValue.remove would invalidate the iterator.
        mapIter.delete();
        break;
    }
    mapIter.next();
}
```

```
// C#
dictKeyValue.Remove(104);
```

Comparison: Exceptions

There are some similarities but many differences when we compare exception related behavior between X++ and C#. The **try**, **catch**, and **throw** keywords behave the same in X++ and C#. But the types of exceptions thrown and caught are different for the two languages.

Similarities

Similarities between X++ and C# regarding their exception features include the following:

- Both languages have the same **try** keyword.
- Both have the same **catch** keyword.
- Both enable for a **catch** statement that does not specify any particular exception. Such a **catch** statement catches all exceptions that reach it.
- Both have the same **throw** keyword.

Differences

Exception-related differences between X++ and C# are described in the following table.

FEATURE	X++	C#	COMMENTS
retry	Jumps to the first instruction in the associated **try** block. For more information, see Exception Handling with try and catch Keywords.	The functionality of the **retry** keyword can be mimicked in C# code, but there is no corresponding keyword.	Only X++ has a **retry** keyword. C# has no counterpart. For more information, see X++, C# Comparison: Automated Retry After an Exception.
finally	The `finally` keyword is supported to follow the `try` and `catch` keywords.	The **finally** keyword marks a block of code that follows the **try** and **catch** blocks. The finally will be executed regardless of whether any exception is thrown or caught.	The semantics are identical to the semantics in C#.
Specific exceptions	In X++ an exception is an element of the `Exception` enum, such as **Error**, **Deadlock**, or **CodeAccessSecurity**. No exception can contain another.	In C# an exception is an instance of the `System.Exception` base class, or any class that inherits from it. An exception can be contained in the `InnerException` property of the thrown exception.	In X++ each thrown exception is a value of the Exception enum. For more information, see Exception Enumeration.
Exception message	In X++ the message that is created when an exception is raised is available only in the Infolog, and the message is not directly tied to the exception.	In C# the message is the `Message` member of the `System.Exception` object.	In X++ the Global::error method is the mechanism that display exception messages in the Infolog. For more information, see Exception Handling with try and catch Keywords.

FEATURE	X++	C#	COMMENTS
Exception conditions	In X++ an error occurs when you call an instance method on an object variable that has not yet had anything assigned to it. However, no exception is raised along with this error. Therefore no `catch` block can gain control even if the unassigned variable is misused in a `try` block. In the following code example, the error caused by the code `box4.toString();` does not cause control to transfer to any `catch` block: `DialogBox box4;` `try` { `box4.toString();` `info("toString did not error, but expected an error.");` } catch (Exception::Error) // No Exception value catches this. { `info("Invalid use of box4 gave control to catch, unexpected.");` }	In C# a `System.NullReferenceException` is raised when an uninitialized variable is treated as an object reference.	There might be several other differences in the conditions that raise exceptions.
SQL transactions	In X++ when an SQL exception occurs in a **ttsBegin** - **ttsCommit** transaction, no **catch** statement inside the transaction block can process the exception.	In C# a catch block inside an SQL transaction can catch the exception.	

Examples

The following X++ features are demonstrated:

- **try** keyword.
- **catch** keyword.
- The behavior after an Exception::Error exception occurs.

X++ Example

```
// X++
static void JobRs008a_Exceptions(Args _args)
{
    str sStrings[4];
    int iIndex = 77;
    try
    {
        info("On purpose, this uses an invalid index for this array: " + sStrings[iIndex]);
        warning("This message does not appear in the Infolog," + " it is unreached code.");
    }
    // Next is a catch for some of the values of
    // the X++ Exception enumeration.
    catch (Exception::CodeAccessSecurity)
    {
        info("In catch block for -- Exception::CodeAccessSecurity");
    }
    catch (Exception::Error)
    {
        info("In catch block for -- Exception::Error");
    }
    catch (Exception::Warning)
    {
        info("In catch block for -- Exception::Warning");
    }
    catch
    {
        info("This last 'catch' is of an unspecified exception.");
    }
    //finally
    //{
    //    //Global::Warning("'finally' is not an X++ keyword, although it is in C#.");
    //}
    info("End of program.");
}
```

Output

Here is the output from the Infolog window:

```
Message (18:07:24)
Error executing code: Array index 77 is out of bounds.
Stack trace
(C)\Jobs\JobRs008a_Exceptions - line 8
In catch block for -- Exception::Error
End of program.
```

C# Sample

The following C# program is a rewrite of the previous X++ program.

```
// C#
using System;
public class Pgm_CSharp
{
    static void Main( string[] args )
    {
        new Pgm_CSharp().Rs008a_CSharp_Exceptions();
    }
    void Rs008a_CSharp_Exceptions()
    {
        //str sStrings[4];
        string[] sStrings = new string[4];
        try
        {
            Console.WriteLine("On purpose, this uses an invalid index for this array: " + sStrings[77]);
            Console.Error.WriteLine("This message does not appear in the Infolog, it is unreached code.");
        }
        catch (NullReferenceException exc)
        {
            Console.WriteLine("(e1) In catch block for -- " + exc.GetType().ToString() );
        }
        catch (IndexOutOfRangeException exc)
        {
            Console.WriteLine("(e2) In catch block for -- " + exc.GetType().ToString() );
        }
        // In C#, System.Exception is the base of all
        // .NET Framework exception classes.
        // No as yet uncaught exception can get beyond
        // this next catch.
        catch (Exception exc)
        {
            Console.WriteLine("This last 'catch' is of the abstract base type Exception: "
                + exc.GetType().ToString());
        }
        // The preceding catch of System.Exception makes this catch of
        // an unspecified exception redundant and unnecessary.
        //catch
        //{
        //    Console.WriteLine("This last 'catch' is"
        //        + " of an unspecified exception.");
        //}
        finally
        {
            Console.WriteLine("'finally' is not an X++ keyword, although it is in C#.");
        }
        Console.WriteLine("End of program.");
    }
} // EOClass
```

Output

Here is the output to the C# console:

```
(e2) In catch block for -- System.IndexOutOfRangeException
'finally' is not an X++ keyword, although it is in C#.
End of program.
```

Comparison: Automated Retry After an Exception

Sometimes you can write code in a catch block that fixes the cause of an exception that occurs during run time. X++ provides a **retry** keyword that can be used only inside a **catch** block. The **retry** keyword enables a program to jump back to the start of the **try** block after the problem has been corrected by code in the **catch** block. C# does not have a **retry** keyword. However, C# code can be written to provide equivalent behavior.

Code Samples for Retry

The following X++ sample program causes an Exception::Error to be raised. This occurs when it first tries to read an element from the `sStrings` array by using an invalid index value. When the exception is caught, corrective action is taken during run time inside the **catch** block. The retry statement then jumps back to the first statement in the **try** block. This second iteration works without encountering any exception.

```
static void JobRs008b_ExceptionsAndRetry(Args _args)
{
    str sStrings[4];
    str sTemp;
    int iIndex = 0;

    sStrings[1] = "First array element.";
    try
    {
        print("At top of try block: " + int2str(iIndex));
        sTemp = sStrings[iIndex];
        print( "The array element is: " + sTemp );
    }
    catch (Exception::Error)
    {
        print("In catch of -- Exception::Error (will retry)." + " Entering catch.");
        ++iIndex;
        print("In catch of -- Exception::Error (will retry)." + " Leaving catch.");
        // Here is the retry statement.
        retry;
    }
    print("End of X++ retry program.");
    pause;
}
```

Output

Here is the output to the Print window:

```
At top of try block: 0
In catch of -- Exception::Error (will retry). Entering catch.
In catch of -- Exception::Error (will retry). Leaving catch.
At top of try block: 1
The array element is: First array element.
End of X++ retry program.
```

C# Sample

The following C# sample is not a line-by-line translation from the previous X++ sample. Instead the C# program has a different structure so that it mimics the behavior of the **retry** keyword that the X++ program relies on. The **try** and **catch** blocks are in a called method. The variables that are used in the **try** block are stored in the caller method. The caller method passes the variables as parameters that are decorated with the **ref** keyword, so that their values can be corrected inside the **catch** block of the called method. The called method captures all exceptions, and returns a **boolean** to communicate back to the caller whether a second call is required.

```
// C#
using System;
public class Pgm_CSharp
{
    static void Main(string[] args)
    {
        new Pgm_CSharp() .Rs008b_CSharp_ExceptionsAndRetry();
    }
    void Rs008b_CSharp_ExceptionsAndRetry() // Caller
    {
        int iIndex = -1
            , iNumRetriesAllowed = 3;
        bool bReturnCode = true; // Means call the callee method.
        for (int xx=0; xx <= iNumRetriesAllowed; xx++)
        {
            if (bReturnCode)
            {
                bReturnCode = this.Rs008b_CSharp_ExceptionsAndRetry_Callee(ref iIndex);
            }
            else
            {
                break;
            }
        }
        Console.WriteLine("End of C# caller method.");
    }

    private bool Rs008b_CSharp_ExceptionsAndRetry_Callee(ref int iIndex)
    {
        bool bReturnCode = true; // Means call this method again.
        string[] sStrings = new string[4];
        string sTemp;
        sStrings[0] = "First array element.";
        try
        {
            Console.WriteLine("At top of try block: " + iIndex.ToString());
            sTemp = sStrings[iIndex];
            Console.WriteLine( "The array element is: " + sTemp );
            bReturnCode = false; // Means do not call this method again.
        }
        catch (Exception)
        {
            Console.WriteLine("In catch of -- Exception. Entering catch.");
            ++iIndex; // The 'ref' parameter in C#.
            Console.WriteLine("In catch of -- Exception. Leaving catch.");
            //retry;
            // In C# we let the caller method do the work
            // that the retry keyword does in X++.
        }
        Console.WriteLine("End of C# callee method.");
        return bReturnCode;
    }
}
```

Output

Here is the output to the console:

```
At top of try block: -1
In catch of -- Exception. Entering catch.
In catch of -- Exception. Leaving catch.
End of C# callee method.
At top of try block: 0
The array element is: First array element.
End of C# callee method.
End of C# caller method.
```

Comparison: Operators

This section compares the operators between X++ and C#.

Assignment Operators

The following table displays the differences between the assignment operators in X++ and C#.

X++ AND C#	DIFFERENCES
`=`	In X++ this operator causes an implicit conversion whenever a loss of precision might occur, such for an assignment from an **int64** to an **int**. But in C# the assignment causes a compile error.
`+=` and `-=`	The only difference is that in C# these operators are also used in delegate manipulation.

++ and --	These are the increment and decrement operators in both languages. The following line is identical in both languages:
	`++myInteger;`
	But in X++ these two operators are for statements, not for expressions. Therefore the following lines generate compile errors in X++:
	`myStr = int2str(++myInteger);`
	`myIntA = myIntBB++;`

Arithmetic Operators

The following table lists the arithmetic operators.

X++ AND C#	DIFFERENCES
*	As the multiplication operator, there are no differences. **Note:** The asterisk is also used in the SQL statements that are part of the X++ language. In these SQL statements the asterisk can also be one of the following: • A wildcard indicating that all the columns should be returned. • A wildcard for characters in a string that is used on a **like** clause.
`/`	The division operator is the same in X++ and C#.
`MOD`	For modulo operations, the only difference is that the % symbol is used in C#.

X++ AND C#	DIFFERENCES
+	The addition operator is the same in X++ and C#. The plus sign is also used for string concatenation. This operator adds numbers and concatenates strings in both languages.
-	The subtraction operator is the same in X++ and C#.

Bitwise Operators

The following table compares the bitwise operators between X++ and C#.

X++ AND C#	DIFFERENCES
<<	The left shift operator is the same in X++ and C#.
>>	The right shift operator is the same in X++ and C#.
~	The bitwise NOT operator is the same in X++ and C#.
&	The binary AND operator is the same in X++ and C#.
^	The binary XOR operator is the same in X++ and C#.

Relational Operators

The following relational operators are the same in X++ and C#:

- `==`
- `<=`
- `<=`
- `>`
- `<`
- `!=`
- `&&`
- `||`
- `!`
- `? :`

Comparison: Events

There are some differences in how X++ and C# implement the event design pattern. For more information, see Event Terminology and Keywords.

Comparison of Events between X++ and C#

There are differences in the way delegates are used for events in X++ versus C#.

CONCEPT	X++	C#	COMMENTS

CONCEPT	X++	C#	COMMENTS
delegate	In X++, a delegate can be declared only as a member on a class. A delegate cannot be a member on a table. All delegates are instance members of their class, not **static** members. No access modifier can be used on a delegate declaration, because all delegates are **protected** members. Therefore, the event can be raised only by code within the same class where the delegate is a member. However, the one exception to the private nature of a delegate is that code outside their class can operate on the delegates by using the += and -= operators.	In C#, each **delegate** is a type, just as every **class** is a type. A delegate is declared independently of any class. Without the **event** keyword, you can have a delegate as a parameter type on a method, just as you can have a class as a parameter type. You can construct an instance of a delegate to pass in for the parameter value.	In X++, each class is a type, but no delegate is a type. You cannot construct an instance of a delegate. No delegate can be a parameter for a method. But you can create a class that has a delegate member, and you can pass instances of the class as parameter values. For more information, see X++ Keywords.
event	In X++ code, an event is one of the following: • An explicit call to a delegate. • The start or end of a method. There is no **event** keyword in X++.	In C#, the **event** keyword is used to declare a **delegate** type as a member of a class. The effect of the **event** keyword is to make the delegate **protected**, yet still accessible for the += and -= operators. You can subscribe event handler methods to an **event** by using the += operator. A **delegate** can be useful without the **event** keyword, as a technique for passing a function pointer as a parameter into a method.	The automatic events that occur before the start of a method, and after the end of a method, can be subscribed to only by using the AOT.
+= and -= operators	In X++, you use the += operator to subscribe methods to a **delegate**. The -= operator unsubscribes a method from a delegate.	In C#, you use the += operator to subscribe methods to an **event**, or to a **delegate** that is not used with the **event** keyword.	The delegate contains a reference to all the objects that have methods subscribed to the delegate. Those objects are not eligible for garbage collection while delegate holds those references.
`eventHandler`	In X++, the **eventHandler** keyword is required when you use either the += or -= operator to subscribe or unsubscribe a method from a delegate.	`System.EventHandler` is a delegate type in the .NET Framework.	This term is used differently in X++ than it is in C# or the .NET Framework. For more information, see X++ Keywords.

X++ Example

The important things to notice in the X++ example are the following:

- The `XppClass` has a delegate member that is named `myDelegate`.

  > **NOTE**
  > The AOT contains a node for the delegate. The node is located at AOT > Classes > XppClass > myDelegate. Several event handler nodes can be located under the myDelegate node. Event handlers that are represented by nodes in the AOT cannot be removed by the -= operator during run time.

- The {} braces at the end of the delegate declaration are required, but they cannot have any code in them.
- The `XppClass` has two methods whose parameter signatures are compatible with the delegate. One method is static.
- The two compatible methods are added to the delegate with the += operator and the **eventHandler** keyword. These statements do not call the event handler methods, the statements only add the methods to the delegate.
- The event is raised by one call to the delegate.
- The parameter value that passed in to the delegate is received by each event handler method.
- The short X++ job at the top of the example starts the test.

```
// X++
// Simple job to start the delegate event test.
static void DelegateEventTestJob()
{
    XppClass::runTheTest("The information from the X++ job.");
}
// The X++ class that contains the delegate and the event handlers.
class XppClass
{
    delegate void myDelegate(str _information)
    {
    }
    public void myEventSubscriberMethod2(str _information)
    {
        info("X++, hello from instance event handler 2: " + _information);
    }
    static public void myEventSubscriberMethod3(str _information)
    {
        info("X++, hello from static event handler 3: " + _information);
    }
    static public void runTheTest(str _stringFromJob)
    {
        XppClass myXppClass = new XppClass();
        // Subscribe two event handler methods to the delegate.
        myXppClass.myDelegate += eventHandler(myXppClass.myEventSubscriberMethod2);
        myXppClass.myDelegate += eventHandler(XppClass::myEventSubscriberMethod3);
        // Raise the event by calling the delegate one time,
        // which calls all the subscribed event handler methods.
        myXppClass.myDelegate(_stringFromJob);
    }
}
```

The output from the previous X++ job is as follows:

```
X++, hello from static event handler
3: The information from the X++ job. X++, hello from instance event handler
2: The information from the X++ job.
```

C# Sample

This section contains a C# code sample for the event design pattern of the previous X++ sample.

```
// C#
using System;
// Define the delegate type named MyDelegate.
public delegate void MyDelegate(string _information);
public class CsClass
{
    protected event MyDelegate MyEvent;
    static public void Main()
    {
        CsClass myCsClass = new CsClass();
        // Subscribe two event handler methods to the delegate.
        myCsClass.MyEvent += new MyDelegate(myCsClass.MyEventSubscriberMethod2);
        myCsClass.MyEvent += new MyDelegate(CsClass.MyEventSubscriberMethod3);
        // Raise the event by calling the event one time, which
        // then calls all the subscribed event handler methods.
        myCsClass.MyEvent("The information from the C# Main.");
    }
    public void MyEventSubscriberMethod2(string _information)
    {
        Console.WriteLine("C#, hello from instance event handler 2: " + _information);
    }
    static public void MyEventSubscriberMethod3(string _information)
    {
        Console.WriteLine("C#, hello from static event handler 3: " + _information);
    }
}
```

The output from the previous C# sample is as follows:

```
CsClass.exe C#, hello from instance event handler
2: The information from the C\# Main. C\#, hello from static event handler
3: The information from the C\# Main.
```

Events and the AOT

There are other event systems that apply only to items in the AOT. For more information, see Event Handler Nodes in the AOT.

Comparison: Precompiler Directives

X++ and C# share some keywords for their precompiler directive syntax, but the meanings are not always the same.

Similarities

The X++ and C# compilers recognize many of the same keywords. In most cases, the keywords mean the same for both language compilers.

Differences

A fundamental difference between the precompiler directives in X++ versus C# is the #define keyword that both language precompilers recognize. Unlike C#, in X++ the #define directive requires a dot in its syntax. In X++, parentheses can be used to give the defined symbol a value. These differences are shown in the following examples:

- In X++: #define.InitialYear(2003)
- In C#: #define InitialYear

A minor difference is that in C# there can be spaces and tab characters between the # character and the directive

keyword, such as # define Testing.

Identical Keywords

The following table lists precompiler directives that are similar in X++ and C#.

KEYWORD	X++	C#	COMMENTS
`#define`	In X++, a precompiler variable name can be defined, and a value can be given to that variable.	In C#, a precompiler variable name can be defined, but no value can be given to that variable. Also, any #define in C# must occur at the top of the file, and cannot occur after any code such as a using statement or a class declaration.	The C# compiler can input a command line parameter of `/define` to define a precompiler variable name without defining the variable in any C# code file. The X++ compiler has no counterpart to `/define`.
`#if`	In X++, #if can determine whether a precompiler variable exists, and whether the variable has a given value.	In C#, #if can only determine whether a precompiler variable exists. It cannot test for any value because no value can be assigned.	
`#endif`	In X++, #endif marks the end of an #if block. It also ends an #ifnot block.	In C#, #endif marks the end of an #if block, regardless of whether the block includes a #else.	

Different Keywords with the Same Processing Result

The following table lists precompiler directives that are named differently in X++ and C#, but that give the same results when processed.

X++	C#	COMMENTS
#ifnot	#if #else	There is no #else directive in X++, but the #ifnot provides similar functionality. In X++, #ifnot can determine whether a precompiler variable exists, and whether the variable does not have a specific given value. In C#, #if can determine whether a precompiler variable exists when the '!' symbol is prefixed to the variable name.
`//BP Deviation documented`	#pragma warning	These X++ and C# entries are not equivalent, but there is a partial similarity. Both suppress compiler warning messages.
#macrolib	.HPP file in C++	There is a partial similarity between the X++ directive #macrolib versus an .HPP file in C++. Both can contain several #define statements.

Precompiler Directives Exclusive to X++

The following table lists X++ precompiler directives that have no direct counterpart in C#.

X++	COMMENTS
#linenumber	The #linenumber directive is for obtaining the line number, so that it can be output to the Infolog. The C# directive #line is different because its purpose is for setting the line number.
#defdec #definc	
#globaldefine	In X++, there is a small difference between #globaldefine versus #define. The difference is that #globaldefine never overwrites a current nonnull value that was assigned to a precompiler variable by #define. C# has nothing similar to this difference, because in C#, a precompiler variable name cannot be given a value.
#localmacro #macro	In X++, #localmacro enables you to assign a multiline value to a precompiler variable. #macro is a synonym, but #localmacro is recommended. In C#, the #define directive has part of this functionality, but it cannot assign a value to a precompiler variable.
#globalmacro	In X++, #globalmacro is almost the same as the preferred #localmacro.

Comparison: Object Oriented Programming

The object oriented programming (OOP) principles of X++ differ from C#.

Conceptual Comparisons

The following table compares the implementation of OOP principles between X++ and C#.

FEATURE	X++	C#	COMMENTS
Casting	The X++ language has the keywords **is** and **as**, which are used to make downcasts safe and explicit. **Tip**: X++ does not require the use of the **as** keyword when you downcast a base class variable to a derived class variable. However, we recommend that all downcast statements use the **as** keyword.	An object can be cast either up or down the inheritance path. Downcasts require the **as** keyword.	For more information about the X++ keywords **is** and **as**, see Expression Operators: Is and As for Inheritance.
Local functions	A method can contain a declaration and code body for zero or more local functions. Only that method can have calls to the local function.	C# 3.0 supports lambda expressions, which have some similarity to anonymous functions and local functions. Lambda expressions are often used with delegates.	

FEATURE	X++	C#	COMMENTS
Method overloading	Method overloading is not supported. A method name can occur only one time per class.	Method overloading is supported. A method name can occur multiple times in one class, with different parameter signatures in each case.	X++ does support optional parameters on methods. Optional parameters can partially mimic method overloading. For more information, see the row for optional parameters in this table.
Method overriding	Method overriding is supported. A derived class can have a method by the same name as in the base class, as long as the parameter signature is the same in both cases. The only exception is that the overriding method can add a default value to a parameter.	Method overriding is supported. The **virtual** keyword must be applied to a method before the method can be overridden in a derived class.	The concept of overriding a method includes the method name, its parameter signature, and its return type. The concept of method overriding does not apply if the base method and the overriding method differ in any of these aspects.
Optional parameters	A parameter declaration can be followed by a default value assignment. The method caller has the option of passing a value for that parameter, or ignoring the parameter to accept the default value. This feature mimics method overloading because two calls to the same method name can pass different numbers of parameters. Each parameter that has a default value must follow the last parameter that does not have a default value.	Optional parameters are supported by the **params** keyword. Even without the **params** keyword, from the point of view of the caller, method overloading can provide partially similar functionality.	For more information, see Parameters and Scoping and Using Optional Parameters.

FEATURE	X++	C#	COMMENTS
Single inheritance	You can derive your X++ class from another X++ class by using the **extends** keyword in the classDeclaration node of your class, in the AOT. No class implicitly derives directly from another class. If you want your class to directly derive from the `Object` class, you must use the **extends** keyword. You can specify only one class on the **extends** keyword. **Caution**: When you modify an X++ base class that other classes derive from, you must recompile that base class using the Compile forward. This option ensures that the derived classes are also recompiled. To ensure the derived classes are also recompiled, right-click the base class node, and then click Add-Ins > Compile forward. The alternative of clicking Build > Compile (or pressing the F7 key) is sometimes insufficient for a base class change. A class can implement zero to many interfaces. An X++ table implicitly inherits from the `Common` table, and from the `xRecord` class.	C# uses the **extends** keyword to derive from another class. All .NET Framework classes implicitly derive from the `System.Object` class, unless they explicitly derive from another class.	

Keyword Comparisons

The following table lists the OOP-related keywords in X++ and C#.

KEYWORD	X++	C#	COMMENTS
abstract			No difference.
class	The modifiers **public** and **private** are ignored on class declarations. There is no concept of a namespace grouping of classes. There are no dots (.) in any class names.	The modifiers **public** and **private** can be used to modify class declarations. C# also has the keyword **internal**, which relates to how classes are grouped together in assembly files.	There is no concept of a **protected** class, only **protected** members of a class.

KEYWORD	X++	C#	COMMENTS
extends	A class declaration can inherit from another class by using the **extends** keyword.	A colon (:) is used where the keywords **extends** and **implements** are used in X++.	
final	A **final** method cannot be overridden in a derived class. A **final** class cannot be extended.	The keyword **sealed** on a class means the same thing that **final** means on an X++ class.	
implements	A class declaration can implement an **interface** by using the **implements** keyword.		
interface	An **interface** can specify methods that the class must implement.	An **interface** can specify methods that the class must implement.	
new	The **new** keyword is used to allocate a new instance of a class. Then the constructor is automatically called. Each class has exactly one constructor, and the constructor is named `new`. You can decide what parameters the constructor should input.	The **new** keyword is used to create a new instance of a class. Then the constructor is automatically called. Constructor methods themselves are not named `new`, they have the same name as the class. **Note:** The **new** keyword can also be used on a method, to modify the way in which the method overrides the same method in the base class.	Both X++ and C# assume a default constructor for classes that have no constructor explicitly written in their code.
null			No difference.
private and **protected**	The **private** and **protected** keywords can be used to modify the declaration of a class member.	The **private** and **protected** keywords can be used to modify the declaration of a class member.	
public	A method that is not modified with **public**, **protected**, or **private** has the default access level of **public**.	A method that is not modified with **public**, **protected**, or **private** has the default access level of **private**.	
static	A method can be **static**, but a field cannot.	Both methods and fields can be **static**.	

KEYWORD	X++	C#	COMMENTS

super	The **super** keyword is used in a derived class to access the same method on its base class.
	`void method2()`
	`{`
	`// Call method2 method`
	`// on the base class.`
	`super();`
	`}`
		The **base** keyword is used in a derived class to access various methods in its base class.
		`void method2()`
		`{`
		`// Call methods on`
		`// the base class.`
		`base.method2();`
		`base.method3();`
		`}`
			In C#, there is special syntax for using **base** to call the base constructor.

this	For a call from one instance method to another on the same object, a qualifier for the called method is required. The keyword **this** is available as a qualifier for the current object.	For a call from one instance method to another on the same object, a qualifier for the called method is not required. However, the **this** keyword is available as a qualifier for the current object. In practice, the keyword **this** can be helpful by displaying IntelliSense information.	
`finalize`	The `Object` class contains the `finalize` method. The `finalize` method is not **final**, and it can be overridden. The `finalize` method appears to resemble the `System.Object.Finalize` method in C#, but in X++ the `finalize` method has no special meaning of any kind. An object is automatically removed from memory when the last reference to the object stops referencing the object. For example, this can happen when the last reference goes out of scope or is assigned another object to reference.	The methods `Finalize` and `Dispose` are common on some types of classes. The garbage collector calls the `Finalize` and `Dispose` methods when it destroys and object.	In C#, the `System.GC.Collect` method in the .NET Framework can be called to start the garbage collector. There is no similar function in X++ because X++ uses a deterministic garbage collector.
`main`	Classes that are invoked from a menu have their `main` method called by the system.	Classes that are invoked from a command line console have their `Main` method called by the system.	

Comparison: Classes

When you use C# in the .NET Framework, classes are grouped into namespaces. Each namespace focuses on a functional area such as file operations or reflection. However, when you use the classes in X++, there are no visible groupings like a namespace.

Comparison: Classes about Reflection

In X++ the `TreeNode` class provides access to the Application Object Tree (AOT). The `TreeNode` class is the center of reflection functionality in X++. The `TreeNode` class and its methods can be compared to the `System.Reflection` namespace in the .NET Framework that C# uses.

The following table lists several classes that are available to you when you write C# code. These are .NET Framework classes. For this table, all C# classes are in the `System.Reflection` namespace unless otherwise specified. Each row shows the corresponding class, or class member, that is available to you when your write X++ code.

X++	C#	COMMENTS
`TreeNode`	`System .Assembly`	Assembly is the first class to use when a C# program must gather reflection information. Static methods on the X++ class `TreeNode` are the starting point for reflection in X++.
`TreeNode`	`System .Type`	Instance methods on `TreeNode` correspond to instance methods on `System.Type`.
`TreeNode .AOTgetSource`	`MethodInfo`	The `AOTgetSource` method returns several pieces of information together in one string. This includes the X++ source code in the method. In contrast, `MethodInfo` has a separate member for each piece of information.

`TreeNode .AOTfirstChild`
`TreeNode .AOTnextSibling`
`TreeNode .AOTiterator`
`AOTiterator`
	MethodInfo[] (an array)	In C#, the `GetMethods` method on `System.Type` returns an array of MethodInfo objects. You can loop through the array by the common technique of incrementing an indexer. In contrast, the X++ model is to navigate the tree control of the AOT. The `TreeNode` methods of `AOTfirstChild` and `AOTnextSibling` accomplish the navigation. As an equivalent alternative, the X++ `AOTiterator` class is designed to navigate the tree control of the AOT. A class node is the parent over several method nodes. The `AOTiterator` steps through child nodes, returning each as another `TreeNode` instance. Additional resources the `TreeNode` methods that are named `AOTparent` and `AOTprevious`.

`TreeNode .AOTgetProperty`
`TreeNode .AOTgetProperties`
`TreeNode .AOTname`
	`PropertyInfo`	In X++, the `AOTgetProperties` method returns a long string that contains name-value pairs for all the properties of the `TreeNode`. The `AOTname` method returns a string that contains only the value for the name property.

X++	C#	COMMENTS
`TreeNode .AOTsave` `TreeNode .AOTinsert`	`System .Reflection .Emit` (namespace of classes)	The `AOTsave` method applies changes from a `TreeNode` object in your X++ code to the AOT, and the changes are persisted. For a large code sample, see TreeNode.AOTsave Method.

Comparison: Classes about File IO

There are several classes that perform file input and output (IO) operations. In the .NET Framework that is used in C#, the counterparts to these classes reside in the `System.IO` namespace.

The following table lists several .NET Framework classes for C# that are in the `System.IO` namespace. Each row in the table shows the X++ class or method that best corresponds to the .NET Framework class.

X++	C#	COMMENTS
`BinaryIo`	`FileStream` `BinaryReader` `BinaryWriter`	X++ classes such as `BinaryIo` that extend from the abstract class `Io` serve as a stream, and they also serve as a reader and writer for that stream. In C#, the stream is a separate class from the class that has more specific read and write methods.
`TextBuffer`	`MemoryStream`	These classes contain an in-memory buffer, and some of the methods treat the buffer as if it were a file on the hard disk.
WINAPI::createDirectory WINAPI::folderExists WINAPI::removeDirectory	`Directory` `DirectoryInfo` `Path`	X++ can use static methods in the `WINAPI` class for many basic operating system functions that involve directories.
WINAPI::getDriveType	`DriveInfo` `DriveType`	These classes and methods are used to obtain drive related information.
WINAPI::copyFile WINAPI::createFile WINAPI::deleteFile WINAPI::fileExists	`File` `FileAttributes` `FileInfo`	X++ can use static methods in the `WINAPI` class for many basic operating system functions that involve files.
`CommaIo` `Comma7Io`	(No corresponding class.)	These X++ classes can generate files that Microsoft Excel can import. In X++ an EPPlus library reference is available for additional interaction with Excel.
`AsciiIo` `TextIo`	`FileStream` `TextReader` `TextWriter`	These classes use different code pages.
`Io`	`Stream` `StreamReader` `StreamWriter` `FileStream`	These are often used as base classes that other classes extend.

X++	C#	COMMENTS
`CodeAccessPermission` `FileIoPermission`	`System.Security.CodeAccessPermission` The namespace `System.Security.Permissions` includes the following classes: • `CodeAccessSecurityAttribute` • `FileIOPermissionAttribute` • `FileIOPermission` • `FileIOPermissionAccess`	The concepts and methods of `assert`, `demand`, and `revertAssert` apply to both languages. However, the `deny` and `revertDeny` methods that are available in C# are not available in X++.

X++, ANSI SQL Comparison: SQL Select

In X++, the SQL **select** statement syntax differs from the American National Standards Institute (ANSI) specification.

Single Table Select

The following table lists differences between the select statements of X++ SQL and ANSI SQL.

FEATURE	X++ SQL	ANSI SQL	COMMENTS
Table name on the **from** clause.	The **from** clause lists a record buffer instance that is declared from a table, such as from the `CustTable` table.	The **from** clause lists a table name, not the name of a buffer.	The record buffer has all the methods that the `xRecord` class has in X++.
Syntax sequence of the order by versus **where** clauses.	The order by clause must appear before the **where** clause. The order by clause must appear after the **from** or **join** clause. The group by clause must follow the same syntax positioning rules that the order by follows.	The order by clause must appear after the **where** clause. The **where** clause must appear after the **from** or **join** clause.	In both X++ and ANSI SQL, the **from** and **join** clauses must appear before the order by and **where** clauses.
Condition negation.	The exclamation mark ('!') is used for negation.	The **not** keyword is used for negation.	X++ does not support the syntax !like. Instead, you must apply the ! operator to a clause.
Wildcard characters for the **like** operator.	0 to many – Asterisk ('*') Exactly 1 – Question mark ('?')	0 to many – Percent sign ('%') Exactly 1 – Underbar ('_')	
Logical operators in the **where** clause.	And – && Or – ||	And – **and** Or – **or**	

Code Example

The following code example illustrates features in the previous table.

```
static void OByWhere452Job(Args _args)
{
    // Declare the table buffer variable.
    CustTable tCustTable;
    ;
    while
    SELECT * from tCustTable
        order by tCustTable.AccountNum desc
        where (!(tCustTable.Name like '*i*i*') &amp;&amp; tCustTable.Name like 'T?e *')
    {
        info(tCustTable.AccountNum + " , " + tCustTable.Name);
    }
}
/*** InfoLog output
Message (04:02:29 pm)
4010 , The Lamp Shop
4008 , The Warehouse
4001 , The Bulb
***/
```

X++ SQL Keywords

The following X++ SQL keywords are among those that are not part of ANSI SQL:

- crosscompany
- firstonly100
- forceliterals
- forcenestedloop
- forceplaceholders
- forceselectorder
- validtimestate

Join Clause

The following table lists differences about the **join** keyword of X++ SQL and ANSI SQL.

FEATURE	X++ SQL	ANSI SQL	COMMENTS
Columns list.	The columns in the columns list must all come from the table listed in the **from** clause, and not from any table in a **join** clause. Columns in the list cannot be qualified by their table name.	The columns in the columns list can come from any table in the **from** or **join** clauses. It helps others to maintain your code when you qualify the columns in the list with their table name.	For more information, see Select Statements on Fields.
Join clause syntax.	The **join** clause follows the **where** clause.	The **join** clause follows a table in the **from** clause.	In the X++ code example, the **join** criteria is an equality of `SalesPoolId` values.
Inner keyword.	The default **join** mode is inner join. There is no **inner** keyword.	The default **join** mode is inner join. The **inner** keyword is available to make the code explicit.	The **outer** keyword exists in both X++ SQL and ANSI SQL.
Left and **right** keywords.	The **left** and **right** keywords are not available. All joins are left.	The **left** and **right** keywords are available to modify the **join** keyword.	No comments.

FEATURE	X++ SQL	ANSI SQL	COMMENTS
Equality operator.	The double equal sign operator (' `==` ') is used to test for the equality of two values.	The single equal sign operator (' `=` ') is used to test for the equality of two values.	No comments.

Code Example

The following code example illustrates the **join** syntax in X++ SQL.

```
static void OByWhere453Job(Args _args)
{
    // Declare table buffer variables.
    CustTable tCustTable;
    SalesPool tSalesPool;
    ;
    while
    SELECT
            // Not allowed to qualify by table buffer.
            // These fields must be from the table
            // in the from clause.
            AccountNum,
            Name
        from tCustTable
            order by tCustTable.AccountNum desc
            where (tCustTable.Name like 'The *')
        join tSalesPool
            where tCustTable.SalesPoolId == tSalesPool.SalesPoolId
    {
        info(tCustTable.AccountNum + " , " + tCustTable.Name);
    }
}
```

Aggregate Fields

The following table lists some differences in how aggregate fields in the **select** column list are referenced between X++ SQL and ANSI SQL. Aggregate fields are those that are derived by functions such as **sum** or **avg**.

FEATURE	X++ SQL	ANSI SQL	COMMENTS
Aggregate field name alias.	The aggregate value is in the field that was aggregated.	You can use the **as** keyword to tag an aggregate field with a name alias. The alias can be referenced in subsequent code.	For more information, see Aggregate Functions: Differences Between X++ and SQL

Code Example

In the following code example, the call to the info method illustrates the way to reference aggregate fields (see `tPurchLine.QtyOrdered`).

```
static void Null673Job(Args _args)
{
    PurchLine tPurchLine;
    ;
    while
    select
        // This aggregate field cannot be assigned an alias name.
        sum(QtyOrdered)
        from tPurchLine
    {
        info(
            // QtyOrdered is used to reference the sum.
            "QtyOrdered:  " + num2str(tPurchLine.QtyOrdered,
            3,  // Minimum number of output characters.
            2,  // Required number of decimal places in the output.
            1,  // '.'  Separator to mark the start of the decimal places.
            2   // ','  The thousands separator.
            ));
    }
    info("End.");
}

QtyOrdered:  261,550.00
End.
***/
```

Other Differences

The following table lists other differences of the **select** statement between the X++ SQL and ANSI SQL.

FEATURE	X++ SQL	ANSI SQL	COMMENTS
The **having** keyword.	There is no **having** keyword.	The **having** keyword enables you to specify filter criteria for rows that are generated by the group by clause.	No comments.
Null results.	In a **while** select statement, if the **where** clause filters out all rows, no special count row is returned to report that.	In a **select**, if the **where** clause filters out all rows, a special count row is returned. The count value is 0.	No comments.
Cursors for navigating returned rows.	The while select statement provides cursor functionality. The alternative is to use the **next** keyword.	You can declare a **cursor** for looping through the rows that are returned from a **select** statement.	

From clause.	The **from** keyword is optional when no columns are listed and only one table is referenced. The following two syntax options are equivalent:
	`select \* from tCustTable;`
	`select tCustTable;`
		A **select** statement cannot read from a table unless the **from** clause is used.	In X++ SQL, the simple **select** statement fills the table buffer variable with the first row that was returned. This is illustrated by the following code fragment:
			`select \* from tCustTable;`
			`info(tCustTable.Name);`

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

X++ syntax

2/18/2021 • 30 minutes to read • Edit Online

This topic contains the syntax reference for X++.

X++ Keywords

The X++ keywords shown in the following table are reserved. These keywords cannot be used for any other purpose.

RESERVED WORD	DESCRIPTION	MORE INFORMATION
!	Not.	Relational Operators
!=	Inequality operator (not equal to).	Relational Operators
#	Prefix on macro names.	How to: Use #define and #if to Test a Macro
&	Binary AND.	Arithmetic Operators
&&	Logical AND.	Relational Operators
(	Function call operator, which indicates the beginning of the function call.	
)	Function call operator, which indicates the end of the function call.	
*	Multiply. The asterisk (*) is also used in X++ SQL. One use is to signify all fields from the tables on a `select` statement. Another use is as a wildcard with the `like` operator, to signify 0 to many characters of any kind. The `like` operator also uses the ? character.	Arithmetic Operators
^	Binary XOR.	Arithmetic Operators
|	Binary OR.	Arithmetic Operators
||	Logical OR.	Relational Operators
~	Not.	Arithmetic Operators
+	Plus.	Arithmetic Operators
++	Increment.	Assignment Operators
+=	Additive assignment.	Assignment Operators

RESERVED WORD	DESCRIPTION	MORE INFORMATION
,	Comma operator. Expressions separated by commas are evaluated left-to-right.	
-	Minus.	Arithmetic Operators
--	Decrement operator.	Assignment Operators
-=	Subtractive assignment.	Assignment Operators
.	Class member access operator, for example, `formRun.run` accesses the `run` method of an object of the class type `FormRun`.	
/	Divide.	Arithmetic Operators
	Escape in strings. Escapes extra quotation marks, and certain letters such as \t for tab.	
@	Escape of keywords. For example, str @abstract; would fail to compile without the @ sign. Also affects literal strings, by negating the effect of the \ escape character, and by enabling the string to span more than one line in the source code. The new line is represented by one character of hexadecimal 0x0A, which is commonly called a line feed. No carriage return character of hexadecimal 0x0D is included, as in 0x0D0A.	
:	Field declaration or label specifier. The colon (:) character is also used on the `switch` statement.	
::	Used to call static (class) methods: ClassName::methodName.	
;	Terminates statements. Used in `for` loops or as a separator of statements.	
<	Less than.	Relational Operators
<<	Left shift.	Arithmetic Operators
<=	Less than or equal.	Arithmetic Operators
=	Assignment operator. The argument to the left of "=" is set to the value of the argument to the right.	Assignment Operators

RESERVED WORD	DESCRIPTION	MORE INFORMATION
==	Returns true if both expressions are equal.	Relational Operators
>	Greater than.	Relational Operators
>=	Greater than or equal.	Relational Operators
>>	Right shift.	Arithmetic Operators
?	Ternary operator. The question mark (?) character is also used by the `like` operator to signify exactly one character of any kind. The `like` operator also uses the character.	Ternary Operator (?)
[	Array declarator, open. Must be used with "**]**".	
]	Array declarator, close. Must be used with "**[**".	
{	Indicates the beginning of a number of statements. The last of these statements must be followed by a "**}**".	
}	Indicates the end of a number of statements. A "**{**" must appear before the first of these statements.	
abstract	Class and method modifier. An **abstract** class cannot be constructed with the **new** keyword. An **abstract** method cannot be called. A table can also be modified as abstract by setting its Abstract property to Yes in the AOT, or by using the `DictTable` class. The Abstract property defaults to No, and it cannot be set unless the table is extended by another table. Each row in an abstract table must have a dependent row in a derived table. This means that each row in an abstract table has a value greater than 0 (zero) in its InstanceRelationType property field. There are no other effects from marking a table as abstract. Informally, programmers often use the term concrete to describe a class that is non-**abstract**.	Method Modifiers Table Inheritance Overview
anytype	The method can return any data type.	Anytype

RESERVED WORD	DESCRIPTION	MORE INFORMATION
as	Needed when you assign a base class variable to a derived class variable. For example, given a `Derived` class that **extends** a `Base` class, the statement `myDerived = myBase as Derived;` avoids a compiler error by using the **as** keyword. This keyword also applies when you assign a base table variable to a derived table variable.	Expression Operators: Is and As for Inheritance
asc	An option on the `order by` or `group by` clause in a `select` statement. The sorting is ascending.	Select Statement Syntax
at	Specifies the position of a print window.	Print Statements
avg	Returns the average of the fields from the rows specified by the `group by` clause in a `select` statement.	Select Statement Syntax
break	Immediate exit from code block.	Break Statements
breakpoint	Represents a breakpoint that is set for debugging purposes. To set a breakpoint in your code, write: `breakpoint;`	
by	Part of a reserved term, such as group by and order by.	
byref	Specifies that the parameter being passed to the called method is being passed by reference (address), instead of by value. **Byref** is used in X++ when calling a .NET method that takes a parameter by reference (such as with the C# keywords **out** or **ref**).	How to: Use the byref Keyword for CLR Interop.
case	Selection within a `switch` statement.	Switch Statements
catch	Used in exception handling.	Exception Handling with try and catch Keywords
changeCompany	Changes database settings to another company.	Change Company Design Pattern
class	Declares a class.	Classes in X++
client	Method modifier.	Method Modifiers
container	Specifies a variable of type `container` .	Containers

RESERVED WORD	DESCRIPTION	MORE INFORMATION
continue	Forces the next iteration of a loop.	Continue Statements
count	Returns the number of records from the rows specified by the `group by` clause in a `select` statement.	Select Statement Syntax
crossCompany	Causes a `select` statement to return data for all companies that the user is authorized to read from.	Cross-Company X++ Code Basics
date	Specifies a variable of type `date`.	Dates
default	Default case within `switch` statements.	Switch Statements
delegate	A class member that is able to store multiple references to methods in other classes, and to call all those methods when prompted to do so. A delegate can store references to various kinds of methods including the following: • static methods on X++ classes • instance methods on X++ classes • methods on .NET Framework classes	Event Terminology and Keywords X++, C# Comparison: Event
delete_from	Allows you to delete multiple records from the database at the same time.	delete_from
desc	An option on the `order by` or `group by` clause in a `select` statement. The sorting is descending.	Select Statement Syntax
display	Method modifier.	Method Modifiers
div	Integer division.	Arithmetic Operators
do	Beginning of a `do...while` loop.	Do...while Loops
edit	Method modifier.	Method Modifiers
else	Conditional execution (`if...else`).	if and if ... else Statements
eventHandler	Must be used each time you either add or delete a method reference from a delegate by using the += or -= operator. For example: myDelegate += eventHandler(OtherClass::myStaticMethod);	Event Terminology and Keywords X++, C# Comparison: Event

RESERVED WORD	DESCRIPTION	MORE INFORMATION
exists	Used with `join` clauses in `select` statements.	Select Statement Syntax
extends	A class or interface declaration clause. If your class does not explicitly extend another class, your class is considered to extend the `Object` class (as if you had written "extends Object").	Creating a Subclass
false	Boolean literal.	Booleans
final	Class and method modifier.	Method Modifiers
firstFast	Used in `select` statements to speed up the fetch for the first row.	Select Statement Syntax
firstOnly	Used in `select` statements to fetch only the first record. The `firstOnly` keyword does not guarantee that a maximum of one record is retrieved by an X++ SQL `select` statement. If the AOS can use the `EntireTable` cache to satisfy the data demands of the `select` statement, the `firstOnly` keyword is ignored.	Select Statement Syntax Set-based Caching
firstOnly10	Same as **firstOnly**, except returns 10 rows instead of one.	
firstOnly100	Same as **firstOnly**, except returns 100 rows instead of one.	
firstOnly1000	Same as **firstOnly**, except returns 1000 rows instead of one.	
flush	Clears an entire table cache. Here is the syntax for the `flush` statement: `YourTable ytBuffer;` `flush ytBuffer;`	Set-based Caching
for	For loop iteration.	For Loops
forceLiterals	Used in `select` statements to reveal actual values that are used in `where` clauses to the Microsoft SQL Server database at the time of optimization.	Select Statement Syntax
forceNestedLoop	Forces the SQL Server database to use a nested-loop algorithm to process a particular SQL statement containing a `join`.	Select Statement Syntax

RESERVED WORD	DESCRIPTION	MORE INFORMATION
forcePlaceholders	Used in `select` statements to instruct the kernel not to reveal the actual values used in `where` clauses to the Microsoft SQL Server database at the time of optimization.	Select Statement Syntax
forceSelectOrder	Forces the SQL Server database to access the tables in a join in the specified order.	Select Statement Syntax
forUpdate	Selects records exclusively for update. The operation to be performed on the records that are fetched is an update. Depending on the underlying database, the records may be locked for other users.	Select Statement Syntax
from	Part of a `select` statement. The `from` clause specifies the table in which the columns exists.	Select Statement Syntax
group	Part of the `group by` clause in a `select` statement.	Select Statement Syntax
if	Conditional execution.	if and if ... else Statements
implements	Implements an interface.	Interfaces Overview
insert_recordset	Copies data from one or more tables into one resulting destination table on a single server trip.	insert_recordset
int	Specifies a variable of type `integer` (32-bit).	Integers
int64	Specifies a variable of type `integer` (64-bit).	Integers
interface	Interface declaration.	Interfaces Overview
is	Asks whether the object referenced by a class variable either inherits from the given class or is of the given class. For example, given a `Derived` class that **extends** a `Base` class, the expression `(myDerived is Base)` returns **true**. This keyword applies to class inheritance and table inheritance.	Expression Operators: Is and As for Inheritance
join	Tables are joined on columns common to both tables. You can generate a single result set based on multiple tables through the use of joins.	Select Statement Syntax

RESERVED WORD	DESCRIPTION	MORE INFORMATION

like	Tests for matches by pattern, with wildcard symbols * and ?. The string on the right side of the `like` operator must use four backslash characters to represent one backslash. Examples follow:
	• ("" like "") //Resolves to false.
	• ("" like "*") //Resolves to true.
		Relational Operators

maxof	Returns the maximum of the fields from the rows specified by the `group by` clause.	Select Statement Syntax
minof	Returns the minimum of the fields from the rows specified by the `group by` clause.	Select Statement Syntax
mod	Returns the integer remainder of the left expression1 divided by the right expression2. Informally this is sometimes called the modulo operator. `((12 mod 7) == 5)` is true.	
new	Operator. Creates an instance of an anonymous class that is assignment-compatible with the named class/interface reference variables, or allocates memory for an array.	
next	Fetches the next record in a table.	
noFetch	Indicates that no records are to be fetched at present.	Select Statement Syntax
notExists	Used with `join` clauses in `select` statements.	Select Statement Syntax
null	Symbolic constant.	
optimisticLock	Forces a statement to run with optimistic concurrency control, even if a different value is set on the table.	Select Statement Syntax
order	Part of the `order by` clause in a `select` statement.	Select Statement Syntax
outer	outer join.	Select Statement Syntax
pause	Halts the execution of a job. The user is asked to state whether execution should continue.	Select Statements

RESERVED WORD	DESCRIPTION	MORE INFORMATION
pessimisticLock	Forces a statement to run with pessimistic concurrency control, even if a different value is set on the table.	Select Statement Syntax
print	Allows you to display output on the screen.	Print Statements
private	Method access modifier.	Method Access Control
protected	Method access modifier.	Method Access Control
public	Method access modifier.	Method Access Control
real	Specifies a variable of type `real`.	Reals
repeatableRead	Specifies that no other transactions can modify data that has been read by logic inside the current transaction, until after the current transaction completes. An explicit transaction completes at either **ttsAbort** or at the outermost **ttsCommit**. For a stand-alone **select** statement, the transaction duration is the duration of the **select** command. However, the database sometimes enforces the equivalent of **repeatableRead** in individual **select** statements even without this keyword appearing in your X++ code (depending on how the database decides to scan the tables).	For more information, see the documentation for the underlying relational database product.
retry	Used in exception handling.	Exception Handling with try and catch Keywords
return	Exits from a method.	Declaration of Methods
reverse	Records are returned in reverse order.	Select Statement Syntax
select	The `select` clause designates which columns or views are shown in the result set.	Select Statements
server	Method modifier.	Method Modifiers
setting	Used with the update_recordset command.	update_recordset
static	Static methods may not refer to instance variables (only to static variables); may be invoked by using the class name rather than on an instance of the class ("`MyClass.aStaticProcedure`").	Method Modifiers

RESERVED WORD	DESCRIPTION	MORE INFORMATION
str	Specifies a variable of type `string`.	Strings
sum	Returns the sum of the fields from the rows specified by the `group by` clause in a `select` statement.	Select Statement Syntax
super	Calls the method that was overridden by the current method.	Table Methods
switch	Switch selection statement.	Switch Statements
tableLock	Obsolete; **tableLock** is no longer available.	
this	A reference to the current instance of the class. Used in X++ code inside a method of the class. Used to reference *method* members of the class, but not *field* members of the class. `public str getFullName()` { // Next statement fails to compile without 'this.'. `return this.concatenateFirstAndLastNames();` }	Loosely similar to the system variable that is named `element`. You use `element` in form control methods to reference the containing form. For more information, see Using Variables with Forms.
throw	Used in exception handling.	Exception Handling with try and catch Keywords
true	Boolean literal.	Booleans
try	Used in exception handling.	Exception Handling with try and catch Keywords
ttsAbort	Discards all changes in the current transaction.	Transaction Integrity
ttsBegin	Marks the beginning of a transaction.	Transaction Integrity
ttsCommit	Marks the end of a transaction.	Transaction Integrity
update_recordset	Allows the manipulation of row sets within one operation.	update_recordset
validTimeState	Filters rows that are retrieved from a valid time state table by an X++ SQL `select` statement. For example: select validTimeState(myDateEffective) * from xMyTable; ...or... select validTimeState(myDateFrom, myDateTo) * from xMyTable;	Effects of Valid Time State Tables on Read and Write Operations
void	Identifies a method that does not return a value.	Declaration of Methods

RESERVED WORD	DESCRIPTION	MORE INFORMATION
where	Part of a `select` statement. The `where` clause specifies the conditions to be satisfied; that is, the rows that you want to include in the result.	Select Statement Syntax
while	Iteration statement. Executes a statement or block repeatedly when a test condition is true.	While Loops while select Statements
window	Allows you to alter the size of the output window.	Print Statements

Expressions Syntax

An expression in X++ is used in either a mathematical or logical way. Expressions are built on the data types of the language; that is, an expression returns a value of some type. This value can be used in calculations, assignments, conditional statements, and so on.

EBNF Description of Expressions in X++

TERM		DEFINITION
Expression	=	Simple-expression [RelationalOperator Simple-expression]
RelationalOperator	=	=
Simple-expression	=	Simple-expression [+
Term	=	Compfactor { Mult-operator CompFactor }
Mult-operator	=	*
CompFactor	=	[!] [-
Factor	=	Literal
Enum	=	EnumName :: Literal
Variable	=	Identifier [[Expression]] [. Expression]
FunctionCall	=	[Expression (.
If-expression	=	Expression ? Expression : Expression

Semantic restrictions apply on the preceding syntax. You cannot call any method using the :: operator. Similarly, you cannot use the **this** keyword without an active object; that is, if you are not within a method and so on.

Examples

EXAMPLE OF EXPRESSION	DESCRIPTION
`1`	An integer literal.
NoYes::No	An enum-reference.
`A`	A variable-reference.
Debtor::Find("1")	A static method-call (returns a customer variable).
(A > 3 ? true : false)	An if-expression that returns **true** or **false**.
(select CustTable where CustTable.Account == "100").NameRef	A select-expression. Returns the nameref field in the customer table. This is a string.
A >= B	A logical expression. Returns **true** or **false**.
A + B	An arithmetic expression. Sums A and B.
A + B / C	Calculates B/C, and then adds this to A.
~A + this.Value()	Sums binary not A and the result of the method-call Value on the object in scope (this).
Debtor::Find("1").NameRef	Returns the NameRef field of the found customer record.
Debtor::Find("1").Balance()	A method call to `Balance` in the customer table (Debtor::Find returns a customer). Returns the balance of the customer with account number 1.

EBNF Overview

Extended Backus Naur Form (EBNF) is a metalanguage and is used in this guide to describe the language syntax. An EBNF definition consists of production rules, nonterminals, and terminals. The key terms are shown in the following table.

KEY TERMS	EXAMPLE	DESCRIPTION
Terminals	Work_Team	A terminal is one character or a string of characters that never change.
Nonterminals	`Employee`	A nonterminal is a description of part of a valid sentence in the language that is defined either by a production rule or a textual description. A nonterminal symbol can always be expanded to one or more terminal symbols.
Production rules	Employee = Developer	Tester

Example

Work_Team = Manager Employee {, Employee} Employee = Developer | Tester This example defines a Work_Team as consisting of a `Manager` and one or more `Employees`. An `Employee` is defined as being a

`Developer`, or a `Tester`. The symbols used in the example are described in the following table.

Special Symbols in EBNF

SYMBOL	DESCRIPTION
(*Expression*)	Parentheses hold the symbols (terminals and nonterminals) together. They can be placed anywhere on the right side of a production rule.
Expression1	*Expression2*
[*Expression*]	Optional: The items between [and] are optional. All or none of the items in the brackets are included.
{Expression}	Repeat: The items between { and } are optional, but can be repeated as many times as necessary.

For example, if the accessories you buy for your bicycle consist of a saddle, water-bottle holders, bells, and horns, and you could have either a bell or a horn, and zero, one, or more water bottle holders, and exactly one saddle, this could be expressed as: Bicycle_Accessories = saddle [bell | horn] {water_bottle_holders} This grammar defines the following possibilities: `saddle` `saddle bell` `saddle horn` saddle water_bottle_holder saddle bell water_bottle_holder saddle bell water_bottle_holder water_bottle_holder And so on.

X++ Grammar

This topic shows the formal grammar of the X++ language.

How to Interpret the Formal BNF Grammar

This section describes the grammar of X++ in Backus Naur Form (BNF). A small example of BNF is described here.

```
AA ::= BB  CC_SYM
BB ::= JJ_SYM
   ::= KK_SYM
```

`AA` is the name of a production rule. An `AA` requires a `BB`, followed by a CC_SYM. A `BB` is also a production rule. Therefore, `BB` is not a terminal. `BB` must be either a JJ_SYM or a KK_SYM. Both JJ_SYM and KK_SYM are terminals because they are not the names of any other production rules. CC_SYM is also a terminal.

In the BNF for X++ grammar, most of the terminals have _SYM as the suffix of their name.

The Formal X++ Grammar in BNF

This section contains the BNF that defines the grammar of X++.

X++ Language Syntax is Stricter in Microsoft Dynamics AX 2012

Starting in Microsoft Dynamics AX 2012, the syntax rules for X++ are stricter than in previous versions of the product. This topic describes the syntax changes.

Table of X++ Syntax Changes

The following table displays a list of syntax changes that start in Microsoft Dynamics AX 2012.

AREA	SYNTAX RULE	BEFORE MICROSOFT DYNAMICS AX 2012	STARTING WITH MICROSOFT DYNAMICS AX 2012
Escape	The backslash character is rejected by the compiler for unrecognized escapes	The compiler used to accept "31\12\2002", but during run time the literal string was interpreted as a different value.	Now the following X++ statement is rejected by the compiler: str myDateString = "31\12\2002"; The proper syntax is "31\12\2002".
Exceptions	Retry is no longer allowed outside of a catch block	It was possible to write the **retry** keyword outside of a **catch** block. This caused the program to end when the **retry** was reached during runtime.	Now **retry** can occur only inside a **catch** block. For more information, see Exception Handling with try and catch Keywords.
Exceptions	Now you can throw and catch only `int` values	It was possible to throw scalar expressions like strings and dates, such as `throw "hello world";`, and get no compile error. At runtime this was catch-able by a `catch` block that was not decorated with any specific value, such as catch {print("Catch worked.");}.	Now the only expression you can put on the **throw** keyword is an `int`. Often the best thing to throw is Global::error("Explanation");. Often the best thing to catch is an element of the `Exception` enum. For more information, see Exception Handling with try and catch Keywords.

AREA	SYNTAX RULE	BEFORE MICROSOFT DYNAMICS AX 2012	STARTING WITH MICROSOFT DYNAMICS AX 2012

Inheritance	Downcasting can now be explicit.
	NOTE
	It is good programming practice to avoid implicit downcasts.
		It was possible to assign a base object to a derived object with the simple assignment operator, which is the equals sign (`=`). The compiler accepted these assignments, but during run time any misuse of an improper downcast assignment caused an error.	Now all downcasts can be explicit. This is accomplished with the new **as** expression operator. Explicit downcasting with the **as** keyword is illustrated by the following code example, in which `ThingClass` extends `Object` :
			`ThingClass myThing = new ThingClass();`
			`Object myObject = myThing;`
			`myThing = myObject as ThingClass; // Explicit downcast, good.`
			For more information, see Expression Operators: Is and As for Inheritance.

Inheritance	Override of a base method cannot be less accessible than the base method	It was possible to have a base method be decorated with **protected** and yet have an override of that method be **private**.	Now when a base method is **protected**, the override method must be either **protected** or **public**, and the override method cannot be **private**. For more information, see Method Access Control.
Inheritance	Override of a base method must have the exact same return type and parameter signature as the base method	Suppose a base class had a method that inputs a parameter of the `Common` table, which is the base of all tables. In a derived class it was possible to override the method to instead input `MyTable` .	Now the parameter signatures of the base method and its override method must match exactly. Also, the return types must match exactly. For more information, see Overriding a Method.
Interfaces	Implementation of an interface method must match the parameter signature exactly	Suppose an interface had a method that input a parameter of an `int` . In a class that implements the interface, it was possible to write the method with a parameter of a `str` .	Now the parameter signatures of the method must exactly match between the interface and the implementation of the method on a class. Also, the return types must match exactly. For more information, see Interfaces Overview.

AREA	SYNTAX RULE	BEFORE MICROSOFT DYNAMICS AX 2012	STARTING WITH MICROSOFT DYNAMICS AX 2012
Interfaces	A non-abstract base class that implements an interface cannot rely on a derived class for that implementation	When a base class implements an interface, it was possible for the class to not implement the methods of the interface if a derived class implemented the methods. The only limitation was that the `new` constructor method could not be called on the class.	Now the compiler requires that every class that implements an interface must have or inherit a complete implementation of every method of the interface. For more information, see X++, C# Comparison: Object Oriented Programming.
Modifiers	The **static** modifier should not be applied to an interface	It was possible to write static interface IMyInterface {}, but the **static** modifier had no effect because it makes no sense in this context.	Sometime after Dynamics AX 2009 the X++ compiler might stop allowing the **static** modifier on interface declarations. For more information, see Interfaces Overview.
Modifiers	The **static** modifier must not be applied to the `new` constructor	It was possible to apply the **static** modifier to the declaration of the `new` constructor method. This caused `new MyClass();` to behave as a null operation. Instead, the statement MyClass::new(); would call the static `new` method, but that would not construct an object.	Now the compiler issues an error when the **static** modifier is applied to the `new` method. For more information, see Constructors.
Modifiers	Use an explicit access modifier on each method	In the past the menu item of AOT > Classes > *MyClass* > New Method created the method without any access modifier. This meant that the method was implicitly **public**, although some X++ developers might not have been fully aware of the default. This created extra work later when a developer needed to modify the code in the method, because the developer had to research everywhere that the method might be called from.	Now the New Method menu item explicitly includes the **private** keyword in its automatic declaration of the new method. The developer can type in a different modifier if appropriate. For more information, see Method Modifiers.

AREA	SYNTAX RULE	BEFORE MICROSOFT DYNAMICS AX 2012	STARTING WITH MICROSOFT DYNAMICS AX 2012
Parameters	Parameters given in a call to a `new` constructor method must match the parameters on the `new` constructor method	It was possible to pass in multiple parameters on call to a `new` constructor method even when the `new` method was declared to input no parameters.	Now the call to the `new` method must exactly match the declared parameter signature of the `new` method. For more information, see Creating a Subclass.
Parameters	Parameters with default values must come after all parameters that do not have default values	It was possible to declare a method that takes in two parameters, and have only the first parameter offer a default value. There was no purpose to this. There was no way to accept the default of the first parameter because the call must specify a value for the second parameter and cannot omit the first parameter.	Now in the declaration of a method, any parameter that offers a default value must come after all the parameters that do not. For more information, see the following topics: • Using Optional Parameters • Best Practices for Parameters
Parameters	Override of a method must have the same default parameters as the overridden method	It was possible to declare a method as public void myMethod(int i=22){} and the override as public void myMethod(){}. But if the override method was called as `derivedObject(333);` an error occurred.	Now the override method must list the same parameter types in the same sequence that they are declared in the overridden method. For more information, see Overriding a Method.
Preprocessor	A **TODO** in a comment must be the first non-whitespace in the first line of the comment	The X++ preprocessor used to detect the **TODO** keyword in a multi-line /* ... */ task comment even when the **TODO** appeared after other text after the first comment line.	Now the X++ preprocessor detects the **TODO** keyword only if **TODO** appears on the first line of the comment, and as the first non-whitespace in the comment. For more information, see TODO Comments for X++ Developer Tasks.

X++ Language Reference

API, class, and table resources

2/18/2021 • 2 minutes to read • Edit Online

This topic describes where to find API documentation in Visual Studio and on the Microsoft docs site.

Application classes and tables

Application class and table documentation is in Visual Studio

You can find documentation for the Application classes in Microsoft Visual Studio. Search for the class name in Application Explorer and then display the code. You can find additional metadata about the class in the **Properties** window. You can download a list of all the tables in the Technical Reference Reports. For more information, see Find information about standard data entities.

Programming with application tables and classes

Application tables are similar to application classes, but with the following differences from classes:

- Tables are persistent.
- Table fields are always public.
- A table almost always corresponds to a real object.
- The definition of a table must sometimes be erased if you later want another table to extend it.

Design pattern of private new in application classes

All application classes are under Application Explorer > Classes. Every application class has the constructor method named `new`, even if the class has no **new** node in the Application Explorer. If the class has no explicit **new** node, the implicit **new** method is public. A design pattern that is sometimes used in the application classes is to declare the explicit **new** constructor method as **private**. Then a **public static** method is added to call the **new** method. The static method can restrict or control the call the **new** method based on various conditions, if necessary.

System classes and tables

System API, class, and table documentation is on the Microsoft docs site

Documentation for the classes and functions that are listed under **System Documentation** in Application Explorer is available on the Microsoft docs site.

X++ compile-time functions

X++ compile-time functions

X++ run-time functions

X++ run-time functions:

- X++ container run-time functions
- X++ business run-time functions
- X++ conversion run-time functions
- X++ date run-time functions
- X++ math run-time functions
- X++ reflection run-time functions

- X++ session run-time functions
- X++ string run-time functions

X++ compile-time functions

2/18/2021 • 32 minutes to read • Edit Online

This topic lists the compile-time functions and describes their syntax, parameters, and return values.

Overview

Compile-time functions are executed early during compilation of X++ code. They should be used wherever possible in X++ code to make the code resilient to changes to the metadata stored in the Application Explorer. Compile-time functions have their input value verified by the compiler. If the input value is not found to match any existing object in the Application Explorer, the compiler issues an error. The inputs to these functions must be literals, because the compiler cannot determine the value that a variable contains at run time. A compile-time function is a metadata assertion function. It takes arguments that represents an entity in the Application Explorer and validates the arguments at compile time. It has no effect at run time. Attributes are classes that inherit from the **SysAttribute** class. To support the validation of form, report, query, and menu metadata, use the **AutoDeclaration** property on controls. Most of these functions retrieve metadata about items that are in the Application Explorer. Some common compile time functions are as follows:

- `classNum` – Retrieves the ID of a class.
- `classStr` – During compile time, verifies that a class of that name exists. This approach is better than discovering the error later during run time.
- `evalBuf` – Evaluates the input string of X++ code, and then returns the results as a string.
- `literalStr` – retrieves a label ID when given the string representation of a label, such as the string `"@SYS12345"`. For example, `myLabel.exists(literalStr("@SYS12345"));`.

> **NOTE**
> X++ compile time functions cannot be called from a .NET program.

Functions

attributeStr

Validates that the specified attribute class exists in the Application Explorer; if not, a compiler error occurs.

Syntax

```
str classStr(class class)
```

Parameters

PARAMETER	DESCRIPTION
class	The name of the attribute to validate.

Return Value

The name of the attribute.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
static void attributeStrExample(Args _args)
{
    str s;
    ;
    s = attributeStr(AifDocumentOperationAttribute);
    print s;
    pause;
}
```

classNum

Retrieves the ID of the specified class.

Syntax

```
int classNum(class class)
```

Parameters

PARAMETER	DESCRIPTION
class	The class for which to retrieve the ID.

Return Value

The ID of the specified class.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
static void classNumExample(Args _args)
{
    int i;
    ;
    i = classNum(Global);
    print i;
    pause;
}
```

classStr

Retrieves the name of a class as a string.

Syntax

```
str classStr(class class)
```

Parameters

PARAMETER	DESCRIPTION
class	The name of the class to return.

Return Value

The name of the class.

Remarks

Use this function instead of literal text to retrieve a string that contains the class name. If the class does not exist, the function generates a syntax error at compile time. This is a compile-time function. For more information, see Overview.

Example

```
static void clStrExample(Args _args)
{
    str s;
    ;
    s = classStr(Global);
    print s;
    pause;
}
```

configurationKeyNum

Retrieves the ID of the specified configuration key.

Syntax

```
int configurationKeyNum(str keyname)
```

Parameters

PARAMETER	DESCRIPTION
keyname	The configuration key for which to return the ID.

Return Value

The ID of the specified configuration key.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
static void configurationKeyNum(Args _args)
{
    int i;
    ;
    i = configurationKeyNum(AIF);
    print i;
    pause;
}
```

configurationKeyStr

Retrieves the name of a configuration key as a string.

Syntax

```
str configurationKeyStr(str keyname)
```

Parameters

PARAMETER	DESCRIPTION
keyname	The name of the configuration key.

Return Value

The name of the configuration key.

Remarks

Use this function instead of literal text to retrieve a string that contains the configuration key name. If the key does not exist, the function generates a syntax error at compile time. This is a compile-time function. For more information, see Overview.

Example

```
static void configurationKeyStrExample(Args _args)
{
    str s;
    ;
    s = configurationKeyStr(AIF);
    print s;
    pause;
}
```

dataEntityDataSourceStr

Retrieves the name of a data source of a data entity.

Syntax

```
str dataEntityDataSourceStr(str dataEntity, str dataSource)
```

Parameters

PARAMETER	DESCRIPTION
dataEntity	The name of the data entity.
dataSource	The name of the data source.

Return Value

The name of the data source.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

delegateStr

Returns the name of the delegate.

Syntax

```
str delegateStr(str class, str instanceDelegate)
```

Parameters

PARAMETER	DESCRIPTION
class	The name of the class, table, or form.
instanceDelegate	The name of the instance delegate.

Return Value

The name of the delegate.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

dimensionHierarchyLevelStr

Returns the name of the dimension hierarchy level.

Syntax

```
str dimensionHierarchyLevelStr(str dimensionHierarchyLevel)
```

Parameters

PARAMETER	DESCRIPTION
dimensionHierarchyLevel	The name of the dimension hierarchy level.

Return Value

The name of the dimension hierarchy level.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

dimensionHierarchyStr

Returns the name of the dimension hierarchy.

Syntax

```
str dimensionHierarchyStr(str dimensionHierarchy)
```

Parameters

PARAMETER	DESCRIPTION
dimensionHierarchy	The name of the dimension hierarchy.

Return Value

The name of the dimension hierarchy.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

dimensionReferenceStr

Returns the name of the dimension reference.

Syntax

```
str dimensionReferenceStr(str dimensionReference)
```

Parameters

PARAMETER	DESCRIPTION
dimensionReference	The name of the dimension reference.

Return Value

The name of the dimension reference.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

dutyStr

Retrieves a string that represents the name of the specified security duty.

Syntax

```
str dutyStr(str securityDuty)
```

Parameters

PARAMETER	DESCRIPTION
securityDuty	The name of the security duty.

Return Value

The name of the security duty in a string.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

enumCnt

Retrieves the number of elements in the specified enumeration type.

Syntax

```
int enumCnt(enum enumtype)
```

Parameters

PARAMETER	DESCRIPTION
enumtype	The enumeration type.

Return Value

The number of elements in the specified enumeration type.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
enumCnt(NoYes); //Returns 2, as the two elements are Yes and No.
```

enumLiteralStr

Indicates whether the specified string is an element of the specified enumeration type.

Syntax

```
\enumLiteralStr(enum enum, string str)
```

Parameters

PARAMETER	DESCRIPTION
enum	The enumeration type from which to retrieve the specified value.

Return Value

The value of the *str* parameter if the specified string was found; otherwise, a compilation error.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
static void getEnumValueAsString()
{
    str i;
    i = enumLiteralStr(ABCEnum, "valueInABCEnum");
    print i;
    pause;
}
```

enumNum

Retrieves the ID of the specified enumeration type.

Syntax

```
int enumNum(enum enum)
```

Parameters

PARAMETER	DESCRIPTION
enum	The enumeration for which to return the ID.

Return Value

The ID of the specified enumeration type.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
static void enumNum(Args _args)
{
    int i;
    ;
    i = enumNum(ABC);
    print i;
    pause;
}
```

enumStr

Retrieves the name of an enumeration as a string.

Syntax

```
str enumStr(enum enum)
```

Parameters

PARAMETER	DESCRIPTION
enum	The name of the enumeration.

Return Value

The name of the enumeration.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
static void enumStrExample(Args _args)
{
    str s;
    ;
    s = enumStr(ABC);
    print s;
    pause;
}
```

extendedTypeNum

Retrieves the ID of the specified extended data type.

Syntax

```
int extendedTypeNum(int str)
```

Parameters

PARAMETER	DESCRIPTION
str	The extended data type for which to return the ID.

Return Value

The ID of the specified extended data type.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
static void EDTNum(Args _args)
{
    int i;
    str s;
    ;

    i = extendedTypeNum(AccountName);
    s = extendedTypeStr(AccountName);
    print  int2Str(i);
    print  s;
    pause;
}
```

extendedTypeStr

Retrieves the name of an extended data type as a string.

Syntax

```
str extendedTypeStr(int str)
```

Parameters

PARAMETER	DESCRIPTION
str	The name of the extended data type.

Return Value

The name of the extended data type.

Remarks

Use this function instead of literal text to return a string that contains the extended data type name. If the data type does not exist, the **extendedTypeStr** function generates a syntax error at compile time. This is a compile-time function. For more information, see Overview.

Example

```
static void EDTStr(Args _args)
{
    int i;
    str s;
    ;

    i = extendedTypeNum(AccountName);
    s = extendedTypeStr(AccountName);
    print  int2Str(i);
    print  s;
    pause;
}
```

fieldNum

Returns the ID number of the specified field.

Syntax

```
int fieldNum(str tableName, str fieldName)
```

Parameters

PARAMETER	DESCRIPTION
tableName	The name of the table.
fieldName	The name of the field.

Return Value

The ID of the specified field.

Remarks

This is a compile-time function. For more information, see Overview.

Example

The following example prints the number of the **CashDisc** field in the **CustTable** table.

```
static void fieldNumExample(Args _args)
{
    int myInt;
    ;

    myInt = fieldNum(CustTable, CashDisc);
    Global::info(strfmt("CashDisc has a field ID of %1 in the CustTable table.", myInt));
}
/****Infolog Display
Message (10:40:00 am)
CashDisc has a field ID of 10 in the CustTable table.
****/
```

fieldPName

Retrieves the label of the specified field.

Syntax

```
str fieldPName(str tableid, str fieldid)
```

Parameters

PARAMETER	DESCRIPTION
tableid	The table that contains the specified field.
fieldid	The field to convert.

Return Value

The label of the field.

Remarks

This is a compile-time function. For more information, see Overview.

Example

The following example prints the label of the **CashDisc** field.

```
static void fieldPNameExample(Args _arg)
{
    str myText;
    ;

    myText = fieldPName(CustTable, CashDisc);
    Global::info(strfmt("%1 is the label of the CashDisc field.", myText));
}
/****Infolog Display
Message (02:00:57 pm)
Cash discount is the label of the CashDisc field.
****/
```

fieldStr

Retrieves the field name of the specified field.

Syntax

```
str fieldStr(str tableid, str fieldid)
```

Parameters

PARAMETER	DESCRIPTION
tableid	The table that contains the field.
fieldid	The field to convert.

Return Value

The field name of the specified field.

Remarks

This is a compile-time function. For more information, see Overview.

Example

The following example assigns the name of the **CashDisc** field to the *myText* variable.

```
static void fieldStrExample(Args _arg)
{
    str myText;
    ;

    myText = fieldStr(CustTable, CashDisc);
    Global::info(strfmt("%1 is the specified field.", myText));
}
/****Infolog Display
Message (09:11:52 am)
CashDisc is the specified field.
****/
```

formControlStr

Causes the X++ compiler to check whether the control exists on the form, and to replace the function call with a string of the valid control name.

Syntax

```
str formControlStr(formName, controlName)
```

Parameters

PARAMETER	DESCRIPTION
formName	The name of the form, not in quotation marks.
controlName	The name of the control that is on the form, not in quotation marks.

Return Value

A string that contains the name of the control as it appears in the Application Explorer.

Remarks

A compile error is issued if the compiler determines that the control does not exist on the form. If your X++ code uses a string that contains quotation marks to supply the control name, the error cannot be discovered until run time. Use of this function enables the compiler to discover the error earlier at compile time. X++ functions such as **formControlStr** that are executed by the compiler are called compile-time functions or compile-time functions. That is why the input parameters are not standard strings in quotation marks. Compile-time functions are not represented in the p-code or other executable that is output by the compiler. This is a compile-time function. For more information, see Overview.

Example

No example.

formDataFieldStr

Returns the name of a data field in a form.

Syntax

```
str formDataFieldStr(str formName, str dataSource, str dataField)
```

Parameters

PARAMETER	DESCRIPTION
formName	The name of the form.
dataSource	The data source of the form.
dataField	The data field of the data source.

Return Value

The name of a data field in a form.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
str a = formDataFieldStr(FMVehicle, FMModelRate, RatePerDay);
```

formDataSourceStr

Returns the name of a data source in a form.

Syntax

```
str formDataSourceStr(str formName, str dataSource)
```

Parameters

PARAMETER	DESCRIPTION
formName	The name of the form.

PARAMETER	DESCRIPTION
dataSource	The data source of the form.

Return Value

The name of a data source in a form.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
str b = formDataSourceStr(FMVehicle, FMModelRate);
```

formMethodStr

Returns the name of a method of a form.

Syntax

```
str formMethodStr(str formName, str methodName)
```

Parameters

PARAMETER	DESCRIPTION
formName	The name of the form.
methodName	The method of the form.

Return Value

The name of a method in a form.

Remarks

This is a compile-time function. For more information, see Overview.

Example

The following example prints the name of the **showDialog** method.

```
str c = formMethodStr(Batch,showDialog);
```

formStr

Retrieves the name of a form.

Syntax

```
str formStr(str form)
```

Parameters

PARAMETER	DESCRIPTION
form	The name of a form.

Return Value

A string that represents the name of the form.

Remarks

This is a compile-time function. For more information, see Overview.

Example

The following example prints the name of the InventDim form.

```
static void formStrExample(Args _arg)
{
    ;

    Global::info(formStr(InventDim));
}
/****Infolog Display
Message (11:04:39 am)
InventDim
****/
```

identifierStr

Converts the specified identifier to a string.

Syntax

```
str identifierStr(str ident)
```

Parameters

PARAMETER	DESCRIPTION
ident	The identifier to convert.

Return Value

A string that represents the specified identifier.

Remarks

You will receive a best practice warning if you use the **identifierStr** function. This occurs because existence checking is performed for **identifierStr**. Try to use a more specific compile-time function if one is available. This is a compile-time function. For more information, Overview.

Example

The following code example assigns the *myvar* variable name to the *thevar* variable.

```
static void indentifierStrExample(Args _args)
{
    str myvar;
    str thevar
    ;

    thevar = "[" + identifierStr(myvar) + "]";
    Global::info(strfmt(thevar));
}
/****Infolog Display
Message (09:19:49 am)
[myvar]
****/
```

indexNum

Converts the specified index to a number.

Syntax

```
int indexNum(str tableid, str indexid)
```

Parameters

PARAMETER	DESCRIPTION
tableid	The table that contains the index.
indexid	The index to convert.

Return Value

The index number that represents the specified index.

Remarks

This is a compile-time function. For more information, see Overview.

Example

The following example returns the index value of the Party index.

```
static void indexNumExample(Args _arg)
{
    ;

    Global::info(strfmt("%1 is the index number of Party.", indexNum(CustTable, Party)));
}
/****Infolog Display
Message (11:28:03 am)
3 is the index number of Party.
****/
```

indexStr

Converts the specified index to a string.

Syntax

```
str indexStr(str tableid, str indexid)
```

Parameters

PARAMETER	DESCRIPTION
tableid	The table that contains the index.
indexid	The index to convert.

Return Value

A string that represents the specified index.

Remarks

This is a compile-time function. For more information, see Overview.

Example

The following example assigns the **CashDisc** index value to the *myText* variable.

```
static void fieldStrExample(Args _arg)
{
    str myText;
    ;

    myText = fieldStr(CustTable, CashDisc);
    Global::info(strfmt("%1 is the specified index.", myText));
}
/****Infolog Display
Message (09:11:52 am)
CashDisc is the specified index.
****/
```

licenseCodeNum

Validates that the specified license code exists in the Application Explorer; if not, a compiler error occurs.

Syntax

```
int licenseCodeNum(str codename)
```

Parameters

PARAMETER	DESCRIPTION
codename	The name of the license code to validate.

Return Value

The number of the specified license code.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
static void licenseCodeNumExample(Args args)
{
    int i;
    ;

    i = licenseCodeNum(SysMorphX);
    Global::info(strfmt("%1 is the license code number for SysMorphX.", i));
}
/****Infolog Display
Message (01:52:35 pm)
24 is the license code number for SysMorphX.
****/
```

licenseCodeStr

Validates that the specified license code exists in the Application Explorer; if not, a compiler error occurs.

Syntax

```
str licenseCodeStr(str codename)
```

Parameters

PARAMETER	DESCRIPTION
codename	The name of the license code to validate.

Return Value

The name of the specified license code.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
static void licenseCodeStrExample(Args _arg)
{
    str s;
    ;

    s = licenseCodeStr(SysMorphX);
    Global::info(strfmt("%1 is the license code string for SysMorphX.", s));
}
/****Infolog Display
Message (02:33:56 pm)
SysMorphX is the license code string for SysMorphX.
****/
```

literalStr

Validates that the specified string can be a literal string; if not, a compiler error occurs.

Syntax

```
str literalStr(int str)
```

Parameters

PARAMETER	DESCRIPTION
codename	The string to validate.

Return Value

The literal string if valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s;
    ;

    s = literalStr("This is a literal str");
    print s;
    pause;
}
```

maxDate

Retrieves the maximum value allowed for a variable of type date.

Syntax

```
date maxDate()
```

Return Value

The maximum value allowed for a variable of type **date**, which is **2154-12-31**.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
static void maxDateExample(Args _arg)
{
    date maximumDate;
    ;
    maximumDate = maxDate();
    print maximumDate;
    pause;
}
```

maxInt

Retrieves the maximum signed value that can be stored in an **int** type.

Syntax

```
int maxInt()
```

Return Value

The maximum value allowed value of an integer.

Remarks

Any other integer will be less than or equal to the returned value. This is a compile-time function. For more information, see Overview.

Example

```
static void maxIntExample(Args _arg)
{
    int i;
    ;
    print "The maximum value for type int is " + int2Str(maxInt());
    pause;
}
```

measurementStr

Returns the name of a measurement.

Syntax

```
str measurementStr(str measurement)
```

Parameters

PARAMETER	DESCRIPTION
measurement	The name of the measurement.

Return Value

The name of the measurement.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

measureStr

Returns the name of a measure.

Syntax

```
str measureStr(str measure)
```

Parameters

PARAMETER	DESCRIPTION
measure	The name of the measure.

Return Value

The name of the measure.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

menuItemActionStr

Validates that the specified menu item action exists in the Application Object Tree (Application Explorer); if it does not, a compiler error occurs.

Syntax

```
str menuItemActionStr(class menuitem)
```

Parameters

PARAMETER	DESCRIPTION
codename	The name of the menu item action to validate.

Return Value

The name of the menu item action, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s1, s2, s3, s4;
    ;

    s1 = menuItemActionStr(AssetCopy);
    s2 = menuItemDisplayStr(Address);
    s3 = menuItemOutputStr(AssetBarcode);
    s4 = menuStr(Administration);

    print "menuItemActionStr for AssetCopy is " + s1;
    print "menuItemDisplayStr for Address is " + s2;
    print "menuItemOutputStr for AssetBarcode is " + s3;
    print "menuStr for Administration is " + s4;

    pause;
}
```

menuItemDisplayStr

Validates that the specified menu item display exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str menuitemdisplaystr(class menuItem)
```

Parameters

PARAMETER	DESCRIPTION
codename	The name of the menu item display to validate.

Return Value

The name of the specified menu item display, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s1, s2, s3, s4;
    ;

    s1 = menuItemActionStr(AssetCopy);
    s2 = menuItemDisplayStr(Address);
    s3 = menuItemOutputStr(AssetBarcode);
    s4 = menuStr(Administration);

    print "menuItemActionStr for AssetCopy is " + s1;
    print "menuItemDisplayStr for Address is " + s2;
    print "menuItemOutputStr for AssetBarcode is " + s3;
    print "menuStr for Administration is " + s4;

    pause;
}
```

menuItemOutputStr

Validates that the specified menu item output exists in the Application Explorer; if not, a compiler error occurs.

Syntax

```
str menuItemOutputStr(class menuitem)
```

Parameters

PARAMETER	DESCRIPTION
codename	The name of the menu item output to validate.

Return Value

The specified menu item output if valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s1, s2, s3, s4;
    ;

    s1 = menuItemActionStr(AssetCopy);
    s2 = menuItemDisplayStr(Address);
    s3 = menuItemOutputStr(AssetBarcode);
    s4 = menuStr(Administration);

    print "menuItemActionStr for AssetCopy is " + s1;
    print "menuItemDisplayStr for Address is " + s2;
    print "menuItemOutputStr for AssetBarcode is " + s3;
    print "menuStr for Administration is " + s4;

    pause;
}
```

menuStr

Validates that the specified menu exists in the Application Explorer; if not, a compiler error occurs.

Syntax

```
str menuStr(class menu)
```

Parameters

PARAMETER	DESCRIPTION
menu	The name of the menu to validate.

Return Value

The name of the specified menu item if valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s1, s2, s3, s4;
    ;

    s1 = menuItemActionStr(AssetCopy);
    s2 = menuItemDisplayStr(Address);
    s3 = menuItemOutputStr(AssetBarcode);
    s4 = menuStr(Administration);

    print "menuItemActionStr for AssetCopy is " + s1;
    print "menuItemDisplayStr for Address is " + s2;
    print "menuItemOutputStr for AssetBarcode is " + s3;
    print "menuStr for Administration is " + s4;

    pause;
}
```

methodStr

Validates that the specified method exists in the specified class; if it does not, a compiler error occurs.

Syntax

```
str methodStr(class class, int method)
```

Parameters

PARAMETER	DESCRIPTION
class	The name of the class.
method	The name of the method to validate.

Return Value

The name of the specified method, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    #define.timeout(50)
    str s;
    SysHelpInitTimeOut SysHelpInitTimeOut;
    ;

    s = methodStr(SysHelpInitTimeOut, timeout);
    print s;
    pause;
}
```

minInt

Retrieves the minimum signed value that can be stored in an **int** type.

Syntax

```
int minInt()
```

Return Value

The minimum value of an **int** type.

Remarks

Any other integer value will be greater than or equal to the returned value. This is a compile-time function. For more information, see Overview.

Example

```
static void minIntExample(Args _arg)
{
    int i;
    ;
    i = minInt();
    print "minInt() is " + int2Str(i);
    pause;
}
```

privilegeStr

Returns the name of the privilege.

Syntax

```
str privilegeStr(str privilege)
```

Parameters

PARAMETER	DESCRIPTION
privilege	The privilege for which to return the name.

Return Value

The name of the privilege.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

queryDatasourceStr

Causes the X++ compiler to check whether the data source exists on the query, and to replace the function call with a string of the valid data source name.

Syntax

```
str queryDataSourceStr(queryName, dataSourceName)
```

Parameters

PARAMETER	DESCRIPTION
queryName	The name of the query, not in quotation marks.
dataSourceName	The name of the data source that is on the query, not in quotation marks.

Return Value

A string that contains the name of the data source as it appears in the Application Explorer.

Remarks

A compile error is issued if the compiler determines that the data source does not exist on the query. If your X++ code uses a string that contains quotation marks to supply the data source name, the error cannot be discovered until run time. Use of this function enables the compiler to discover the error earlier at compile time. X++ functions such as **queryDataSourceStr** that are executed by the compiler are referred to as compile-time functions or compile-time functions. That is why the input parameters are not standard strings in quotation marks. Compile-time functions are not represented in the p-code or other executable that is output by the compiler. This is a compile-time function. For more information, see Overview.

Example

No example.

queryMethodStr

Returns the name of a method of a query.

Syntax

```
str queryMethodStr(str queryName, str methodName)
```

Parameters

PARAMETER	DESCRIPTION
queryName	The name of the query.
methodName	The method of the form.

Return Value

The name of a method in a query.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

queryStr

Retrieves a string that represents an existing query.

Syntax

```
str queryStr(str query)
```

Parameters

PARAMETER	DESCRIPTION
query	The query to retrieve.

Return Value

The name of the query.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
static void queryStrExample(Args _arg)
{
    str myText;
    ;

    myText = queryStr(AssetTable);
    Global::info(strfmt("%1 is the name of the query.",myText));
}
/****Infolog Display
Message (09:45:16 am)
AssetTable is the name of the query.
****/
```

reportStr

Retrieves a string that represents the name of the specified report.

Syntax

```
str reportStr(str report)
```

Parameters

PARAMETER	DESCRIPTION
report	The report for which to return the name.

Return Value

The name of the report.

Remarks

This is a compile-time function. For more information, see Overview.

Example

The following example assigns the name of the **AssetAddition** report to the *MyTxt* variable.

```
static void reportStrExample(Args _args)
{
    str MyTxt;
    ;

    MyTxt = reportStr(AssetAddition);
    Global::info(strfmt("%1 is the name of the report.", MyTxt));
}
/****Infolog Display.
Message (10:46:36 am)
AssetAddition is the name of the report.
****/
```

resourceStr

Validates that the specified resource exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str resourceStr(str resourcename)
```

Parameters

PARAMETER	DESCRIPTION
resourcename	The name of the resource to validate.

Return Value

The name of the specified resource, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    print "Str for resource StyleSheet_Help_Axapta is "
        + resourceStr(StyleSheet_Help_Axapta);
    pause;
}
```

roleStr

Retrieves a string that represents the name of the specified security role.

Syntax

```
str roleStr(str securityRole)
```

Parameters

PARAMETER	DESCRIPTION
securityRole	The name of the security role.

Return Value

The name of the security role in a string.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

ssrsReportStr

Retrieves a string that represents the name of the specified report. Use this function when you want to specify the report that should be run by a report controller class.

Syntax

```
str ssrsReportStr(str report, str design)
```

Parameters

PARAMETER	DESCRIPTION
report	The report to return the name for.
design	The name of the design that is associated with the report.

Return Value

The name of the report.

Remarks

The **ssrsReportStr** function parses the two values that are passed to it, to validate whether they belong to a valid report. The report name must be set when a menu item points to a controller(), so that the controller can determine which report-design combination must be invoked. Use of the **ssrsReportStr** function provides the benefit of compile-time validation for the report and design name. This is a compile-time function. For more information, see Overview.

Example

```
public static void main(Args _args)
{
    // Initializing the object for a controller class, in this case, the class named AssetListingController.
    SrsReportRunController controller = new AssetListingController();

    // Getting the properties of the called object (in this case AssetListing MenuItem)
    controller.parmArgs(_args);
    // Setting the Report name for the controller.
    controller.parmReportName(ssrsReportStr(AssetListing, Report));

    // Initiate the report execution.
    controller.startOperation();
}
```

staticDelegateStr

Returns the name of a static delegate.

Syntax

```
str staticDelegateStr(str class, str delegate)
```

Parameters

PARAMETER	DESCRIPTION
class	The name of a class, table, or form.
delegate	The name of the delegate.

Return Value

The name of the delegate.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

staticMethodStr

Validates that the specified static method exists in the specified class; if it does not, a compiler error occurs.

Syntax

```
str staticMethodStr(class class, int method)
```

Parameters

PARAMETER	DESCRIPTION
class	The name of the class.
method	The name of the static method to validate.

Return Value

The name of the static method, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

tableCollectionStr

Validates that the specified table collection exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str tableCollectionStr(class tablecollection)
```

Parameters

PARAMETER	DESCRIPTION
tablecollection	The name of the table collection to validate.

Return Value

The name of the specified table collection, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

tableFieldGroupStr

Retrieves the name of a field group as a string.

Syntax

```
str tableFieldGroupStr(str tableName, str fieldGroupName)
```

Parameters

PARAMETER	DESCRIPTION
tableName	The table that contains the field group.
fieldGroupName	The field group in the table.

Return Value

The name of the field group as a string.

Remarks

This is a compile-time function. For more information, see Overview.

Example

The following example retrieves the name of the **Editing** field group as a string.

```
static void tableFieldGroupStrExample(Args _arg)
{
    ;

    Global::info(tableFieldGroupStr(AccountingDistribution, Editing));
}
/****Infolog Display
Message (03:14:54 pm)
Editing
****/
```

tableMethodStr

Validates that the specified method exists in the specified table; if it does not, a compiler error occurs.

Syntax

```
str tableMethodStr(int table, int method)
```

Parameters

PARAMETER	DESCRIPTION
table	The name of the table.
method	The name of the method to validate.

Return Value

The name of the method, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

tableNum

Retrieves the table ID of the specified table.

Syntax

```
int tableNum(str table)
```

Parameters

PARAMETER	DESCRIPTION
table	The table to retrieve the table ID for.

Return Value

The table ID of the specified table.

Remarks

This is a compile-time function. For more information, see Overview.

Example

The following example sets the **tableID** variable to 77, which is the **ID** of the **CustTable** table.

```
static void tableNumExample(Args _args)
{
    int tableID;
    ;

    tableID = tableNum(CustTable);
    Global::info(strfmt("%1 is the table ID for the CustTable table.", tableID));

}
/****Infolog Display
Message (11:15:54 am)
77 is the table ID for the CustTable table.
****/
```

tablePName

Retrieves a string that contains the printable name of the specified table.

Syntax

```
str tablePName(str table)
```

Parameters

PARAMETER	DESCRIPTION
table	The table to retrieve the printable name for.

Return Value

The name of the specified table.

Remarks

This is a compile-time function. For more information, see Overview.

Example

The following example assigns the label of the **CustTable** table to the *MyText* variable.

```
static void tablePNameExample(Args _args)
{
    str MyText;
    ;

    MyText = tablePname(CustTable);
    Global::info(strfmt("%1 is the label of the CustTable table.", MyText));
}
/**** Infolog Display.
Message (12:13:53 pm)
Customers is the label of the CustTable table.
****/
```

tableStaticMethodStr

Validates that the specified static method exists in the specified table; if it does not, a compiler error occurs.

Syntax

```
str tableStaticMethodStr(int table, int method)
```

Parameters

PARAMETER	DESCRIPTION
table	The name of the table.
method	The name of the static method to validate.

Return Value

The name of the specified static method.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

tableStr

Retrieves a string that contains the name the specified table.

Syntax

```
str tableStr(str table)
```

Parameters

PARAMETER	DESCRIPTION
table	The table to retrieve a string for.

Return Value

A string value that contains the name of the specified table.

Remarks

This is a compile-time function. For more information, see Overview.

Example

The following example assigns the name of the **CustTable** table to the *MyTxt* variable.

```
static void tableStrExample(Args _args)
{
    str MyTxt;
    ;

    MyTxt = tableStr(CustTable);
    Global::info(strfmt("%1 is the str output of the input of CustTable.", MyTxt));
}
/**** Infolog Display.
Message (01:21:49 pm)
CustTable is the str output of the input of CustTable.
****/
```

tileStr

Retrieves a string that represents the name of the specified tile.

Syntax

```
str tileStr(str tile)
```

Parameters

PARAMETER	DESCRIPTION
tile	The name of the tile.

Return Value

The name of the tile in a string.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

varStr

Retrieves a string that contains the name of the specified variable.

Syntax

```
str varStr(str var)
```

Parameters

PARAMETER	DESCRIPTION
var	The name of the variable.

Return Value

A string that contains the name of the specified variable.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
static void varStrExample(Args _arg)
{
    str myString;
    anytype myVariable;
    ;

    myString = varStr(myVariable);
    Global::info(strfmt("%1 is the variable name.", myString));
}
/****Infolog Display.
Message (02:26:56 pm)
myVariable is the variable name.
****/
```

webActionItemStr

Validates that the specified web action item exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str webActionItemStr(class webactionitem)
```

Parameters

PARAMETER	DESCRIPTION
webactionitem	The name of the web action item to validate.

Return Value

The name of the specified web action item, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s;
    ;
    s = webActionItemStr(EPFlushData);
    print "webactionitem str is " + s;
    pause;
}
```

webDisplayContentItemStr

Validates that the specified web display content item exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str webDisplayContentItemStr(class webdisplaycontentitem)
```

Parameters

PARAMETER	DESCRIPTION
webdisplaycontentitem	The name of the web display content item to validate.

Return Value

The name of the specified web display content item, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s;
    ;

    s = webDisplayContentItemStr(EPAdmin);
    print "string for webcontent display item EPAdmin is " + s;
    pause;
}
```

webFormStr

Validates that the specified web form exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str webFormStr(str name)
```

Parameters

PARAMETER	DESCRIPTION
name	The name of the web form to validate.

Return Value

The name of the specified web form, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s;
    ;
    s = webFormStr(EPAdmin);
    print "String for web form EPAdmin is " + s;
    pause;
}
```

webletItemStr

Validates that the specified weblet item exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str webletItemStr(class webletitem)
```

Parameters

PARAMETER	DESCRIPTION
webletitem	The name of the weblet item to validate.

Return Value

The name of the specified weblet item, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s;
    ;
    s = webletItemStr(WebFormWeblet);
    print "String for WebFormWeblet is " + s;
    pause;
}
```

webMenuStr

Validates that the specified web menu exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str webMenuStr(str name)
```

Parameters

PARAMETER	DESCRIPTION
name	The name of the web menu to validate.

Return Value

The name of the specified web menu, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s;
    ;
    s = webMenuStr(ECPAdmin);
    print "String for web menu ECPAdmin is " + s;
    pause;
}
```

webOutputContentItemStr

Validates that the specified web output content item exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str webOutputContentItemStr(class weboutputcontentitem)
```

Parameters

PARAMETER	DESCRIPTION
weboutputcontentitem	The name of the web output content item to validate.

Return Value

The name of the specified web output content item, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s;
    ;
    s = webOutputContentItemStr(EPPriceList);
    print "string for weboutput content item EPPriceList is " + s;
    pause;
}
```

webpageDefStr

Validates that the specified Web page definition exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str webpageDefStr(str pagename)
```

Parameters

PARAMETER	DESCRIPTION
pagename	The name of the Web page definition to validate.

Return Value

The name of the specified web-page definition, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

webReportStr

Validates that the specified web report exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str webReportStr(str name)
```

Parameters

PARAMETER	DESCRIPTION
name	The name of the web report to validate.

Return Value

The name of the specified web report, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s;
    ;
    s = webReportStr(EPCSSSalesConfirm);
    print "String for web report EPCSSalesConfirm is " + s;
    pause;
}
```

websiteDefStr

Validates that the specified web-site definition exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str websiteDefStr(str resourcename)
```

Parameters

PARAMETER	DESCRIPTION
resourcename	The name of the Web site definition to validate.

Return Value

The name of the specified web-site definition, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s;
    ;

    s = websiteDefStr(AxSiteDef_1033_xip);
    print "string for web site definition AxSiteDef_1033_xip is " + s;
    pause;
}
```

webSiteTempStr

Validates that the specified web-site template exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str websiteTempStr(str resourcename)
```

Parameters

PARAMETER	DESCRIPTION
resourcename	The name of the Web site template to validate.

Return Value

The name of the specified web-site template, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

No example.

webStaticFileStr

Validates that the specified web static file exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str webStaticFileStr(str pagename)
```

Parameters

PARAMETER	DESCRIPTION
pagename	The name of the web static file to validate.

Return Value

The name of the specified web static file, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s;
    ;

    s = webStaticFileStr(AXEP);
    print "string for web static file AXEP is " + s;
    pause;
}
```

webUrlItemStr

Validates that the specified web URL item exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str webUrlItemStr(class weburlitem)
```

Parameters

PARAMETER	DESCRIPTION
weburlitem	The name of the web URL item to validate.

Return Value

The name of the specified web URL item, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s;
    ;

    s = webUrlItemStr(EPAdmin);
    print "string for web url item EPAdmin is " + s;
    pause;
}
```

webWebPartStr

Validates that the specified web part exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str webWebpartStr(str resourcename)
```

Parameters

PARAMETER	DESCRIPTION
resourcename	The name of the web part to validate.

Return Value

The name of the specified web part, if it is valid.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
{
    str s;
    ;

    s = webWebpartStr(AxWebParts_cab);
    print "string for web part AxWebParts_cab is " + s;
    pause;
}
```

workflowApprovalStr

Retrieves the name of a workflow approval in the Application Object Tree (Application Explorer) as a string.

Syntax

```
str workflowapprovalstr(approval approval)
```

Parameters

PARAMETER	DESCRIPTION
approval	The Application Explorer name of the workflow approval.

Return Value

A string that represents the Application Explorer name of the workflow approval.

Remarks

Use this function instead of literal text to retrieve a string that contains the workflow approval name. If the workflow approval does not exist, the function generates a syntax error at compile time. This is a compile-time function. For more information, see Overview.

Example

The following code example sets the variable *str s* to **MyWorkflowApproval** which is the name of the workflow approval in the Application Explorer.

```
static void MyWorkflowApprovalStrExample(Args _args)
{
    str s;
    ;
    s = workflowapprovalstr(MyWorkflowApproval);
    print s;
    pause;
}
```

workflowCategoryStr

Retrieves the name of a workflow category in the Application Object Tree (Application Explorer) as a string.

Syntax

```
str workflowcategorystr(category category)
```

Parameters

PARAMETER	DESCRIPTION
category	The Application Explorer name of the workflow category.

Return Value

A string that represents the Application Explorer name of the workflow category.

Remarks

Use this function instead of literal text to retrieve a string that contains the workflow category name. If the workflow category does not exist, the function generates a syntax error at compile time. This is a compile-time function. For more information, see Overview.

Example

The following code example sets the variable *str s* to **MyWorkflowCategory** which is the name of the workflow category in the Application Explorer.

```
static void MyWorkflowCategoryStrExample(Args _args)
{
    str s;
    ;
    s = workflowcategorystr(MyWorkflowCategory);
    print s;
    pause;
}
```

workflowTaskStr

Retrieves the name of a workflow task in the Application Object Tree (Application Explorer) as a string.

Syntax

```
str workflowtaskstr(task task)
```

Parameters

PARAMETER	DESCRIPTION
task	The Application Explorer name of the workflow task.

Return Value

A string that represents the Application Explorer name of the workflow task.

Remarks

Use this function instead of literal text to retrieve a string that contains the workflow task name. If the workflow task does not exist, the function generates a syntax error at compile time. This is a compile-time function. For more information, see Overview.

Example

The following code example sets the variable *str s* to **MyWorkflowTask** which is the name of the workflow task in the Application Explorer.

```
static void MyWorkflowTaskStrExample(Args _args)
{
    str s;
    ;
    s = workflowtaskstr(MyWorkflowTask);
    print s;
    pause;
}
```

workflowTypeStr

Validates that the specified workflow type exists in the Application Explorer; if it does not, a compiler error occurs.

Syntax

```
str workflowTypeStr(str workflow)
```

Parameters

PARAMETER	DESCRIPTION
workflow	The name of the workflow type to validate.

Return Value

The name of the workflow type.

Remarks

This is a compile-time function. For more information, see Overview.

Example

```
static void workFlowTypeStrExample(Args _args)
{
    str s;
    ;
    s = workFlowTypeStr(BudgetAccountEntryType);
    print s;
    pause;
}
```

X++ runtime function resources

2/18/2021 • 3 minutes to read • Edit Online

This topic describes the X++ run-time functions.

The X++ language provides nearly 200 system functions that aren't part of any class and are executed at run time. Run-time functions are used for data type conversions, mathematical operations, and so on. Here are some common run-time functions:

- **str2Int** – Creates an int value from a str value.
- **abs** – Creates a positive real value from a real value that is either positive or negative.
- **conFind** – Retrieves the location of an element in a container.

Call run-time functions from .NET

The logic of the X++ run-time functions is also implemented in the following .NET assembly.

```
Microsoft.Dynamics.AX.Xpp.Support.DLL
```

Inside this assembly, the X++ run-time functions are implemented as static methods of the following class.

```
Microsoft.Dynamics.AX.Xpp.PredefinedFunctions
```

Categories and functions

The following table lists and describes only the categories of X++ functions. These categories are intended to help you understand the many functions. However, the categories don't represent any formal construct.

CATEGORY	DESCRIPTION
Business	Functions that enter financial data and calculate formulas. For more information, see X++ Business Run-Time Functions.
Container	Functions that operate on the container data type of X++. For more information, see X++ Container Run-Time Functions.
Conversion	Functions that translate data of one type into data of another type. For more information, see X++ Conversion Run-Time Functions.
Date	Functions that operate on the date data type. For more information, see X++ Date Run-Time Functions.
Math	Functions that perform mathematical calculations. For more information, see X++ Math Run-Time Functions.

CATEGORY	DESCRIPTION
Reflection	Functions that access the metadata about objects and return other metadata about them. For more information, see X++ Reflection Run-Time Functions.
Session	Functions that change or report on the context of the current user connection. For more information, see X++ Session Run-Time Functions.
String	Functions that operate on the str data type. For more information, see X++ String Run-Time Functions.
Other	beep, newGuid, sleep

Business

For more information, see X++ Business Run-Time Functions.

cTerm	ddb	dg	fV
idg	intvMax	intvName	intvNo
intvNorm	pmt	pt	pv
rate	sln	syd	term

Container

For more information, see X++ Container Run-Time Functions.

- conDel
- conFind
- conIns
- conLen
- conNull
- conPeek
- conPoke

Conversion

For more information, see X++ Conversion Run-Time Functions.

any2Date	any2Enum	any2Guid	any2Int
any2Int64	any2Real	any2Str	anytodate
anytoenum	anytoguid	anytoint	anytoint64

anytoreal	anytostr	char2Num	date2Num
date2Str	datetime2Str	enum2str	guid2Str
int2Str	int642Str	num2Char	num2Date
num2Str	str2Date	str2Datetime	str2Enum
str2Guid	str2Int	str2Int64	str2Num
str2Time	time2Str	uint2Str	

Date

For more information, see X++ Date Run-Time Functions.

dayName	dayOfMth	dayOfWk	dayOfYr
endMth	mkDate	mthName	mthOfYr
nextMth	nextQtr	nextYr	prevMth
prevQtr	prevYr	systemDateGet	systemDateSet
timeNow	today	wkOfYr	year

Math

For more information, see X++ Math Run-Time Functions.

abs	acos	asin	atan
corrFlagGet	corrFlagSet	cos	cosh
decRound	exp	exp10	frac
log10	logN	max	min
power	round	sin	sinh
tan	tanh	trunc	

Reflection

For more information, see X++ Reflection Run-Time Functions.

classIdGet	dimOf	fieldId2Name	fieldId2PName
fieldName2Id	indexId2Name	indexName2Id	refPrintAll
tableId2Name	tableId2PName	tableName2Id	typeOf

Session

For more information, see X++ Session Run-Time Functions.

curExt	curUserId	funcName	getCurrentPartition
getCurrentPartitionRecId	getPrefix	sessionId	prmIsDefault
runAs	setPrefix		

String

For more information, see X++ String Run-Time Functions.

match	strAlpha	strCmp	strColSeq
strDel	strFind	strFmt	strIns
strKeep	strLen	strLine	strLTrim
strLwr	strNFind	strPoke	strPrompt
strRem	strRep	strRTrim	strScan
strUpr	subStr		

beep

Emits a short sound from the speakers on the computer.

```
void beep()
```

beep example

```
static void beepExample(Args _args)
{
        beep();
}
```

newGuid

Creates a globally unique identifier (GUID).

```
guid newGuid()
```

Return value

A GUID.

newGuid example

The following example creates a GUID.

```
static void newGuidExample(Args _arg)
{
    guid myGuid;

    myGuid = newguid();
    print strfmt("The GUID is: %1", myGuid);
}
```

sleep

Pauses the execution of the current thread for the specified number of milliseconds.

```
int sleep(int _duration)
```

Parameters

PARAMETER	DESCRIPTION
_duration	The number of milliseconds to pause.

sleep return value

The number of milliseconds that the thread actually paused.

Example

```
static void sleepExample(Args _arg)
{
    int seconds = 10;
    int i;

    i = sleep(seconds*1000);
    print "job slept for " + int2str(i/1000) + " seconds";
}
```

X++ business runtime functions

2/18/2021 • 8 minutes to read • Edit Online

This topic describes the business run-time functions.

These functions enter financial data and calculate formulas.

cTerm

Calculates the number of periods that are required for the current investment value to yield a target value.

Syntax

```
real cTerm(real interest, real future_value, real current_value)
```

Parameters

PARAMETER	DESCRIPTION
interest	The interest rate.
future_value	The target value.
current_value	The current investment value.

Return value

The number of periods that are required in order to reach *future_value*.

Remarks

The *current_value* and *future_value* parameters must have the same prefixed sign (plus or minus).

Example

```
static void cTermExample(Args _arg)
{
    real r;
    ;
    r = cTerm(10.0, 500.00, 100.00);
    print "The cTerm is " + num2Str(r, 2, 2, 1, 1);
    pause;
}
```

ddb

Calculates the accelerated depreciation of an asset.

Syntax

```
real ddb(real price, real scrap, real life, int period)
```

Parameters

PARAMETER	DESCRIPTION
price	The purchase price of the asset.
scrap	The residual value of the asset that has been written off.
life	The expected lifetime of the asset.
period	The period to calculate depreciation over.

Return value

The depreciation of the asset.

Remarks

The book value for a specific period is equal to the purchase price minus the accumulated depreciation for previous periods:

- Book value for Period 1 = Price
- Book value for Period 2 = Book value for Period 1 – Depreciation for Period 1
- Book value for Period n = Book value for Period (n–1) – Depreciation for Period (n–1)

There are three variations for the calculation of depreciation: If Period > Life:

- Depreciation = 0

If (Book value for Period n) – ((Book value for Period n) × 2 ÷ Life) < Residual value:

- Depreciation = (Book value for Period n) – Residual value

In all other cases: Depreciation = (Book value for Period n) × 2 ÷ Life The **syd** and **sln** functions also calculate the depreciation of an asset. The **syd** and **ddb** functions enables higher depreciation for the earlier years, whereas **sln** calculates a linear depreciation.

```
ddb(12000,2000,10,1); //Returns the value 2400.
ddb(12000,2000,10,3); //Returns the value 1536.
```

dg

Calculates the contribution ratio, which is based on the sales price and the purchase price. If the value of the *sale* parameter is **0.0**, the calculation can't be done.

Syntax

```
real dg(real sale, real purchase)
```

Parameters

PARAMETER	DESCRIPTION
sale	The sale price.
purchase	The purchase price.

Return value

The contribution ratio.

Remarks

```
dg(1000,300); //Returns the value 0.7.
dg(100,30); //Returns the value 0.7.
dg(20000, 11000); //Returns the value 0.45.
```

fV

Calculates the future value of an investment.

Syntax

```
real fV(real amount, real interest, real life)
```

Parameters

PARAMETER	DESCRIPTION
amount	The amount that was paid in during each period.
interest	The interest rate.
life	The number of investment periods.

Return value

The future value of the investment.

Remarks

```
fV(100,0.14,10); //Returns the value 1933.73.
fV(400,0.10,5); //Returns the value 2442.04.
```

idg

Calculates the sale price, based on the purchase price and the contribution ratio.

```
real idg(real purchase, real contribution_ratio)
```

Parameters

PARAMETER	DESCRIPTION
purchase	The purchase price.
contribution_ratio	The contribution ratio.

Return value

The sale price.

Remarks

If the contribution ratio is equal to `1.0`, the calculation can't be done. The `idg` function is the inverse of the `dg`

function.

```
idg(300,0.7); //Returns the value 1000.
idg(11000,0.45); //Returns the value 20000.
```

intvMax

Retrieves the number of intervals for the specified period when the period is divided into parts as specified by the *func* parameter.

```
int intvMax(date input_date, date ref_date, int func)
```

Parameters

PARAMETER	DESCRIPTION
input_date	The end of the period, which must be later than the *ref_date* parameter.
ref_date	The start of the period.
func	A **IntvScale** system enumeration value that indicates the division unit.

Remarks

Here are the possible values for the *func* parameter:

- None
- YearMonthDay
- YearMonth
- Year
- MonthDay
- Month
- Day
- YearQuarter
- Quarter
- YearWeek
- Week
- WeekDay

Example

```
static void intvMaxExample()
{
    date refDate = str2Date("4/9/2007", 213);
    date inputDate = str2Date("10/5/2007", 213);
    int numberOfIntervals;
    ;
    numberOfIntervals = intvMax(inputDate, refDate, intvScale::YearMonth);
    print numberOfIntervals;
    pause;
}
```

intvName

Returns the name of the interval that is the specified number of intervals ahead of the specified date.

```
str intvName(date input_date, int col, enum func)
```

Parameters

PARAMETER	DESCRIPTION
input_date	A date in the first interval.
col	The number of intervals ahead of the date that is specified by the *input_date* parameter.
func	An **intvScale** enumeration value.

Return value

The name of the interval.

Remarks

For example, if the *func* parameter is the **IntvScale::WeekDay** enumeration value, this method returns the name of the weekday. If the *func* parameter is the **IntvScale::Week** enumeration value, this method returns a string that contains the number of the week.

Example

```
static void intvNameExample(Args _args)
{
    date refDate = 2672010;
    str name;
    ;
    name = intvName(refDate, 3,  intvScale::WeekDay);
    Global::info(strfmt("%1 is the output, which indicates the day of the week 3 days after 26\7\2010.",
name));
}
/**** Infolog display.
Message (09:56:55 am)
Thu is the output, which indicates the day of the week 3 days after 2672010.
****/
```

intvNo

Calculates the number of intervals between two dates when you divide the time into the specified intervals.

Syntax

```
int intvNo(date input_date, date ref_date, int func)
```

Parameters

PARAMETER	DESCRIPTION
input_date	A date that indicates the end of the period

PARAMETER	DESCRIPTION
ref_date	A date that indicates the start of the period.
func	An **intvScale** enumeration value.

Return value

The number of intervals between the dates that are specified by the *ref_date* and *input_date* parameters.

Example

```
static void intvNoExample(Args _args)
{
    date inputDate = str2Date("1/1/2007", 213);
    date refDate = str2Date("3/1/2007", 213);
    int noOfIntervals;
    ;
    noOfIntervals = intvNo(refDate, inputDate, intvScale::Month);
    print noOfIntervals;
    pause;
    //noOfIntervals now holds the difference in months between March and January (2).
}
```

intvNorm

Returns the normalized date for the period.

Syntax

```
date intvNorm(date input_date, date ref_date, int func)
```

Parameters

PARAMETER	DESCRIPTION
input_date	The end of the period, which must be later than the date that is specified by the *ref_date* parameter.
ref_date	The start of the period.
func	An **intvScale** enumeration value that indicates the interval division unit.

Return value

The normalized date for the period.

Remarks

The returned date will equal the date of the first day in the interval in which the date that is specified by the *ref_date* parameter exists.

Example

```
static void example()
{
    print intvNorm(today(), today()-1, IntVScale::WeekDay);
    pause;
}
```

pmt

Calculates the amount that must be paid every period to repay a loan.

Syntax

```
real pmt(real principal, real interest, real life)
```

Parameters

PARAMETER	DESCRIPTION
principal	The amount that was originally borrowed.
interest	The interest that is applied each period to the amount that was borrowed.
life	The number of periods that the loan is repaid over.

Return value

The amount that must be paid every period.

Remarks

The *life* and *interest* parameters must be expressed in the same time units. The value of the *life* parameter must be more than **0.0**.

Example

```
pmt(4000,0.14,4); //Returns the value 1372.82.
pmt(10000,0.10,20); //Returns the value 1174.60.
```

pt

Retrieves the sum of a number plus a specified percentage of that number.

Syntax

```
real pt(real amount, real percentage)
```

Parameters

PARAMETER	DESCRIPTION
amount	The original number.
percentage	The percentage supplement.

Return value

The number that is equal to ((*amount* *× *percentage*) + *amount*).

Remarks

```
pt(2000.0,0.10); //Returns the value 2200.0.
pt(20.0,0.10); //Returns the value 22.0.
```

pv

Calculates the present value of an annuity, where an amount is received over multiple periods and the interest rate is deducted for each period.

Syntax

```
real pv(real amount, real interest, real life)
```

Parameters

PARAMETER	DESCRIPTION
amount	The amount that is paid during each period.
interest	The interest rate.
life	The number of times that the value that is specified by the *amount* parameter is paid.

Return value

The current value of an annuity.

Remarks

```
pv(300,0.14,4); //Returns the value 874.11.
```

rate

Calculates the interest that is required for the current investment value to attain the future value over the specified number of periods.

Syntax

```
real rate(real _future_value, real _current_value, real _terms)
```

Parameters

PARAMETER	DESCRIPTION
_future_value	The future value of the investment.
_current_value	The current value of the investment.
_terms	The number of periods that the investment spans.

Return value

The calculated interest rate.

Remarks

```
rate(10000,1000,20); //Returns the value 0.12.
```

sln

Retrieves the constant depreciation amount for the specified asset for each depreciation period.

Syntax

```
real sln(real price, real scrap, real life)
```

Parameters

PARAMETER	DESCRIPTION
price	The purchase price of the asset.
scrap	The scrap value of the asset.
life	The number of periods in the expected life of the asset.

Return value

The depreciation amount.

Example

```
static void slnExample(Args _arg)
{
    real r;
    ;
    r = sln(100.00, 50.00, 50.00);
    print r;
    pause;
}
```

syd

Calculates the depreciation of an asset over a specified period.

Syntax

```
real syd(real _price, real _scrap, real _life, int _period)
```

Parameters

PARAMETER	DESCRIPTION
_price	The purchase price of the asset.
_scrap	The scrap value of the asset.

PARAMETER	DESCRIPTION
_life	The expected life of the asset (the number of periods).
_period	The period to calculate depreciation for.

Return value

The amount of depreciation over the specified period.

Remarks

In contrast to the **sln** function, the **syd** function can allow for an accelerated depreciation of the asset. As with the **ddb** function, this enables higher depreciation during the early periods of the life of an asset.

Example

In the following examples, the periodic depreciation is calculated for an asset that has a purchase price of 10,000, a scrap value of 2,000, and a life of 5. In comparison, **sln(10000,2000,5)** would calculate 1600.00 for each period.

```
// Returns the value 2666.67 (for the 1st period).
syd(10000,2000,5,1);
// Returns the value 2133.33 (for the 2nd period).
syd(10000,2000,5,2);
// Returns the value 1600.00 (for the 3rd period).
syd(10000,2000,5,3);
// Returns the value 1066.67 (for the 4th period).
syd(10000,2000,5,4);
// Returns the value 533.33 (for 5th - and final- period).
syd(10000,2000,5,5);
```

term

Calculates the number of periods that an investment must run for.

Syntax

```
real term(real amount, real interest, real future_value)
```

Parameters

PARAMETER	DESCRIPTION
amount	The amount of the periodic investment.
interest	The interest rate for each period.
future_value	The future value that is anticipated for the investment

Return value

The number of periods that the investment must run for.

Example

```
static void termExample(Args _args)
{
    print term(400,0.08,5000);  //returns the value '9.01'.
    print term(100,0.14,3000);  //returns the value '12.58'.
    pause;
}
```

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

X++ container runtime functions

2/18/2021 • 4 minutes to read • Edit Online

This topic describes the container run-time functions.

These functions manipulate the contents of containers.

conDel

Removes the specified number of elements from a container.

Syntax

```
container conDel(container container, int start, int number)
```

Parameters

PARAMETER	DESCRIPTION
container	The container to remove elements from.
start	The one-based position at which to start removing elements.
number	The number of elements to delete.

Return value

A new container that doesn't include the removed elements.

Example

```
static void conDelExample(Args _args)
{
    container c = ["Hello world", 1, 3.14];
        // Deletes the first two items from the container.
        c = conDel(c, 1, 2);
}
```

conFind

Locates the first occurrence of an element or a sequence of elements in a container.

Syntax

```
int conFind (container container, anytype element,... )
```

Parameters

PARAMETER	DESCRIPTION
container	The container to search.

PARAMETER	DESCRIPTION
element	One or more elements to search for, separated by commas.

Remarks

If several elements are specified in the sequence, they must be separated by commas and specified in the correct sequence. The elements can be of any data type.

Return value

0 if the item was not found; otherwise, the sequence number of the item.

Example

```
static void conFindExample(Args _args)
{
    container c = ["item1", "item2", "item3"];
    int i;
    int j;
    i = conFind(c, "item2");
    j = conFind(c, "item4");
    print "Position of 'item2' in container is " + int2Str(i);
    print "Position of 'item4' in container is " + int2Str(j);
}
```

conIns

Inserts one or more elements into a container.

Syntax

```
container conIns (container container, int start, anytype element, ... )
```

Parameters

PARAMETER	DESCRIPTION
container	The container to insert elements into.
start	The position to insert elements at.
element	One or more elements to insert, separated by commas.

Return value

A new container that contains the inserted elements.

Remarks

The first element of the container is specified by the number **1**. To insert after the n element, the *start* parameter should be n+1. You can also use the **+=** operator to add values of any type to a container. For example, to create a container that contains the squared values of the first 10 loop iterations, use the following code.

```
int i;
container c;

for (i = 1; i < = 10; i++)
{
    c += i*i;
}
```

Example

```
static void conInsExample(Args _arg)
{
    container c;
    int i;

    c = conIns(c,1,"item1");
    c = conIns(c,2,"item2");
    for (i = 1 ; i <= conLen(c) ; i++)
    {
        // Prints the content of a container.
        print conPeek(c, i);
    }
}
```

conLen

Retrieves the number of elements in a container.

Syntax

```
int conLen(container container)
```

Parameters

PARAMETER	DESCRIPTION
container	The container to count the number of elements in.

Return value

The number of elements in the container.

Example

```
static void conLenExample(Args _arg)
{
    container c;
    int i;

    c = conins(["item1", "item2"], 1);
    for (i = 1 ; i <= conLen(c) ; i++)
    {
            print conPeek(c, i);
    }
}
```

conNull

Retrieves an empty container.

```
container conNull()
```

Remarks

Use this function to explicitly dispose of the contents of a container.

Return value

An empty container.

Example

```
static void conNullExample(Args _arg)
{
    container c = ["item1", "item2", "item3"];

    print "Size of container is " + int2str(conLen(c));
    // Set the container to null.
    c = conNull();
    print "Size of container after conNull() is " + int2Str(conLen(c));
}
```

conPeek

Retrieves a specific element from a container and converts it into another data type, if conversion is required.

Syntax

```
anytype conPeek(container container, int number)
```

Parameters

PARAMETER	DESCRIPTION
container	The container to return an element from.
number	The position of the element to return. Specify **1** to get the first element. An invalid position number, such as **-3**, **0**, or a number that is higher than the length of the container, might cause unpredictable errors.

Return value

The element in the container at the position that is specified by the *number* parameter. The **conPeek** function automatically converts the peeked item into the expected return type. Strings can automatically be converted into integers and real numbers, and integers and real numbers can be converted into strings.

Example

```
static void main(Args _args)
{
    container cnI, cnJ;
    int i, j;
    anytype aty;
    info("container cnI ...");
    cnI = ["itemBlue", "itemYellow"];
    for (i=1; i <= conLen(cnI); i++)
    {
        aty = conPeek(cnI, i);
        info(int2str(i) + " :  " + aty);
    }

    info("container cnJ ...");
    cnJ = conIns(cnI, 2, "ItemInserted");
    for (j=1; j <= conLen(cnJ); j++)
    {
        aty = conPeek(cnJ, j);
        info(int2str(j) + " :  " + aty);
    }
}
/***  Output pasted from InfoLog ...
Message (10:20:03 am)
container cnI ...
1 :  itemBlue
2 :  itemYellow
container cnJ ...
1 :  itemBlue
2 :  ItemInserted
3 :  itemYellow
***/
```

conPoke

Modifies a container by replacing one or more of the existing elements.

Syntax

```
container conPoke(container container, int start, anytype element, ...)
```

Parameters

PARAMETER	DESCRIPTION
container	The container to modify.
start	The position of the first element to replace.
element	One or more elements to replace, separated by commas.

Return value

A new container that includes the new elements.

Remarks

The first element of the container is specified by the number **1**.

Example

```
static void conPokeExample(Args _arg)
{
    container c1 = ["item1", "item2", "item3"];
    container c2;
    int i;
    void conPrint(container c)
    {
        for (i = 1 ; i <= conLen(c) ; i++)
        {
            print conPeek(c, i);
        }
    }

    conPrint(c1);
    c2 = conPoke(c1, 2, "PokedItem");
    print "";
    conPrint(c2);
}
```

X++ conversion runtime functions

2/18/2021 • 18 minutes to read • Edit Online

This topic describes the conversion run-time functions.

any2Date

Converts an **anytype** value to a **date** value.

```
date any2Date(anytype object)
```

Parameters

PARAMETER	DESCRIPTION
object	The value to convert to a date.

Return value

A **date** value.

Remarks

The *object* parameter can be of most data types, but useful output is obtained when it's of the **str** or **int** type. Inappropriate content generates a run-time error.

Example

```
static void any2DateExample(Args _args)
{
    date myDate;
    str s;
    int i;
    s = "2010 6 17"; // A string object, of yyyy mm dd.
    myDate = any2Date(s);
    Global::info(strFmt("%1  is output, from input of "2010 6 17"", myDate));
    i = 40361; // An int object, which represents the number of days from 1900/01/01.
    myDate = any2Date(i);
    Global::info(strFmt("%1  is output, from input of 40361", myDate));
}
/**** Infolog display.
Message (04:44:15 pm)
6/17/2010 is output, from input of "2010 6 17"
7/4/2010 is output, from input of 40361
****/
```

any2Enum

Converts an **anytype** value to the **Name** property value of an element in the target enum.

```
enum any2Enum(anytype object)
```

Parameters

PARAMETER	DESCRIPTION
object	The value to match the **Value** property of an element in the target enum.

Return value

The value of the **Name** property for whichever element in the target enum has a **Value** property that matches the input parameter.

Remarks

The *object* parameter can be of most data types, but useful data is obtained only when you use a parameter of the **str** or **int** type. This input *object* parameter refers to the **Value** property of an individual element in the target enum.

Example

```
static void any2EnumExample(Args _args)
{
    NoYes myNoYes;  // NoYes is an enum.
    int i;
    str s;
    i = 0;  // An int that will be converted.
    myNoYes = any2Enum(i);
    Global::info(strfmt("'%1' - is the output, from input of the %2 as int.", myNoYes, i));
    s = "1";  // A str that will be converted.
    myNoYes = any2Enum(s);
    Global::info(strfmt("'%1' - is the output, from input of the %2 as str.", myNoYes, s));
    /**** Infolog display.
    Message (01:05:32 pm)
    'No' - is the output, from input of the 0 as int.
    'Yes' - is the output, from input of the 1 as str.
    ****/
}
```

any2Guid

Converts the specified **anytype** object to a GUID object.

```
guid any2Guid(anytype object)
```

Parameters

PARAMETER	DESCRIPTION
object	The value to convert to a GUID object.

Return value

A GUID object.

any2Int

Converts an **anytype** value to an **int** value.

```
int any2Int(anytype object)
```

Parameters

PARAMETER	DESCRIPTION
object	The value to convert.

Return value

An **int** value.

Remarks

The *object* parameter can be of most data types, but useful data is obtained only when you use parameters of the **enum**, **real**, or **str** type.

Example

```
static void any2IntExample(Args _args)
{
    int myInt;
    str s;
    NoYes a;
    real r;
    s = "31";
    myInt = any2Int(s);
    Global::info(strfmt("%1 is the output, from input of 31 as a str value.", myInt));
    a = NoYes::No;
    myInt = any2Int(a);
    Global::info(strfmt("%1 is the output, from input of NoYes::No as an enum value.", myInt));
    r = 5.34e2;
    myInt = any2Int(r);
    Global::info(strfmt("%1 is the output, from the input of 5.34e2 as a real value.", myInt));
}
/**** Infolog display.
Message (02:23:59 pm)
31 is the output, from input of 31 as a str value.
0 is the output, from input of NoYes::No as an enum value.
534 is the output, from the input of 5.34e2 as a real value.
****/
```

any2Int64

Converts an **anytype** object to an **int64** object.

```
int64 any2Int64(anytype object)
```

Parameters

PARAMETER	DESCRIPTION
object	The **anytype** object to convert.

Return value

An **int64** object.

any2Real

Converts an **anytype** value to a **real** value.

```
real any2Real(anytype object)
```

Parameters

PARAMETER	DESCRIPTION
object	The value to convert.

Return value

A **real** value.

Remarks

The *object* parameter can be of most data types, but useful output is obtained for input elements of the **date**, **int**, **enum**, and **str** types.

Example

```
static void any2RealExample(Args _args)
{
    real myReal;
    str s;
    int i;
    NoYes a;
    s = "5.12";
    myReal = any2Real(s);
    Global::info(strfmt("%1 is the output from the input of 5.12 as a str object", myReal));
    i = 64;
    myReal = any2Real(i);
    Global::info(strfmt("%1 is the output from the input of 64 as an int object", myReal));
    a = NoYes::Yes;
    myReal = any2Real(a);
    Global::info(strfmt("%1 is the output from the input of NoYes::Yes as an enum object", myReal));
}
/****Infolog display.
Message (02:43:57 pm)
5.12 is the output from the input of 5.12 as a str object
64.00 is the output from the input of 64 as an int object
1.00 is the output from the input of NoYes::Yes as an enum object
****/
```

any2Str

Converts an **anytype** value to a **str** value.

```
str any2Str(anytype object)
```

Parameters

PARAMETER	DESCRIPTION
object	The value to convert.

Return value

A **str** value.

Remarks

The *object* parameter can be of most data types, but useful output is obtained from input elements of the **date**, **int**, and **enum** types.

Example

```
static void any2StrExample(Args _args)
{
    str myStr;
    anytype a;
    a = "Any to string";
    myStr = any2Str(a);
    Global::info(strFmt("%1 is output, from input of Any to string as a str value", myStr));
    a = NoYes::Yes;
    myStr = any2Str(a);
    Global::info(strFmt("%1 is output, from input of NoYes::Yes as an enumeration", myStr));
}
/****Infolog Display
Message (09:08:46 am)
Any to string is output, from input of Any to string as a str value
1 is output, from input of NoYes::Yes as an enumeration
****/
```

anytodate

See any2Date.

anytoenum

See any2Enum.

anytoguid

See any2Guid.

anytoint

See any2Int.

anytoint64

See any2Int64.

anytoreal

See any2Real.

anytostr

See any2Str.

char2Num

Converts a character in a string to the ASCII value of the character.

```
int char2Num(str text, int position)
```

Parameters

PARAMETER	DESCRIPTION
text	The string that contains the character.
position	The position of the character in the string.

Return value

The ASCII value of the character as an **int** object.

Remarks

```
char2Num("ABCDEFG",3); //Returns the numeric value of C, which is 67.
char2Num("ABCDEFG",1); //Returns the numeric value of A, which is 65.
```

date2Num

Converts a date to an integer that corresponds to the number of days since January 1, 1900.

```
int date2Num(date _date)
```

Parameters

PARAMETER	DESCRIPTION
_date	The date to convert.

Return value

The number of days between January 1, 1900, and the specified date.

Example

```
//Returns the value377.
date2Num(1311901);
static void date2NumExample(Args _arg)
{
    date d = today();
    int i;
    i = date2Num(d);
    print i;
}
```

date2Str

Converts the specified date to a string.

```
str date2Str(date date, int sequence, int day, int separator1, int month, int separator2, int year [, int
flags = DateFlags::None])
```

Parameters

PARAMETER	DESCRIPTION
date	The date to convert.
sequence	A three-digit number that indicates the sequence for the components of the date: **1** for day, **2** for month, and **3** for year.
day	An enumeration value that indicates the format for the day component of the date.
separator1	An enumeration value that indicates the separator to use between the first two components of the date.
month	An enumeration value that indicates the format for the month component of the date.
separator2	An enumeration value that indicates the separator to use between the last two components of the date.
year	An enumeration value that indicates the format for the year component of the date.
flags	A **DateFlags** enumeration value that indicates whether the language settings on the local computer should be used to calculate the proper left-to-right or right-to-left sequence in the returned string.

Return value

A string that represents the specified date.

Remarks

MorphX allocates valid values to the formatting parameters if the specified values aren't valid. To use the date format that the user specified in Regional Settings, use the **strFmt** or **date2Str** function and specify **-1** in all the formatting parameters. When the regional settings control the date format, the settings can change from user to user. If **-1** is used for either *separator* parameter, both separators default to Regional Settings. The *sequence* parameter values must be any three-digit number that contains exactly one occurrence of each the digits 1, 2 and 3. The digits 1, 2, and 3 represent day, month, and year, respectively. For example, **321** produces the sequence year, month, and day. Or the value can be **-1** to use Regional Settings. No enumeration type should be used for this parameter, because numbers such as 321 exceed the range of valid values for enumeration values, which is 0 through 250, inclusive. The default value of the *flags* parameter is the **DateFlags::None** enumeration value, which means no left-to-right or right-to-left sequence processing is done.

Example

The following example displays the current date in the sequence of year, month, and day.

```
static void Job2(Args _args)
{
    date currentDate = today();
    str s;
    int iEnum;
    s = date2Str
    (currentDate,
        321,
        DateDay::Digits2,
        DateSeparator::Hyphen, // separator1
        DateMonth::Digits2,
        DateSeparator::Hyphen, // separator2
        DateYear::Digits4
    );
    info("Today is:  " + s);
}
/** Example Infolog output
Message (12:36:21 pm)
Today is:  2009-01-13
**/
```

datetime2Str

Converts a **utcdatetime** value into a string.

```
str datetime2Str(utcdatetime datetime [, int flags = DateFlags::None])
```

Parameters

PARAMETER	DESCRIPTION
datetime	The **utcdatetime** value to convert.
flags	A **DateFlags** enumeration value that indicates whether to use local settings for right-to-left output.

Return value

A string that represents the **utcdatetime** value that was specified as the *datetime* parameter.

Remarks

Null date-time input

If the minimum **utcdatetime** value is specified for the *datetime* parameter, the **datetime2Str** function treats it as a null input value. This causes the function to return an empty string. The date-time **1900-01-01T00:00:00** is returned by the **DateTimeUtil::minValue** method. This minimum value is treated as null.

Right-to-left local settings

The default behavior of this function is to generate the string in left-to-right sequence, where the year portion is leftmost. However, the *flags* parameter value of the **DateFlags::FormatAll** enumeration value directs the function to generate the string in right-to-left sequence if the local settings are configured for right-to-left. The format of the **toStr** method of the **DateTimeUtil** class is unaffected by regional settings.

Example

```
static void jobTestDatetime2str( Args _args )
{
    utcdatetime utc2 = 1959-06-17T15:44:33;
    str s3;
    s3 = datetime2Str( utc2 );
    info( s3 );
}
```

enum2Str

Converts the specified enumerated text to a character representation.

```
str enum2Str(enum enum)
```

Parameters

PARAMETER	DESCRIPTION
enum	The enumerated text to convert.

Return value

The value of the enumeration as a string.

Example

The following example returns the string "Not included." This is the label for the **IncludeNot** value of the **ListCode** enumeration type.

```
static void enum2StrExample(Args _arg)
{
    ListCode l;
    l =  ListCode::IncludeNot;
    print enum2Str(l);
}
```

guid2Str

Converts the specified GUID object to the equivalent string.

```
str guid2String(guid _uuid)
```

Parameters

PARAMETER	DESCRIPTION
_uuid	The GUID object to convert.

Return value

The string equivalent of the specified GUID object.

Example

```
static void guid2StrExample()
{
    guid _guid;
    str stringGuid;
    _guid = Global::guidFromString("{12345678-1234-1234-1234-123456789abc}");
    print strfmt("GUID is %1", _guid);
    stringGuid = guid2str(_guid);
    info("String GUID is " + stringGuid);
}
/**** Output to Infolog
String GUID is {12345678-1234-1234-1234-123456789ABC}
****/
```

int2Str

Converts an integer to the equivalent string.

```
str int2Str(int integer)
```

Parameters

PARAMETER	DESCRIPTION
integer	The integer to convert.

Return value

A string representation of the integer.

Example

```
static void int2StrExample(Args _arg)
{
    print "This is int2Str, value is " + int2Str(intMax());
    print "This is int642Str, value is " + int642Str(int64Max());
}
```

int642Str

Converts the specified *integer* parameter to the equivalent text string.

```
str int642Str(int64 integer)
```

Parameters

PARAMETER	DESCRIPTION
integer	The int64 to convert to a string.

Return value

The equivalent text string of the *integer* parameter.

Example

```
static void example()
{
    print "This is int2Str, value is " + int2Str(intMax());
    print "This is int642Str, value is " + int642Str(int64Max());
}
```

num2Char

Converts an integer to the corresponding ASCII character.

```
str num2Char(int figure)
```

Parameters

PARAMETER	DESCRIPTION
figure	The integer to convert to a character.

Return value

The character that is represented by the specified integer.

Example

```
static void num2CharExample(Args _arg)
{
    str s;
    s = num2Char(42);
    // Prints an asterisk * -the character represented by 42.
    print s;
}
```

num2Date

Retrieves the date that corresponds to the specified number of days after January 1, 1900.

```
date num2Date(int _days)
```

Parameters

PARAMETER	DESCRIPTION
_days	The number of days after January 1, 1900 to return the date for. **Note:** The first valid date is January 1, 1901. Therefore, the **num2Date** function doesn't return a valid date unless *_days* is more than **365**.

Return value

The date that is the number of days that is specified by the *_days* parameter after January 1, 1900.

Remarks

```
num2Date(366); //Returns the date 01/01/1901 (1 January 1901).
```

num2Str

Converts a real number to a string.

```
str num2Str(real number, int character, int decimals, int separator1, int separator2)
```

Parameters

PARAMETER	DESCRIPTION
number	The real number to convert to a string.
character	The minimum number of characters that are required in the text.
decimals	The required number of decimal places.
separator1	A **DecimalSeparator** enumeration value.
separator2	A **ThousandSeparator** enumeration value.

Return value

A string that represents the number.

Remarks

For the *decimals* parameter, the maximum value is **16**. If a larger number is used, this method obtains a value for the *decimals* parameter from the local computer instead. In both cases, rounding occurs. Here are the possible enumeration values for the *separator1* parameter:

- **99** – Auto (the formatting settings of the user determine what decimal separator is used), enumeration value DecimalSeparator::Auto
- **1** – Dot (.), enumeration value DecimalSeparator::Dot
- **2** – Comma (,), enumeration value DecimalSeparator::Comma

Here are the possible values for the *separator2* parameter:

- **99** – Auto (the formatting settings of the user determine what thousand separator is used)
- **0** – None (no thousand separator), enumeration value ThousandSeparator::None
- **1** – Dot (.), enumeration value ThousandSeparator::Dot
- **2** – Comma (,), enumeration value ThousandSeparator::Comma
- **3** – Apostrophe ('), enumeration value ThousandSeparator::Apostrophe
- **4** – Space ( ), enumeration value ThousandSeparator::Space

Example

In the following code example, the first call to the **num2str** method provides **16** for the *decimals* parameter, and the second call provides **17**.

```
static void Job_Num2Str(Args _args)
{
    real realNum = 0.1294567890123456777; // 19 decimals places.
    info(Num2Str(realNum, 0, 16, DecimalSeparator::Dot, ThousandSeparator::Space)); // 16 decimal places
    info(Num2Str(realNum, 0, 17, DecimalSeparator::Dot, ThousandSeparator::Space)); // 17 decimal places
}
```

Output

The messages are in the following Infolog output. The first number in the output contains 16 decimal place digits, whereas the second number contains only two decimal place digits.

```
Message (10:18:12)
0.1294567890123457
0.13
```

str2Date

Converts the specified string to a **date** value.

```
date str2Date(str _text, str _sequence)
```

Parameters

PARAMETER	DESCRIPTION
_text	The string to convert to a **date** value.
_sequence	A three-digit integer that describes the positions of the day, month, and year in the string to convert.

Return value

A **date** value.

Remarks

Use the following values to specify the positions of the day, month, and year in the *_sequence* parameter:

- **Day:** 1
- **Month:** 2
- **Year:** 3

For example, if the sequence in the string is month, year, and then day, the *_sequence* parameter must be **231**. A **0** (zero) date is returned if the input parameters specify an invalid date. The following two examples specify an invalid date.

```
str2Date("31/12/44", 123) // Year must be four digits to reach the minimum of January 1 1901.
str2Date("31/12/2044", 213) // 213 means the month occurs first in the string, but 31 cannot be a month.
```

Example

```
static void str2DateExample(Args _arg)
{
    date d;
    d = str2Date("22/11/2007", 123);
    print d;
}
```

str2Datetime

Generates a **utcdatetime** value from the specified string of date and time information.

```
utcdatetime str2datetime( str text, int sequence )
```

Parameters

PARAMETER	DESCRIPTION
text	The string to convert to a **utcdatetime** value.
sequence	A three-digit number that describes the sequence of the date components in the *text* parameter.

Return value

A **utcdatetime** value that represents the specified date and time.

Remarks

The syntax requirements for the date portion of the *text* parameter are flexible. The variety of valid formats is the same as in the **date2str** function. Each of the following calls to **str2datetime** is valid, and all of them produce the same output.

```
utc3 = str2datetime( "1985/02/25 23:04:59" ,321 );
utc3 = str2datetime( "Feb-1985-25 11:04:59 pm" ,231 );
utc3 = str2datetime( "2 25 1985 11:04:59 pm" ,123 );
```

Each component of the date time is represented by a digit in the *sequence* parameter:

- **1** – Day
- **2** – Month
- **3** – Year

For example, year, month, day order is **321**. All valid values contain each of these three digits exactly one time. If the value of the *sequence* parameter isn't valid, the regional settings are used to interpret the input *text* parameter. If the input parameters describe an invalid date and time, an empty string is returned.

Example

```
static void JobTestStr2datetime( Args _args )
{
    utcdatetime utc3;
    str sTemp;
    utc3 = str2datetime( "1985/02/25 23:04:59" ,321 );
    sTemp = datetime2str( utc3 );
    print( "sTemp == " + sTemp );
}
```

str2Enum

Retrieves the enum element for which the localized **Label** property value matches the input string.

```
enum str2Enum(enum _type, str _text)
```

Parameters

PARAMETER	DESCRIPTION
_type	A variable that is declared of the **enum** type.
_text	The localized **Label** property text of the target element in the enum.

Return value

An element of the target enum, which also represents an int.

Remarks

The related function **enum2str** returns the value of a **Label** property from one element in the enum. The value that is returned by **enum2str** function can be the input for the *_type* parameter of the **str2enum** function. An appropriate value for the *_text* parameter is **enum2Str(BankAccountType::SavingsAccount)**. Each element of an enum has a **Name** property and a **Label** property. In a fresh install, the **Name** values are almost always English words. In the English edition, the **Label** property value is almost always the same as the **Name** value. However, in non-English editions, the **Label** values are localized and therefore don't match the **Name** values.

Example

To avoid string mismatches that are caused by localization to other spoken languages, we recommend that you use the **enum2str** function to generate the input into the **str2enum** function. The following example shows the appropriate way to use the **str2enum** function together with the **enum2str** function.

```
static void str2Enum_AcrossLangs(Args _arg)
{
    BankAccountType bat;
    str sEnumValueLabelLocalized;
    int nInt;
    // enum2str.
    sEnumValueLabelLocalized = enum2str(BankAccountType::SavingsAccount);
    info("Localized friendly string: "
        + sEnumValueLabelLocalized);
    // str2enum.
    bat = str2Enum(bat, sEnumValueLabelLocalized);
    nInt = bat;
    info("nInt = " + int2str(nInt));
    /********** Actual output:
    Message (04:32:12 pm)
    Localized friendly string: Savings account
    nInt = 1
    **********/
}
```

str2Guid

Converts a string to a GUID object.

```
Guid str2Guid(str text)
```

Parameters

PARAMETER	DESCRIPTION
guid	A string that represents a GUID.

Return value

A GUID that is represented by the input string.

Remarks

For example, a valid value for the *guid* parameter is **{12345678-1234-abCD-3456-123456789012}**, either with or without the braces.

str2Int

Converts a string to the equivalent integer.

```
int str2Int(str _text)
```

Parameters

PARAMETER	DESCRIPTION
_text	The string to convert to an integer.

Return value

The integer equivalent of the specified string.

Example

```
static void str2IntExample(Args _arg)
{
    int i;
    i = str2Int("1234567890");
    print "i = " + int2Str(i);
}
```

str2Int64

Converts a string into an **Int64** value.

```
int str2Int64(str text)
```

Parameters

PARAMETER	DESCRIPTION
text	The string to convert.

Return value

The **Int64** value of the specified string.

Example

```
static void str2Int64Example(Args _args)
{
    str myStr;
    str tooBig;
    Int64 myInt64;
    myStr = "1234567890";
    tooBig = int642str(int64Max()+1);
    myInt64 = str2Int64(mystr);
    print strfmt ("int64: %1",myInt64);
    myInt64 = str2Int64(tooBig);
    print strfmt ("Too big int64: %1",myInt64);
}
```

str2Num

Converts a string to a real number.

```
real str2Num(str _text)
```

Parameters

PARAMETER	DESCRIPTION
_text	The string to convert to a real number.

Return value

The real number if the specified string contains a valid number; otherwise, **0** (zero).

Remarks

The following examples show how this function is used.

```
str2Num("123.45") returns the value 123.45.
str2Num("a123") returns the value 0.0.
str2Num("123a") returns the value 123.00.
```

Scanning occurs from left to right and ends when a character can't be converted to part of a real number.

Example

```
static void str2NumToReal(Args _arg)
{
    real r;
    str s;
    r = str2Num("3.15");
    s = strFmt("r = %1", r);
    info(s);
}
/*** Infolog output.
Message_@SYS14327 (02:36:12 pm)
r = 3.15
***/

static void str2NumExponentialSyntax(Args _args)
{
    Qty qty1, qty2, qty3;
    qty1 = str2num('1e-3'); // Bad syntax by the user.
    qty2 = str2num('1.e-3');
    qty3 = str2num('1.0e-3');
    info(strfmt('Result: %1; Expected: %2', num2str(qty1, 0,3,2,0), '0.001'));
    info(strfmt('Result: %1; Expected: %2', num2str(qty2, 0,3,2,0), '0.001'));
    info(strfmt('Result: %1; Expected: %2', num2str(qty3, 0,3,2,0), '0.001'));
}
/*** Infolog output. The first result differs from expectations.
Message_@SYS14327 (02:20:55 pm)
Result: 1,000; Expected: 0.001
Result: 0,001; Expected: 0.001
Result: 0,001; Expected: 0.001
***/
```

str2Time

Converts a string to a **timeOfDay** value.

```
int str2Time(str _text)
```

Parameters

PARAMETER	DESCRIPTION
_text	The time to use to calculate the number of seconds since midnight.

Return value

The number of seconds between midnight and the *_text* parameter; otherwise, **-1**.

Remarks

```
str2Time("05:01:37") //Returns the value 18097.
str2Time("7 o'clock") //Returns the value -1.
```

Example

```
static void str2TimeExample(Args _arg)
{
    int i;
    i = str2Time("11:30");
    print i;
}
```

time2Str

Converts a **timeOfDay** value to a string that includes hours, minutes, and seconds.

```
str time2Str(int _time, int _separator, int _timeFormat)
```

Parameters

PARAMETER	DESCRIPTION
_time	A **timeOfDay** value.
_separator	A **TimeSeparator** enumeration value that indicates the characters between the hours, minutes, and seconds in the output string.
_timeFormat	A **TimeFormat** enumeration value that indicates whether a 12-hour clock or a 24-hour clock is used.

Return value

A string that represents the specified time.

Remarks

The value of the *_time* parameter is the number of seconds since midnight.

Example

```
static void TimeJob4(Args _args)
{
    timeOfDay theTime = timeNow();
    info( time2Str(theTime, TimeSeparator::Colon, TimeFormat::AMPM) );
}
/**
Message (04:33:56 pm)
04:33:56 pm
**/
```

uint2Str

Converts an integer to a string. The assumption is that the integer is unsigned.

```
str uint2Str(int integer)
```

Parameters

PARAMETER	DESCRIPTION
integer	The integer to convert.

Return value

The string equivalent to the specified unsigned integer.

Remarks

Use this function instead of the **int2str** function for very large integers, such as record IDs.

```
info(int2str(3123456789)); //returns -1171510507 as a string.
info(uint2str(3123456789)); //returns 3123456789 as a string.
```

X++ date runtime functions

2/18/2021 • 8 minutes to read • Edit Online

This topic describes the date run-time functions.

dayName

Retrieves the name of the day of the week that is specified by a number.

```
str dayName(int number)
```

Parameters

PARAMETER	DESCRIPTION
number	The number of a day in a week.

Return value

The day of the week specified by the number parameter.

Remarks

The valid values for the number parameter are **1** through **7**. Monday is represented by **1**, Tuesday by **2**, and Sunday by **7**.

Example

```
static void dayNameExample(Args _arg)
{
    str s;
    ;
    s = dayName(01);
    print "First day of the week's name is " + s;
    pause;
}
```

dayOfMth

Calculates the number of the day in the month for the specified date.

```
int dayOfMth(date date)
```

Parameters

PARAMETER	DESCRIPTION
date	The date to test.

Return value

An integer between 1 and 31 that indicates the day of the month for the specified date.

Remarks

```
dayOfMth(31122001) //returns 31.
```

Example

```
static void dayOfMthExample(Args _arg)
{
    date d = today();
    int i;
    ;
    i = dayOfMth(d);
    print "Today's day of the month is " + int2Str(i);
    pause;
}
```

dayOfWk

Calculates the number of day in the week for the specified date. **Note:** Monday is represented by **1**, Tuesday by **2**, and Sunday by **7**.

```
int dayOfWk(date date)
```

Parameters

PARAMETER	DESCRIPTION
date	A **date** value that indicates the year, month, and day.

Return value

The number of the specified day in the week.

Example

```
static void dayOfWkExample(Args _arg)
{
    date d = today();
    int i;
    ;
    i = dayOfWk(d);
    print "Today's day of the week is " + int2Str(i);
    pause;
}
```

dayOfYr

Calculates the number of days between January 1 and the specified date.

```
int dayOfYr(date _date)
```

Parameters

PARAMETER	DESCRIPTION
_date	A date that specifies the year, month, and day.

Return value

The number of days between January 1 and the specified date, inclusive.

Remarks

January 1 is **1**, and December 31 is either **365** or **366**.

Example

```
static void dayOfYrExample(Args _arg)
{
    date d = today();
    int i;
    ;
    i = dayOfYr(d);
    print "Today's day of the year is " + int2Str(i);
    pause;
}
```

endMth

Calculates the last date in the month of the specified date.

```
date endMth(date date)
```

Parameters

PARAMETER	DESCRIPTION
date	A **date** value that indicates a year, month, and day.

Return value

The **date** value of the last day in the specified month.

Remarks

```
endMth(0221988); //Returns the date 2921988 because 1988 is a leap year.
endMth(0221989); //Returns the date 2821989.
```

mkDate

Creates a date, based on three integers that indicate the day, month, and year, respectively.

```
date mkDate(int day, int month, int year)
```

Parameters

PARAMETER	DESCRIPTION
day	An integer that represents the day of the month.

PARAMETER	DESCRIPTION
month	An integer that represents the month of the year.
year	An integer that represents the year, which must be between 1900 and 2154.

Return value

A **date** value that is based on the values of the *day*, *month*, and *year* parameters.

Remarks

If the date isn't valid, this method returns a **0** (zero, 1/1/1900) date. Beginning with Dynamics AX 7.0(February 2016), shortcut values for the year, e.g. 75 for 1975, are not supported. If you provide a shortcut value for the year, a date of 1/1/1900 is returned.

Example

```
static void mkDateExample(Args _arg)
{
    date d;
    ;
    // Returns the date 0112005.
    d = mkDate(1, 1, 2005);
    print d;
    pause;
}
```

mthName

Retrieves the name of the specified month

```
str monthName(int number)
```

Parameters

PARAMETER	DESCRIPTION
number	The number of the month.

Return value

The name of the specified month.

Remarks

The valid values of the *number* parameter are **1** through **12**. January is represented by **1** and December by **12**.

Example

```
static void mthNameExample(Args _arg)
{
    str s;
    ;
    // MthName(6) returns the text string "June".
    s = mthName(6);
    print "Month name is " + s;
    pause;
}
```

mthOfYr

Retrieves the number of the month in the year for the specified date. **Note:** January is **1**, February is **2**, and December is **12**.

```
int mthOfYr(date date)
```

Parameters

PARAMETER	DESCRIPTION
date	A date that specifies a year, month, and day.

Return value

The number of the month in the year, for the month that is represented by the *date* parameter.

Example

```
static void mthOfYrExample(Args _arg)
{
    int i;
    ;
    i = mthOfYr(today());
    print "The number of the month in today's date is " + int2Str(i);
    pause;
}
```

nextMth

Retrieves the date in the following month that corresponds most closely to the specified date.

```
date nextMth(date date)
```

Parameters

PARAMETER	DESCRIPTION
date	The date to match in the following month.

Return value

The closest match to the specified date that is found in the next month.

Remarks

```
nextMth(2921996); //returns 29/03/1996.
nextMth(3111996); //returns 2921996, because 1996 is a leap year.
```

Example

```
static void nextMthExample(Args _arg)
{
    date d;
    ;
    d = nextMth(today());
    print "Closest date next month is "
    + date2Str(d, 2, 2, -1, 2, -1, 4);
    pause;
}
```

nextQtr

Retrieves the date in the following quarter that corresponds most closely to the specified date.

```
date nextQtr(date date)
```

Parameters

PARAMETER	DESCRIPTION
date	The date to match in the following quarter.

Return value

The closest match to specified date that is found in the next quarter.

Remarks

For example, **nextQtr(3111998)** returns **3041998**.

Example

```
static void nextQtrExample(Args _arg)
{
    date d;
    ;
    d = nextQtr(today());
    print "Closest date next quarter is "
        + date2Str(d, 2, 2, -1, 2, -1, 4);
    pause;
}
```

nextYr

Retrieves the date in the following year that corresponds most closely to the specified date.

```
date nextYr(date date)
```

Parameters

PARAMETER	DESCRIPTION
date	The date to match in the following year.

Return value

The closest match to the specified date that is found in the following year.

Remarks

For example, **nextyr(2921998)** returns **2821999**.

Example

```
static void nextYrExample(Args _arg)
{
    date d;
    ;
    d = nextYr(today());
    print "Closest date next year is "
        + date2Str(d, 2, 2, -1, 2, -1, 4);
    pause;
}
```

prevMth

Retrieves the date in the previous month that corresponds most closely to the specified date.

```
date prevMth(date date)
```

Parameters

PARAMETER	DESCRIPTION
date	The date to match in the previous month.

Return value

The closest match to the specified date that is found in the previous month.

Remarks

```
prevMth(3131996); //Returns the date 29/02/1996 because 1996 is a leap year.
prevMth(2821998); //Returns the date 28/01/1998.
```

prevQtr

Retrieves the date in the previous quarter that corresponds most closely to the specified date.

```
date prevQtr(date date)
```

Parameters

PARAMETER	DESCRIPTION
date	The date to match in the previous quarter.

Return value

The closest match to the specified date that is found in the previous quarter.

Remarks

```
prevQtr(3041998); //Returns the date 30/01/1998.
prevQtr(2951996); //Returns the date 29/02/1996, because 1996 is a leap year.
```

prevYr

Retrieves the date in the previous year that corresponds most closely to the specified date.

```
date prevYr(date date)
```

Parameters

PARAMETER	DESCRIPTION
date	The date to match in the previous year.

Return value

The closest match to the specified date that is found in the previous year.

Remarks

```
prevYr(2921996); //Returns the date 28/02/1995 because 1996 is a leap year.
prevYr(2821998); //Returns the date 28/02/1997.
```

systemDateGet

Retrieves the session date, if it has been set.

```
date systemDateGet()
```

Return value

The session date if it has been set; otherwise, the system date.

Remarks

Consider using **Session date and time** on the **Tools** menu to open the **Session date and time** page. This page can be used to actively set the session date. After this set action is detected by the system, subsequent calls to the **systemDateGet** function return the session date. The **today** function returns the system date. This function doesn't support time zones.

Example

The following example shows the date in the Infolog window.

```
static void Job_systemDateGet(Args _arg)
{
    info( date2Str(
        systemDateGet(),        // X++ language function.
        321,                    // 321 = ymd
        DateDay::Digits2,
        DateSeparator::Hyphen,  // separator1
        DateMonth::Digits2,
        DateSeparator::Hyphen,  // separator2
        DateYear::Digits4
    )
);
/********** Actual Infolog output
Message (03:46:00 pm)
2012-04-16
**********/
}
```

systemDateSet

Changes the system date.

```
date systemDateSet(date _date)
```

Parameters

PARAMETER	DESCRIPTION
_date	The new date for the system.

Return value

The new system date.

Remarks

This function doesn't affect the session date. This method changes the date, but the time will be set to **0** (zero).

Example

The following example sets the system date to today's date.

```
static void systemDateSetExample(Args _arg)
{
    date d = today();
    d = systemDateSet(d);
    print d;
}
```

timeNow

Retrieves the current system time.

```
int timeNow()
```

Return value

The number of seconds that have passed since midnight.

Example

```
static void timeNowExample(Args _arg)
{
    int i;
    ;
    i = timeNow();
    print "The number of seconds since midnight is " + int2Str(i);
    pause;
}
```

today

Retrieves the current date on the system.

```
date today()
```

Return value

The current date.

Example

```
static void todayExample(Args _arg)
{
    date d;
    ;
    d = today();
    print "Today's date is " + date2Str(d, 0, 2, -1, 2, -1, 4);
    pause;
}
```

wkOfYr

Calculates the week of the year that a date falls in, according to the ISO 8601 specification.

```
int wkOfYr(date _date)
```

Parameters

PARAMETER	DESCRIPTION
_date	The date to calculate the week of the year for.

Return value

The sequence number of the week that the *_date* parameter occurs in.

Example

The following code example compares the **wkOfYr** function with the **Global::weekOfYear** method. The function and the method produce different results.

```
// X++ job, under AOT > Jobs.
static void WeekTests3Job(Args _args)
{
int weekNum, i;
date dateTest;
str sMessages[];
//-------------------------------------------
sMessages[1] = "----- #1.  For Sunday, January 5, 2003 -----";
dateTest = 512003; // DayMonthYear  format.
weekNum = wkOfYr(dateTest);
sMessages[2] = int2str(weekNum) + " = wkOfYr funtion";
weekNum = Global::weekOfYear(dateTest);
sMessages[3] = int2str(weekNum) + " = Global::weekOfYear method";
//-------------------------------------------
sMessages[4] = " ";
sMessages[5] = "----- #2.  For Wednesday, August 20, 2003 -----";
dateTest = 2082003;
weekNum = wkOfYr(dateTest);
sMessages[6] = int2str(weekNum) + " = wkOfYr funtion";
weekNum = Global::weekOfYear(dateTest);
sMessages[7] = int2str(weekNum) + " = Global::weekOfYear method";
//-------------------------------------------
sMessages[8] = " ";
sMessages[9] = "----- #3.  For Sunday, December 28, 2003 -----";
dateTest = 28122003;
weekNum = wkOfYr(dateTest);
sMessages[10] = int2str(weekNum) + " = wkOfYr funtion";
weekNum = Global::weekOfYear(dateTest);
sMessages[11] = int2str(weekNum) + " = Global::weekOfYear method";
for (i=1; i<= 11; i++)
{
Global::info(sMessages[i]);
}
}
```

The previous example sent the following information to the Infolog for display. The output shows that there are differences between **wkOfYr** and **Global::weekOfYear**.

```
Message (01:59:13 pm) -----
#1. For Sunday, January 5, 2003 ----- 1 = wkOfYr function 2 = Global::weekOfYear method -----
#2. For Wednesday, August 20, 2003 ----- 34 = wkOfYr function 34 = Global::weekOfYear method -----
#3. For Sunday, December 28, 2003 ----- 52 = wkOfYr function 1 = Global::weekOfYear method
```

year

Retrieves the year from a **date** value.

```
int year(date _date)
```

Parameters

PARAMETER	DESCRIPTION
_date	The date to return the year from.

Return value

The year of the specified date.

Remarks

```
year(0221998); //Returns the value 1998.
```

The survey will take about seven minutes. No personal data is collected (privacy statement).

X++ math runtime functions

2/18/2021 • 8 minutes to read • Edit Online

This topic describes the math run-time functions.

These functions perform mathematical calculations.

abs

Retrieves the absolute value of a real number. Examples:

- **abs(-100.0)** returns the value **100.0**.
- **abs(30.56)** returns the value **30.56**.

Syntax

```
real abs(real arg)
```

Parameters

PARAMETER	DESCRIPTION
arg	The number to get the absolute value of.

Return value

The absolute value of *arg*.

Example

```
static void absExample(Args _args)
{
    real r1;
    real r2;
    ;
    r1 = abs(-3.14);
    r2 = abs(3.14);
    if (r1 == r2)
    {
        print "abs of values are the same";
        pause;
    }
}
```

acos

Retrieves the arc cosine of a real number.

> **NOTE**
> Argument values that are outside the -1 to 1 range cause the following run-time error: "Argument for trigonometric function out of range."

Syntax

```
real acos(real arg)
```

Parameters

PARAMETER	DESCRIPTION
arg	The number to retrieve the arc cosine of.

Return value

The arc cosine of *arg*.

Example

```
static void acosExample(Args _args)
{
    real r;
    str  s;
    ;
    r = acos(0.0);
    s = strFmt("The arc cosine of 0.0 is %1 ", r);
    print s;
    pause;
}
```

asin

Retrieves the arc sine of a real number.

> **NOTE**
> Argument values that are outside the -1 to 1 range cause the following run-time error: "Argument for trigonometric function out of range."

Syntax

```
real asin(real arg)
```

Parameters

PARAMETER	DESCRIPTION
arg	The number to calculate the arc sine for.

Return value

The arc sine of the specified number.

Remarks

aSin(0.36) returns **0.37**.

atan

Retrieves the arc tangent of a real number.

Syntax

```
real atan(real arg)
```

Parameters

PARAMETER	DESCRIPTION
arg	The number to calculate the arc tangent for.

Return value

The arc tangent of the specified number.

Remarks

aTan(0.36) returns **0.35**.

Example

```
static void atanExample(Args _args)
{
    real r;
    ;
    r = atan(1.0);
    print strFmt("The Arc Tangent of 1.0 is %1", r);
    pause;
}
```

corrFlagGet

Retrieves the state of the correction flag for a real number.

Syntax

```
int corrFlagGet(real arg)
```

Parameters

PARAMETER	DESCRIPTION
arg	The flag to retrieve the state for.

Return value

A non-zero value if the flag is set; **0** (zero) if the flag is cleared.

Example

The following example displays **1**.

```
static void corrFlagGetExample(Args _args)
{
    real rr;
    rr = corrFlagSet(0.36,2);
    print(corrFlagGet(rr));
}
```

corrFlagSet

Controls the correction flag for a real number.

Syntax

```
real corrFlagSet(real real, int arg)
```

Parameters

PARAMETER	DESCRIPTION
real	The number in which to turn the correction flag on or off.
arg	**0** to turn the flag off; a non-zero value to turn the flag on.

Return value

0 if the flag is now off; a non-zero value if the flag is now on.

COS

Retrieves the cosine of a real number.

Syntax

```
real cos(real arg)
```

Parameters

PARAMETER	DESCRIPTION
arg	The number to find the cosine for.

Return value

The cosine of the specified number.

Remarks

The value of the *arg* parameter must be in radians.

Example

The following code example displays **0.76**.

```
static void cosExample(Args _arg)
{
    real r;
    ;
    r = cos(15);
    print strFmt("Cos of 15 is %1", r);
    pause;
}
```

cosh

Retrieves the hyperbolic cosine of a real number.

> **NOTE**
>
> Argument values that are outside the -250 to 250 range cause the following run-time error: "Argument for trigonometric function out of range."

Syntax

```
real cosh(real arg)
```

Parameters

PARAMETER	DESCRIPTION
arg	The hyperbolic number to calculate the cosine for.

Return value

The hyperbolic cosine of the specified number.

Remarks

The value of the *arg* parameter must be in radians.

Example

```
static void coshExample(Args _arg)
{
    real r;
    ;
    r = cosh(0.1);
    print "The hyperbolic cosine of 0.1 is " + num2Str(r, 2, 2, 1, 1);
    pause;
}
```

decRound

Rounds a number to the specified number of decimal places.

Syntax

```
real decRound(real figure, int decimals)
```

Parameters

PARAMETER	DESCRIPTION
figure	The number to round.
decimals	The number of decimal places to round to.

Return value

The value of the specified number, rounded to the specified number of decimal places.

Remarks

The value of the *decimals* parameter can be positive, 0 (zero), or negative.

- **decRound(1234.6574,2)** returns the value **1234.66**.
- **decRound(1234.6574,0)** returns the value **1235**.
- **decRound(1234.6574,-2)** returns the value **1200**.
- **decRound(12345.6789,1)** returns the value **12345.70**.
- **decRound(12345.6789,-1)** returns the value **12350.00**.

exp

Retrieves the natural antilogarithm of the specified real number.

Syntax

```
real exp(real arg)
```

Parameters

PARAMETER	DESCRIPTION
arg	The real number to calculate the natural antilogarithm for.

Return value

The natural antilogarithm of the specified real number.

Remarks

The calculated natural antilogarithm is the natural logarithm e raised to the power that is indicated by the *arg* parameter.

Example

```
static void expExample(Args _arg)
{
    real r1;
    real r2;
    ;
    r1 = exp(2.302585093);
    r2 = exp10(2.302585093);
    print strFmt("exp of 2.302585093 is %1", r1);
    print strFmt("exp10 of 230258 is %1", r2);
    pause;
}
```

exp10

Retrieves the base-10 antilogarithm of the specified real number.

Syntax

```
real exp10(real decimal)
```

Parameters

PARAMETER	DESCRIPTION
decimal	The real number to calculate the base-10 antilogarithm for.

Return value

The 10-based antilogarithm of the value of the *decimal* parameter.

Example

```
static void exp10Example(Args _arg)
{
    real r1;
    real r2;
    ;
    r1 = exp(2.302585093);
    r2 = exp10(2.302585093);
    print strFmt("exp of 2.302585093 is %1", r1);
    print strFmt("exp10 of 230258 is %1", r2);
    pause;
}
```

frac

Retrieves the decimal part of a real number.

Syntax

```
real frac(real decimal)
```

Parameters

PARAMETER	DESCRIPTION
decimal	The real number to retrieve the decimal part for.

Return value

The decimal part of the specified number.

Remarks

`frac(12.345)` returns the value `0.345`.

log10

Retrieves the 10-digit logarithm of a real number.

Syntax

```
real log10(real arg)
```

Parameters

PARAMETER	DESCRIPTION
arg	The number to calculate the logarithm for.

Return value

The base-10 logarithm of the specified number.

Remarks

`log10(200)` returns the value `2.30`.

logN

Retrieves the natural logarithm of the specified real number.

Syntax

```
real logN(real arg)
```

Parameters

PARAMETER	DESCRIPTION
arg	The number to calculate the natural logarithm for.

Return value

The natural logarithm of the specified number.

Remarks

`logN(45)` returns the value `3.81`.

max

Retrieves the larger of two specified values.

```
anytype max(anytype object1, anytype object2)
```

Parameters

PARAMETER	DESCRIPTION
object1	The first value.
object2	The second value.

Return value

The larger of the two values that are specified by the *object1* and *object2* parameters.

Remarks

- `max(12.0,12.1)` returns the value `12.1`.
- `max(2,33)` returns the value `33`.

min

Retrieves the smaller of two specified values.

```
anytype min(anytype object1, anytype object2)
```

Parameters

PARAMETER	DESCRIPTION
object1	The first value.
object2	The second value.

Return value

The smaller of the two values that are specified by the *object1* and *object2* parameters.

Remarks

`min(2,33)` returns the value `2`.

Example

```
static void minExample(Args _arg)
{
    anytype a;
    real r = 3.0;
    real s = 2.0;

    a = min(r, s);
    print num2Str(a, 1, 2, 1, 1) + " is less than the other number.";
}
```

power

Raises a real number to the power of another real number.

Syntax

```
real power(real arg, real exponent)
```

Parameters

PARAMETER	DESCRIPTION
arg	The number to calculate the power of.
exponent	The number to raise the number that is specified by the *arg* parameter to.

Return value

The real number that is the number specified by the *arg* parameter to the power of the number specified by the *exponent* parameter.

Remarks

- `power(5.0,2.0)` returns the value `25.0`.
- `power(4.0,0.5)` returns the value `2.0`.

round

Rounds a real number to the nearest multiple of another real number.

Syntax

```
real round(real _arg, real _decimals)
```

Parameters

PARAMETER	DESCRIPTION
_arg	The original number.
_decimals	The number that the value of the *_arg* parameter must be rounded to a multiple of.

Return value

The number that is a multiple of the value specified by the *_decimals* parameter and is closest to the value specified by the *_arg* parameter.

Remarks

To round a real number to a specified number of decimal places, use the decround function.

Remarks

- **round(123.45,5.00)** returns the value **125.00**.
- **round(7.45,1.05)** returns the value **7.35**.
- **round(23.9,5.0)** returns the value **25.00**.
- **round(26.1,5.0)** returns the value **25.00**.

sin

Retrieves the sine of a real number.

Syntax

```
real sin(real _arg)
```

Parameters

PARAMETER	DESCRIPTION
_arg	The number to calculate the sine for.

Return value

The sine of the specified real number.

Remarks

The value of the *_arg* parameter must be in radians.

Example

```
static void sinExample(Args _arg)
{
    real angleDegrees = 15.0;
    real angleRadians;
    real pi = 3.14;
    real r;
    ;
    angleRadians = pi * angleDegrees / 180;
    r = sin(angleRadians);
    print "sin of a "
        + num2Str(angleDegrees, 2, 2, 1, 1)
        + " degree angle is "
        + num2Str(r, 2, 10, 1, 1);
    pause;
}
```

sinh

Retrieves the hyperbolic sine of a real number.

Syntax

```
real sinh(real _arg)
```

Parameters

PARAMETER	DESCRIPTION
_arg	The number to calculate the hyperbolic sine for.

Return value

The hyperbolic sine of the specified real number.

Remarks

Values for the *_arg* parameter that are outside the -250 to 250 range cause the following run-time error: "Argument for trigonometric function out of range."

Example

The following example illustrates the **sinh** function.

```
static void sinhExample(Args _arg)
{
    real angleDegrees = 45.0;
    real angleRadians;
    real pi = 3.14;
    real r;
    ;
    angleRadians = pi * angleDegrees / 180;
    r = sinh(angleRadians);
    print "sinh of a "
    + num2Str(angleDegrees, 2, 2, 1, 1)
    + " degree angle is "
    + num2Str(r, 2, 15, 1, 1);
    pause;
}
```

tan

Retrieves the tangent of a real number.

Syntax

```
real tan(real arg)
```

Parameters

PARAMETER	DESCRIPTION
arg	The real number to calculate the tangent for.

Return value

The tangent of the specified real number.

Remarks

Values for the *arg* parameter that are outside the -250 to 250 range cause the following run-time error: "Argument for trigonometric function out of range."

Example

The following example illustrates the **tan** function.

```
static void tanExample(Args _arg)
{
    real r;
    ;
    r = tan(250);
    print strFmt("Tan of 250 is %1", r);
    pause;
}
```

tanh

Retrieves the hyperbolic tangent of a real number.

Syntax

```
real tanh(real _arg)
```

Parameters

PARAMETER	DESCRIPTION
_arg	The number to calculate the hyperbolic tangent for.

Return value

The hyperbolic tangent of the specified real number.

Example

The following example illustrates the **tanh** function.

```
static void tanhExample(Args _arg)
{
    real r;
    ;
    r = tanh(0.1);
    print "The hyperbolic tangent of angle 0.1 is "
    + num2Str(r, 2, 10, 1, 1);
    pause;
}
```

trunc

Truncates a real number by removing any decimal places.

Syntax

```
real trunc(real _decimal)
```

Parameters

PARAMETER	DESCRIPTION
_decimal	The number to truncate.

Return value

A number that is equivalent to the value of the *_decimal* parameter after the decimal places have been removed.

Remarks

This function always rounds numbers down to a complete integer.

Example

The following example truncates 2.7147 to 2.00.

```
static void truncExample(Args _arg)
{
    real r;
    ;
    r = trunc(2.7147);
    print strFmt("r = %1",  r);
    pause;
}
```

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

X++ reflection runtime functions

2/18/2021 • 7 minutes to read • Edit Online

This topic describes the reflection run-time functions.

classIdGet

Retrieves the numeric identifier (the class ID) of the class that the object that is initialized belongs to.

```
int classIdGet(class object)
```

Parameters

PARAMETER	DESCRIPTION
object	The object to get the class ID for.

Return value

The class ID of the specified object.

Example

```
static void classIdGetExample(Args _args)
{
    int i;
    WorkTimeCheck w;

    i = classIdGet(w);
    print "Class ID for object is " + int2Str(i);
}
```

dimOf

Retrieves the number of index elements that space has been allocated for in an X++ array.

```
int dimOf(anytype object)
```

Parameters

PARAMETER	DESCRIPTION
object	The array to determine the dimension size of.

Return value

If the value of the *object* parameter is an array, the number of elements in the array; otherwise, **0** (zero).

Remarks

The **dimOf** function is intended for X++ arrays that are declared as the following X++ primitive types:

- boolean

- date
- int
- int64
- real
- utcDateTime

An example is **int iAmounts[6];**. Arrays of enumeration values and extended data types are also supported if they are ultimately based on one of the preceding primitive data types (such as **int**). The **dimOf** function doesn't accept arrays of all X++ primitive types. Here are the array types that the **dimOf** function doesn't accept:

- **str**
- **container**
- **anytype**
- Arrays of class objects
- Instances of the **Array** class

Example

```
static void JobDimOfArrays(Args _args)
{
    int iAmounts[20], iCounts[];
    ABCModel enumAbcModel[22]; // Enum
    ABCModelType exdtAbcModelType[24]; // Extended data type
    anytype anyThings[26];
    str sNames[28];
    Array myArrayObj; // Class

    info("Start of job.");
    info("--(Next, normal int array, dimOf() accepts it.)");
    info(int2Str(dimOf(iAmounts)));
    info("--(Next, normal enum array, dimOf() accepts it.)");
    info(int2Str(dimOf(enumAbcModel)));
    info("--(Next, normal extended data type array (based on enum), dimOf() accepts it.)");
    info(int2Str(dimOf(exdtAbcModelType)));
    info("--(Next, dynamic int array, dimension not yet set.)");
    info(int2Str(dimOf(iCounts)));
    info("--(Next, dynamic int array, after dimension established.)");

    iCounts[13] = 13;
    info(int2Str(dimOf(iCounts)));
    info(" == == == == == (Next, array types that dimOf() does not support.)");
    info("--(Next, normal anytype array, dimOf() always returns 0.)");
    info(int2Str(dimOf(anyThings)));
    info("--(Next, an instance of class X++ Array, dimOf() always returns 0.)");

    myArrayObj = new Array(Types::Integer);
    myArrayObj.value(1,501);
    info(int2Str(dimOf(myArrayObj)));
    info("--(Next, the lastIndex method provides size information about Array instances.)");
    info(int2Str(myArrayObj.lastIndex()));
    info("--(Next, normal str array, dimOf() does not accept it, job is halted.)");
    info(int2Str(dimOf(sNames)));
    info("End of job.");

}
/************  Actual Infolog output

```

fieldId2Name

Retrieves a string that represents the name of the field that is specified by a table ID number and a field ID number.

```
str fieldId2Name(int tableid, int fieldid)
```

Parameters

PARAMETER	DESCRIPTION
tableid	The ID number of the table. **Note:** Use the **tableName2Id** function to specify the ID of a table.
fieldid	The ID number of the field.

Return value

The name of the field.

Remarks

To return a printable version of the field name, use the **fieldId2PName** function.

Example

The following example sets **fn** to the name of the field in the Customer (CustGroup) table that has a field ID of 7.

```
static void fieldId2NameExample(Args _arg)
{
    str fn;
    fn = fieldId2Name(tableName2Id("Customer"),7);
}
```

fieldId2PName

Retrieves the printable name of the field that is specified by a table ID number and a field ID number.

```
str fieldId2PName(int tableid, int fieldid)
```

Parameters

PARAMETER	DESCRIPTION
tableid	The ID number of the table. **Note:** Use the **tableName2Id** function to specify the ID of a table.
fieldid	The ID number of the field. **Note:** Use the **fieldName2Id** function to specify the ID of a field.

Return value

The name of the field.

Example

```
static void fieldId2PNameExample(Args _arg)
{
    str name;
    tableid _tableId;
    fieldid _fieldid;

    _tableId = tableName2Id("Address");
    _fieldId = fieldName2Id(_tableId, "Name");
    name = fieldId2PName(_tableId, _fieldid);
    print name;
}
```

fieldName2Id

Retrieves the field ID of the table field that is specified by a table ID number and a field ID number.

```
int fieldName2Id(int tableid, str fieldname)
```

Parameters

PARAMETER	DESCRIPTION
tableid	The ID number of the table. **Note:** Use the **tableName2Id** function to specify the ID of a table.
fieldname	The name of the field.

Return value

The ID of the field that is specified by the *tableid* and *fieldname* parameters.

Example

```
static void fieldName2IdExample(Args _arg)
{
    int id;

    id = fieldName2Id(tableName2Id("Address"), "Name");
    // Returns 6. Name is the 6th field in the Address table.
    print id;
}
```

indexId2Name

Retrieves the name of an index.

```
str indexId2Name(int tableid, int indexid)
```

Parameters

PARAMETER	DESCRIPTION
tableid	The ID of the table that the index belongs to.
indexid	The ID of the index.

Return value

The name of the index.

Example

```
static void indexId2NameExample(Args _arg)
{
    str s;
    tableid id;
    indexid idx;

    id  = tableName2Id("Address");
    idx = indexName2Id(id, "AddrIdx");
    s = indexId2Name(id, idx);
    print "The result of calling indexId2Name is " + s;
}
```

indexName2Id

Retrieves the ID of an index.

```
int indexName2Id(int tableid, str indexname)
```

Parameters

PARAMETER	DESCRIPTION
tableid	The ID of the table that the index belongs to.
indexname	The name of the index.

Return value

The ID of the index.

Example

```
static void indexName2IdExample(Args _arg)
{
    indexid idx;
    tableid id;

    id  = tableName2Id("Address");
    idx = indexName2Id(id, "AddrIdx");
    print "Index ID for index name AddrIdx of table Address is " + int2Str(idx);
}
```

tableId2Name

Retrieves a string that contains the name of a table.

```
str tableId2Name(int _tableid)
```

Parameters

PARAMETER	DESCRIPTION
_tableid	The ID of the table.

Return value

The name of the table.

Example

```
static void tableId2NameExample(Args _arg)
{
    str s;
    tableid id;

    // Get the ID for table name Address.
    id = tableName2Id("Address");
    print "ID for table name Address is " + int2Str(id);

    // Get the name from the table ID.
    s = tableId2Name(id);
    print "Name for table ID " + int2Str(id) + " is " + s;

    // Get the printable name from the table ID.
    s = tableId2PName(id);
    print "Printable name for table ID " + int2Str(id) + " is " + s;
}
```

tableId2PName

Retrieves a string that contains the printable name (the label) of a table.

```
str tableId2PName(int _fieldid)
```

Parameters

PARAMETER	DESCRIPTION
_fieldid	The ID of the table.

Return value

The label of the table.

Example

```
static void tableId2NameExample(Args _arg)
{
    str s;
    tableid id;

    // Get the ID for table name Address.
    id = tableName2Id("Address");
    print "ID for table name Address is " + int2Str(id);

    // Get the name from the table ID.
    s = tableId2Name(id);
    print "Name for table ID " + int2Str(id) + " is " + s;

    // Get the printable name from the table ID.
    s = tableId2PName(id);
    print "Printable name for table ID " + int2Str(id) + " is " + s;
}
```

tableName2Id

Retrieves the ID of a table.

```
int tableName2Id(str _name)
```

Parameters

PARAMETER	DESCRIPTION
_name	The name of the table.

Return value

The ID of the table.

Example

```
static void tableName2IdExample(Args _arg)
{
    str s;
    tableid id;

    // Get the ID for the Address table name.
    id = tableName2Id("Address");
    print "ID for the Address table name is " + int2Str(id);

    // Get the name from the table ID.
    s = tableId2Name(id);
    print "Name for table ID " + int2Str(id) + " is " + s;

    // Get the printable name from the table ID.
    s = tableId2PName(id);
    print "Printable name for table ID " + int2Str(id) + " is " + s;
}
```

typeOf

Retrieves the type of an element.

```
enum typeOf(anytype _object)
```

Parameters

PARAMETER	DESCRIPTION
_object	The element to return the type for.

Return value

A **Types** system enumeration value.

Example

The following example tests whether the first element in a container, **c**, is another container that contains a single integer.

```
if(typeof(conpeek(c, 1)) != Types::Container ||
conlen(conpeek(c, 1)) != 1 ||
typeof(conpeek(conpeek(c, 1), 1)) != Types::Integer)
{
    // More code.
}
```

X++ session runtime functions

2/18/2021 • 5 minutes to read • Edit Online

This topic describes the session run-time functions.

curExt

Retrieves the extension that is used for the current company.

```
str curExt()
```

Return value

The extension for the current company.

Example

```
static void curExtExample(Args _arg)
{
    str s;
    // Sets s to the extension of the current company.
    s = curExt();
    print "Current extension is " + s;
}
```

curUserId

Retrieves the nonnumeric ID that represents the current user.

```
str curUserId()
```

Return value

The nonnumeric ID that represents the current user.

Example

```
static void curUserIdExample(Args _arg)
{
    str s;
    s = curUserId();
    print "Current user ID is " + s;
}
```

funcName

Retrieves a string that contains the current function context.

```
str funcName()
```

Return value

The name of the method that is executing this method.

Remarks

If execution is currently within the member of a table or class, the name of the method is prefixed with the name of that table or class.

Example

```
static void funcNameExample(Args _arg)
{
    print "Current function context is " + funcName();
}
```

getCurrentPartition

Retrieves the short name of the current partition.

```
str getCurrentPartition()
```

Return value

The short name of the current partition.

Remarks

The maximum length of the data partition name that is returned is eight characters.

Example

The following code example shows calls to, and output from, the **getCurrentPartition** function of the X++ language, and related functions or methods.

```
static public void Main(Args _args)  // X++ method.
{
    int64 iPartition;
    str sPartition;
    SelectableDataArea oSelectableDataArea;  // System ExDT.
    iPartition = getCurrentPartitionRecId();
    sPartition = getcurrentpartition();
    oSelectableDataArea = Global::getCompany( tableNum(BankAccountTable) );
    Global::info( strFmt(
            "getCurrentPartitionRecId =%1 , getCurrentPartition =%2 , getCompany =%3",
            iPartition, sPartition, oSelectableDataArea) );
}
/**** Pasted from Infolog window:
Message_@SYS14327 (03:42:38 pm)
getCurrentPartitionRecId =5637144576 , getCurrentPartition =initial , getCompany =ceu
****/
```

getCurrentPartitionRecId

Retrieves the **RecId** field of the current partition.

```
int64 getCurrentPartitionRecId()
```

Return value

The **RecId** field of the current data partition.

Remarks

To see a code example that relies on the **getCurrentPartitionRecId** function, see How to: Include a Filter for Partition in Direct Transact-SQL.

Example

The following code example shows calls to, and output from, the **getCurrentPartitionRecId** function of the X++ language, and related functions or methods.

```
static public void Main(Args _args)  // X++ method.
{
    int64 iPartition;
    str sPartition;
    SelectableDataArea oSelectableDataArea;  // System ExDT.
    iPartition = getCurrentPartitionRecId();
    sPartition = getcurrentpartition();
    oSelectableDataArea = Global::getCompany( tableNum(BankAccountTable) );
    Global::info( strFmt(
            "getCurrentPartitionRecId =%1 , getCurrentPartition =%2 , getCompany =%3",
            iPartition, sPartition, oSelectableDataArea) );
}
/**** Pasted from Infolog window:
Message_@SYS14327 (03:42:38 pm)
getCurrentPartitionRecId =5637144576 , getCurrentPartition =initial , getCompany =ceu
****/
```

getPrefix

Retrieves the current execution prefix after successive calls to the **setPrefix** function.

```
str getPrefix()
```

Return value

The current execution prefix.

Remarks

The prefix mechanism makes it more straightforward to write precise error messages about the transactions that an application performs. Because a hierarchical display is created in the Infolog, it can be easier to determine where each error came from.

Example

```
static void getPrefixExample(Args _arg)
{
    setPrefix("Prefix");
    setPrefix("Another prefix");
    print getPrefix();
}
```

sessionId

Retrieves the session number of the current session.

```
int sessionId()
```

Return value

The numeric ID of the current session.

Remarks

A session number is assigned when the client is started and connects to Application Object Server (AOS). Every call of this function during the life of the client returns the same integer value. The returned value is compatible with the **SessionID** extended data type. The **contains** methods return information about individual user sessions.

Example

```
static void sessionIdExample(Args _arg)
{
    int session;
    session = sessionId();
    print "This session ID is number " + int2Str(session);
}
```

prmIsDefault

Determines whether the specified parameter for the current method has the default value.

```
int prmIsDefault(anytype argument)
```

Parameters

PARAMETER	DESCRIPTION
Argument	The parameter to test.

Return value

1 if the default value for the parameter was used; otherwise, **0** (zero).

Example

```
static void prmIsDefaultExample(Args _arg)
{
    void fn(boolean b = true, int j = 42)
    {
        if (prmIsDefault(b) == 1)
        {
            print "First parameter is using the default value.";
        }
        else
        {
            print "First parameter is not using the default value.";
        }
    }
    fn();
    fn(false);
}
```

runAs

Enables the caller to run an X++ method in the security context of another user. This function is most often used with batch processing.

```
container runAs(
    str userId,
    int classId,
    str staticMethodName
    [,
    container params,
    str company,
    str language,
    str partition
    ])
```

Parameters

PARAMETER	DESCRIPTION
userId	The user to impersonate.
classId	The class to invoke in the impersonated session.
staticMethodName	The class method to invoke in the new user context.
params	The parameters to pass to the method; optional.
company	The company that is selected for the impersonated session; optional.
language	The language that is selected for the impersonated session; optional.
partition	The partition key of the type that is returned by the **getCurrentPartition** function; optional.

Return value

A container that holds the return value or values of the method that is called by the **runAs** function, if any values were returned.

Remarks

This function makes it possible to run code as another user. This capability presents a security threat. Therefore, this function runs under Code Access Security. Calls to this function on the server require permission from the **RunAsPermission** class. Each use of this application programming interface (API) should be threat-modeled. If a security vulnerability is discovered, validate input to this API. The debugger might ignore breakpoints that are located in a method that is called by using the **runAs** function. X++ code that is executed by the **runAs** function must run as Microsoft .NET Framework Common Intermediate Language (CIL). If CIL hasn't been generated for the target static method, an error message indicates that the method isn't found. The **PartitionKey** system type is the exact type of the *partition* parameter. **PartitionKey** is a string that has a maximum length of eight characters.

Example

The following example calls the **runDueDateEventsForUser** method in the **EventJobDueDate** class. The code runs in the security context of a user. Run this code by applying it to a method in a new class.

```
server static public void Main(Args _args)
{
    RunAsPermission perm;
    UserId runAsUser;
    SysUserInfo userInfo;
    userInfo = SysUserInfo::find();
    runAsUser = userInfo.Id;
    perm = new RunAsPermission(runAsUser);
    perm.assert();
    runAs(runAsUser, classnum(EventJobDueDate), "runDueDateEventsForUser");
    CodeAccessPermission::revertAssert();
}
```

setPrefix

Sets the prefix for the current execution scope.

```
int setPrefix(str _prefix)
```

Parameters

PARAMETER	DESCRIPTION
_prefix	The prefix for the current execution scope.

Return value

0 if the prefix was set successfully.

Remarks

The complete prefix for the execution can be fetched by using the **getPrefix** function. When the scope is left, the prefix is automatically reset to the previous level. The prefix mechanism makes it more straightforward to write precise error messages about the transactions that an application performs. For example, the **AA** method calls the **BB** method, and each method calls the **setPrefix** function. Messages that the **BB** method writes to the Infolog appear nested in a hierarchy. When the **BB** method ends, and control returns to the **AA** method, the prefix that was set by the **BB** method isn't attached to subsequent messages.

Example

```
static void setPrefixExample(Args _arg)
{
    int i;
    i = setPrefix("Prefix");
    print i;
}
```

X++ string runtime functions

2/18/2021 • 14 minutes to read • Edit Online

This topic describes the string run-time functions.

match

Searches for a string or expression in another string.

```
int match(str pattern, str text)
```

Parameters

PARAMETER	DESCRIPTION
pattern	The string or expression to search for.
text	The string to search.

Return value

1 if the pattern is located in the string; otherwise, **0** (zero).

Remarks

The search is case-insensitive. The following special characters can be used to create the pattern for the *pattern* parameter.

- ****: A backslash (\) nullifies, or escapes, the special treatment of special characters, so that a special character can be matched like a normal letter. A pair of backslashes is translated into one non-special backslash. Examples:
  - **match("ab$cd","ab$cd");** returns **0**.
  - **match("ab\$cd","ab$cd");** returns **0**. The backslash isn't escaped.
  - **match("ab\\$cd","ab$cd");** returns **1**. The backslash and dollar sign are escaped.
- **< or ^**: A left angle bracket (<) or a circumflex (^) at the start of an expression is used to match the start of a line. Examples:
  - **match("<abc","abcdef");** returns **1**.
  - **match("<abc","defabc");** returns **0**.
  - **match("^abc","abcdef");** returns **1**.
  - **match("^abc","defabc");** returns **0**.
- **> or $**: A right angle bracket (>) or a dollar sign ($) at the end of the expression is used to match the end of a line. Examples:
  - **match("abc>","abcdef");** returns **0**.
  - **match("abc>","defabc");** returns **1**.
- **? or .**: A question mark (?) or a period (.) matches any one character in the same position. Examples:
  - **match("abc.def","abc#def");** returns **1**.
  - **match("colou?r","colouXr");** returns **1**.

- **:x**: A colon (:) specifies a group of characters to match, as indicated by the character that immediately follows.
- **:a**: Sets the match to letters. Examples:
  - **match("ab:acd","ab#cd");** returns **0**.
  - **match("ab:acd","abxyzcd");** returns **0**.
  - **match("ab:acd","abxcd");** returns **1**.
- **:d**: Sets the match to numeric characters. Examples:
  - **match("ab:dcd","ab3cd");** returns **1**.
  - **match("ab:dcd","ab123cd");** returns **0**.
  - **match("ab:dcd","abcd");** returns **0**.
- **:n**: Sets the match to alphanumeric characters. Examples:
  - **match("ab:ncd","ab%cd");** returns **0**.
  - **match("ab:ncd","ab9cd");** returns **1**.
  - **match("ab:ncd","abXcd");** returns **1**.
- **:SPACE**: SPACE is the space character (" "). Sets the match to blanks, tabulations, and control characters such as Enter (new line). Examples:
  - **match("ab: cd","ab cd");** returns **1**.
  - **match("ab: cd","ab\ncd");** returns **1**.
  - **match("ab: cd","ab\tcd");** returns **1**.
  - **match("ab: cd","ab cd");** returns **0**. Only the first space is matched.
- *****: An expression that is followed by an asterisk ("*") requires a match for zero, one, or more occurrences of the preceding expression. Examples:
  - **match("abc*d","abd");** returns **1**.
  - **match("abc*d","abcd");** returns **1**.
  - **match("abc*d","abcccd");** returns **1**.
  - **match("abc*d","abxd");** returns **0**.
- **+**: An expression that is followed by a plus sign (**+**) requires a match for one or more occurrences of the preceding expression. Examples:
  - **match("abc+d","abd");** returns **0**.
  - **match("abc+d","abcd");** returns **1**
  - **match("abc+d","abcccd");** returns **1**.
  - **match("abc+d","abxd");** returns **0**.
- **-**: An expression that is followed by a minus sign (**-**) requires a match for zero or one occurrence of the preceding expression. In other words, the preceding expression is optional. Examples:
  - **match("colou-r","color");** returns **1**.
  - **match("colou-r","colour");** returns **1**.
- **[]**: Matches a single character with any character that is enclosed in the brackets. A range of characters can be specified by two characters that are separated by a minus sign (-). For example, **[a-z]** matches all letters between a and z, **[0-9]** matches a digit, and **[0-9a-f]** matches a hexadecimal digit. Examples:
  - **match("[abc]","apple");** returns **1**, because it matches the a in "apple."
  - **match("[abc]","kiwi");** returns **0**, because "kiwi" doesn't contain an a, b, or c.
  - **match("gr[ae]y","grey");** returns 1. This expression also matches "gray."
  - **match("gr[ae]y","graey");** returns **0**, because only one character between "gr" and "y" is matched.

- **[^]**: If the first character in the text that is enclosed in brackets is a circumflex (**^**), the expression matches all characters except the characters that are enclosed in the brackets. Examples:
  - **match("[^bc]at","bat");** returns **0**.
  - **match("[^bc]at","hat");** returns **1**.
  - **match("[^abc]","bat");** returns **1**. Anything except a, b, or c is matched. Therefore, the t is matched.

strAlpha

Copies only the alphanumeric characters from a string.

```
str strAlpha(str _text)
```

Parameters

PARAMETER	DESCRIPTION
_text	The string to copy from.

Return value

A new string that contains all the alphanumeric characters from the specified string.

Remarks

For example, **strAlpha("2+2=5 is this correct?")** returns the string **225isthiscorrect**.

Example

```
static void strAlphaExample(Args _arg)
{
    str s;
    ;
    s = strAlpha("?a*bc123.");
    print s;
    pause;
}
```

strCmp

Compares two text strings.

```
int strCmp(str text1, str text2)
```

Parameters

PARAMETER	DESCRIPTION
text1	The first string.
text2	The second string.

Return value

0 if the two strings are identical, **1** if the first string sorts earlier, or **-1** if the second string sorts earlier.

Remarks

The comparison performed by this method is case-sensitive.

```
print strCmp("abc", "abc"); //Returns the value 0.
print strCmp("abc", "ABC"); //Returns the value 1.
print strCmp("aaa", "bbb"); //Returns the value -1.
print strCmp("ccc", "bbb"); //Returns the value 1.
```

strColSeq

Converts all uppercase characters to lowercase characters, and converts all characters that have accents to the corresponding unaccented lowercase characters.

```
str strColSeq(str text)
```

Parameters

PARAMETER	DESCRIPTION
text	The string to copy and convert characters from.

Return value

The converted text string.

Remarks

The **strColSeq** function exists for backward-compatibility purposes. This function supports only the mapping for the following Western European characters:

- AàáâãäÀÁÂÃÄBCçÇDEèéêëÈÉÊËFGHIìíîïÌÍÎÏJKLMNñÑOòóôõöÒÓÔÕÖPQRSTUùúûüÙÚÛÜVWXYýÝZæøåÆØÅ
- aaaaaaaaaaabcccdeeeeeeeeefghiiiiiiiiijklmnnnooooooooooopqrstuuuuuuuuuvwxyyyz~¦Ç~¦Ç

For Unicode-compliant functionality, use the Win32 LCMapString application programming interface (API) via the **DLL** and **DLLFunc** classes.

Example

The following example prints **abcdeabcde**.

```
    static void strColSeqExample(Args _arg)
    {
            ;
            print strColSeq("");
            pause;
    }
```

strDel

Creates a copy of a string, from which the specified substring is removed.

```
str strDel(str _text, int _position, int _number)
```

Parameters

PARAMETER	DESCRIPTION
_text	The string to copy from.
_position	The position at which to begin ignoring characters during the copy operation.
_number	The number of characters to ignore. A minus sign in front of the *_number* parameter indicates that *_number*–1 characters before the character at *_position* should be removed together with the character at *_position*.

Return value

The remaining characters that are copied from the string.

Remarks

The **strDel** function is complementary to the **substr** function.

```
strDel("ABCDEFGH",2,3); //Returns the string "AEFGH".
strDel("ABCDEFGH",4,3); //Returns the string "ABCGH".
```

strFind

Searches a string for the first occurrence of one of the specified characters.

```
int strFind(str _text, str _characters, int _position, int _number)
```

Parameters

PARAMETER	DESCRIPTION
_text	The string to search.
_characters	The characters to search for.
_position	The position in the string where the search begins.
_number	A signed number that indicates the direction of the search and how many positions to search in the string.

Return value

The value of the position of the first occurrence of one of the specified characters.

Remarks

To search from the beginning of the string to the end, use **1** as the value of the *_position* parameter. If the value of the *_number* parameter is negative, the system searches the number of characters backward from the specified position. The search isn't case-sensitive. Here is an example.

```
strFind("ABCDEFGHIJ","KHD",1,10); //Returns the value 4 (the position where "D" was found).
strFind("ABCDEFGHIJ","KHD",10,-10); //Returns the value 8 (the position where "H" was found).
```

The **strFind** function is complementary to the **strNFind** function.

strFmt

Formats the specified string and substitutes any occurrences of n with the nth argument.

```
str strFmt(str _string, ...)
```

Parameters

PARAMETER	DESCRIPTION
_string	The strings to format.

Return value

The formatted string.

Remarks

If an argument isn't provided for a parameter, the parameter will be returned as "%n" in the string. The string conversion of values of the **real** type is limited to two decimal places. Values are rounded, not truncated. The **System.String::Format** method from the Microsoft .NET Framework can be used to gain additional functionality, as shown in the example.

Example

```
static void strFmtExampleJob(Args _arg)
{
    System.Double sysDouble;
    real r = 8.3456789;
    int  i = 42;
    utcDateTime utc = str2DateTime("2008-01-16 13:44:55" ,321); // 321 == YMD.
    str  s;
    ;
    s = strFmt("real = %1, int = %2, utcDateTime = %3, [%4]", r, i, utc);
    info("X1:  " + s);
    //
    sysDouble = r;
    s = System.String::Format("{0:##.####}", sysDouble);
    info("N1:  " + s);
    //
    s = System.String::Format("{0,6:C}", sysDouble); // $
    info("N2:  " + s);
    /**********  Actual Infolog output
    Message (02:16:05 pm)
    X1:  real = 8.35, int = 42, utcDateTime = 1/16/2008 01:44:55 pm, [%4]
    N1:  8.3457
    N2:   $8.35
    **********/
}
```

strIns

Builds a string by inserting one string into another.

```
str strIns(str _text1, str _text2, int _position)
```

Parameters

PARAMETER	DESCRIPTION
_text1	The string to insert the other string into.
_text2	The string to insert into the other string.
_position	The position where the first character of the *_text2* parameter should occur in the output string.

Return value

The combined text string.

Remarks

The **strIns** function is complementary to the **strDel** function. If the value of the *_position* parameter is more than the length of the original string, the string to insert is appended to the end of the original string.

```
strIns("ABFGH","CDE",3); //Returns the string "ABCDEFGH".
strIns("ABCD","EFGH",10); //Returns the string "ABCDEFGH".
```

strKeep

Builds a string by using only the characters from the first input string that the second input string specifies should be kept.

```
str strKeep(str _text1, str _text2)
```

Parameters

PARAMETER	DESCRIPTION
_text1	The string that contains the characters that can be used to build an output string.
_text2	The string that specifies which characters to keep for the output string.

Return value

A string of the characters that are kept.

Remarks

```
strKeep("ABBCDDEFGHB","BCD"); //Returns the string "BBCDDB".
strKeep("abcZcba","bc") //Returns the string "bccb".
```

The **strKeep** function is complementary to the **strRem** function.

strLen

Calculates the length of the specified string.

```
int strLen(str text)
```

Parameters

PARAMETER	DESCRIPTION
text	The string to calculate the length of.

Return value

The length of the specified string.

Remarks

```
strLen("ABC"); //Returns the value 3.
strLen("ABCDEFGHIJ"); //Returns the value 10.
```

strLine

Retrieves a single line from a string that spans multiple lines.

```
str strLine(str string, int count)
```

Parameters

PARAMETER	DESCRIPTION
string	A string that might span multiple lines.
count	The offset of the line to return.

Return value

A copied line of the string that is specified by the *string* parameter.

Remarks

The first line of the string has an offset of 0. You can assign multiple lines to one string by embedding the *\n* or *\r\n* characters in the string. Additionally, you can use the at sign (@) immediately before the opening quotation mark and use the Enter key to spread parts of the string value over multiple lines in the X++ code editor.

Example

```
str mytxt = "first-line\nsecond-line\nlast-line";
// Prints "second-line".
print strLine(mytxt,1);
// Prints "last-line".
print strLine(mytxt,2);
```

strLTrim

Removes leading blanks from a text string.

```
str strLTrim(str text)
```

Parameters

PARAMETER	DESCRIPTION
text	The string to delete the leading blanks from.

Return value

The string equivalent for the text that leading blanks have been removed from.

Remarks

The **strLTrim** function is complementary to the **strRTrim** function.

Example

```
// Returns the text string "ABC-DEFG".
strLTrim("   ABC-DEFG");
```

strLwr

Converts all letters in the specified string to lowercase.

```
str strLwr(str _text)
```

Parameters

PARAMETER	DESCRIPTION
_text	The string to convert to lowercase.

Return value

A copy of the specified string that contains only lowercase letter.

Remarks

The **strLwr** function is complementary to the **strUpr** function. The **strLwr** function uses the **LCMapString** function in the Win32 API.

Example

```
static void strLwrExample(Args _args)
{
    // Returns the text string "abcdd55efghij".
    print strLwr("Abcdd55EFGHIJ");
    pause;
}
```

strNFind

Searches part of a text string for the first occurrence of a character that isn't included in the specified list of characters.

```
int strNFind(str _text, str _characters, int _position, int _number)
```

Parameters

PARAMETER	DESCRIPTION
_text	The text string to search.
_characters	The list of characters to exclude from the search.
_position	The position in the string at which to begin the search.
_number	A signed number that indicates the direction of the search and how many positions to search. If a minus sign precedes *_number*, the system searches *_number* characters in reverse order from *_position*.

Return value

The position of the first occurrence of a character that isn't specified by the *_characters* parameter.

Remarks

The search isn't case-sensitive. To search from the beginning of the string to the end, use a value of **1** for the *_position* parameter. If a minus sign precedes the value of the *_number* parameter, the characters will be searched in reverse order, starting from the position that is specified by the *_position* parameter.

```
strNFind("ABCDEFGHIJ","ABCDHIJ",1,10); //Returns the value 5 (the position of "E");
strNFind("CDEFGHIJ","CDEFGIJ",10,-10); //Returns the value 6 (the position of "H").
strNFind("abcdef","abCdef",3,2) //Returns the value 0.
strNFind("abcdef", "abcef",3,2) //Returns the value 4.
```

The **strNFind** function is complementary to the **strFind** function.

strPoke

Overwrites part of a string with another string.

```
str strPoke(str _text1, str _text2, int _position)
```

Parameters

PARAMETER	DESCRIPTION
_text1	The original string.
_text2	The string to replace part of the original string with.
_position	The position of the original string at which to begin replacing the characters.

Return value

The new string.

Remarks

The new string can be longer than the original string. However, if the value of the *_position* parameter is more than the length of the string, the original string is returned without replacements.

```
strPoke("12345678","AAA",3); //Returns the string "12AAA678".
strPoke("abcde","4567",4); //Returns the string "abc4567".
strPoke("abcde", "4567", "10"); //Returns the string "abcde".
```

strPrompt

Appends a string with the specified number of period characters, followed by a colon and space character.

```
str strPrompt(str _string, _int len)
```

Parameters

PARAMETER	DESCRIPTION
_string	The original string.
_len	The desired final length of the string.

Return value

A string that looks like a prompt for user input.

Remarks

In atypical cases, where the value of the *_len* parameter is only slightly more than the length of the original string, the highest precedence is given to adding the trailing space. Next, precedence is given to the colon. The lowest precedence is given to the periods. Negative values for the *_len* parameter return the input string appended with a trailing space.

```
strPrompt("ab",-1); //Returns "ab ".
strPrompt("ab",3); //Returns "ab ".
strPrompt("ab",4); //Returns "ab: ".
strPrompt("ab",5); //Returns "ab.: ".
strPrompt("ab",6); //Returns "ab..: ".
```

Example

```
static void JobStrPromptDemo(Args _args)
{
    // Printed string is "[abc..: ]"
    print "[", strPrompt("abc", 7), "]";
    pause;
}
```

strRem

Removes the characters that are specified in one string from another string.

```
str strRem(str text1, str text2)
```

Parameters

PARAMETER	DESCRIPTION
text1	The string to remove characters from.
text2	The characters to exclude from the output string.

Return value

The remaining content of the original string.

Remarks

This function is case-sensitive.

```
strRem("abcd_abcd","Bc"); //Returns the string "abd_abd".
strRem("ABCDEFGABCDEFG","ACEG"); //Returns the string "BDFBDF".
```

This function is complementary to the **strKeep** function.

strRep

Repeats a string of characters.

```
str strRep(str _text, str _number)
```

Parameters

PARAMETER	DESCRIPTION
_text	The string to repeat.
_number	The number of times to repeat the string.

Return value

A new string that contains the contents of the original string that are repeated the specified number of times.

Example

The following example prints the text string **ABABABABABAB**.

```
static void strRepExample(Args _arg)
{
    str strL;
    ;
    strL = strRep("AB",6);
    print strL;
    pause;
}
```

strRTrim

Removes the trailing space characters from the end of a string.

```
str strRTrim(str _text)
```

Parameters

PARAMETER	DESCRIPTION
_text	The string to remove the trailing space characters from .

Return value

A copy of the specified string that doesn't include trailing space characters.

Remarks

```
strRTrim("ABC-DEFG- "); //Returns the string "ABC-DEFG-".
strRTrim(" CD "); //Returns " CD".
```

The **strRTrim** function is complementary to the **strLTrim** function.

strScan

Searches a text string for an occurrence of another string.

```
int strScan(str _text1, str _text2, int _position, int _number)
```

Parameters

PARAMETER	DESCRIPTION
_text1	The string to search in.
_text2	The string to find.
_position	The first position in the *_text1* parameter at which to perform a comparison.
_number	The number of positions in the *_text1* parameter to retry the comparison for. If a minus sign precedes the *_number* parameter, the system searches the number of characters in reverse order from the specified position.

Return value

The position at which the specified string was found in the string; otherwise, **0** (zero).

Remarks

The comparisons aren't case-sensitive. Values for the *_position* parameter that are less than **1** are treated as **1**. The direction of the scan is controlled by the sign that is specified in the *_number* parameter. A positive sign indicates that each successive comparison will start one position closer to the end of the string. A negative sign indicates that each comparison will start one position closer to the start of the string.

```
strScan("ABCDEFGHIJ","DEF",1,10); //Returns the value 4.
strScan ("ABCDEFGHIJ","CDE",10,-10); //Returns the value 3.
```

strUpr

Converts all the letters in a string to uppercase.

```
str strUpr(str _text)
```

Parameters

PARAMETER	DESCRIPTION
_text	The string to convert to uppercase letters.

Return value

A copy of the specified string that contains only lowercase letters.

Remarks

The **strUpr** function is complementary to the **strLwr** function. The **strUpr** function uses the **LCMapString()** function in the Win32 API.

Example

The following example will print **ABCDD55EFGHIJ**.

```
static void strUprExample(Args _args)
{
    print strUpr("Abcdd55EFGhiJ");
    pause;
}
```

subStr

Retrieves part of a string.

```
str subStr(str _text, int _position, int _number)
```

Parameters

PARAMETER	DESCRIPTION
_text	The original string.
_position	The position in the original string where the part to retrieve begins.
_number	A signed integer that indicates the direction and number of positions to retrieve from the original string. If a minus sign precedes *_number*, the system selects the substring backward from the specified position.

Return value

A substring of the original string.

Remarks

If a minus sign precedes the value of the *_number* parameter, the substring will be selected backward from the specified position.

```
subStr("ABCDEFGHIJ",3,5); //Returns the string "CDEFG".
subStr("ABCDEFGHIJ",7,-4); //Returns the string "DEFG".
subStr("abcdef"),2,99) //Returns the string "cdef".
subStr("abcdef",2,3) //Returns the string "bcd".
subStr("abcdef",2,-3); //Returns the string "ab".
```

System tables

2/18/2021 • 79 minutes to read • Edit Online

This topic describes the system tables.

Common

The Common table is the base class for all tables. It does not contain any data. It is primarily used in X++ code to refer to any table in a polymorphic way.

Methods

METHOD	DESCRIPTION
aosValidateDelete	Validates on the server that the specified record can be deleted from a table.
aosValidateInsert	Validates on the server that the specified record can be inserted.
aosValidateRead	Validates on the server that the specified record can be read.
aosValidateUpdate	Validates on the server that the specified record can be updated.
buf2con	Packs the table buffers of an xRecord instance into an X++ container.
canSubmitToWorkflow	Indicates whether submission to workflow is possible.
caption	Gets and sets the caption property of a table.
checkInvalidFieldAccess	Gets and sets invalid field access.
checkRecord	Gets and sets the property that indicates whether to check mandatory fields.
checkRestrictedDeleteActions	Gets and sets the property that indicates whether a record can be deleted.
clear	Removes all rows from the table buffer.
company	Gets and sets the property that indicates a legal entity for the record.
con2buf	Unpacks a container into the table buffers.
concurrencyModel	Gets and sets the default concurrency model to use to update records.
context	Gets and sets the context property.

METHOD	DESCRIPTION
data	Retrieves a row from the table.
dataSource	Retrieves the data source of the table.
dbOpInTransaction	Makes sure that database operations are correctly closed if they fail.
defaultField	Populates default values in a field in the table.
defaultRow	Populates default values in fields in the table in the non-interactive case.
delete	Deletes the current record from the table.
disableCache	Gets and sets the property that indicates whether caching is disabled.
dispose	Releases resources that are used by the xRecord object.
doClear	Removes all rows from the table buffer and bypasses any additional logic in the clear method of the table.
doDelete	Deletes the current record from the table and bypasses any additional logic in the delete method of the table.
doInsert	Inserts the record into the table and bypasses any additional logic in the insert method of the table.
doUpdate	Updates the current record and bypasses any additional logic in the update method of the table.
doValidateDelete	Performs the action to validate that a record can be deleted.
equal	Determines whether the specified object is equal to the current one.
fieldAccessRight	Returns the field access right.
fieldBufferAccessRight	Returns the field access right for the current record.
fieldState	Sets or returns the state of a field in the table buffer.
getAllowRedefault	Returns the list of fields that are allowed to re-default.
getDefaultingDependencies	Returns the container that holds defaulting dependencies.
getExtension	Returns the table extension.
getFieldValue	Gets the value of the specified field from a table buffer.
getInstanceRelationType	Returns the table name that corresponds to the InstanceRelationType ID.

METHOD	DESCRIPTION
getPhysicalTableName	Return the physical table name, which, in the case of the SQL Temp DB table, is the table instance name.
getPresenceFieldData	Retrieves the PresenceInfo value from the specified field.
getSQLStatement	Gets the SQL statement that is used to return records from the database.
getTableInInstanceHierarchy	
getTableType	Indicates the type of the table.
helpField	Retrieves a string that contains the Help text for the specified field.
initValue	Initializes a field to the default value.
inputStatus	Sets or returns the current input status of the table buffer.
insert	Inserts the record into the table.
interactiveContext	Sets or returns the current interactive context of the table buffer.
isFieldDataRetrieved	Checks whether the data of the given field has been retrieved.
isFieldSet	Checks whether a field has a Set or Defaulted state.
isFormDataSource	Indicates whether the data source is a form.
isNewRecord	Returns true if the record is a new record that hasn't been persisted yet.
isPartOfUOWSaveChanges	
isTempDb	Indicates whether the type of the table is SQL TempDB.
isTmp	Indicates whether this is a temporary table.
joinChild	Finds the join child of the current record.
joinParent	Finds the join parent of the current record.
linkPhysicalTableInstance	Checks whether there is a link for the physical table instance for the record.
merge	Merges the current table with the specified table.
modifiedField	Modifies the specified field to the original.

METHOD	DESCRIPTION
modifiedFieldValue	Modifies the specified field to the original value.
orig	Retrieves the original values of the current record.
overwriteSystemfields	Gets and sets the property that indicates whether system fields can be overwritten.
postLoad	Is executed after a record is read.
queryTimedOut	Indicates whether the query exceeded the time limit for execution.
queryTimeout	Gets and sets the property that indicates the time limit for the execution of a query.
readCommittedLock	
readPast	Gets and sets the property that indicates whether to skip rows that are locked by other processes when a record is read.
recordLevelSecurity	Gets and sets the property that indicates whether to apply security on a record level.
relatedTable	Sets or returns the related buffer of a link of a table buffer.
hasRelatedTable	Indicates whether a foreign key constraint buffer is linked with the table.
renamePrimaryKey	Renames the foreign keys in other tables according to the change of the corresponding primary key value in this table.
reread	Rereads the record from the table.
RowCount	Retrieves the number of rows in the table.
selectForUpdate	Gets and sets the property that indicates whether to select records for update when they are read.
selectLocked	Indicates whether to select locked records.
selectRefRecord	Selects the record by referenced field ID.
selectWithRepeatableRead	Gets and sets the property that indicates whether repeatable read is enabled.
setConnection	Sets the user connection for this table.
setCrossPartition	Sets or resets cross-partitioning for the table.
setFieldValue	Sets the field value in the record buffer.

METHOD	DESCRIPTION
setSQLTracing	Enables or disables SQL tracing mode.
setTempDB	
setTmp	Sets the table so that it is not persisted to the database.
setTmpData	Sets the contents of the temporary table to the specified data.
setXDSContext	Sets new XDS context.
skipDatabaseLog	Gets and sets the property that indicates whether to skip database log requests.
skipDataMethods	Gets and sets the property that indicates whether to discard overloaded methods.
skipDeleteActions	Gets and sets the property that indicates whether to skip delete actions on the table.
skipDeleteMethod	Gets and sets the property that indicates whether to discard overloaded methods.
skipEvents	Provides an option to turn off calling the Application.event* methods for the lifetime of an xRecord object.
skipPostLoad	Gets and sets the property that indicates whether to skip executing the xRecord.postLoad method on the table.
skipTTSCheck	Gets and sets the property that indicates whether to skip the check to determine whether the record is selected for update.
suppressWarnings	Gets and sets the property that indicates whether to suppress warnings for this pointer.
tableAccessRight	Returns the table access right.
tableBufferAccessRight	Returns the table access right for the current record.
toolTipField	Retrieves the HelpText value for the specified field.
toolTipRecord	Retrieves the ToolTip value for the current record.
ttsabort	Aborts a transaction that was started by a call to the ttsbegin method.
ttsbegin	Starts a transaction that can be either committed by the ttscommit method or aborted by the ttsabort method.
ttscommit	Commits a transaction that was started by a call to the ttsbegin method.

METHOD	DESCRIPTION
update	Updates the current record.
validateDelete	Determines whether the current record is valid and ready to be deleted from the database.
validateField	Determines whether the specified field is valid.
validateFieldValue	
validateRelations	
validateWrite	Determines whether the current record is valid and ready to be written.
validTimeStateUpdateMode	Sets a valid time state update mode on the cursor.
wasCached	Specifies the location from which the data was retrieved.
write	Updates a record if it exists; otherwise, inserts a record.
xml	Retrieves an XML string that represents the current object.
takeOwnershipOfTempDBTable	
useExistingTempDBTable

The SysSetbasedHelper framework helper table for table inheritance set-based operations.

Fields

FIELD	TYPE	EXTENDED TYPE	ENUMERATION TYPE	DESCRIPTION
CandidateRecId	Int64	RecId		Unique ID for the record in the database

FIELD	TYPE	EXTENDED TYPE	ENUMERATION TYPE	DESCRIPTION
RecId	Int64	RecId		
recVersion	Integer	RecVersion		

Indexes

INDEX	ALLOW DUPLICATES	FIELDS
CandidateRecIDIdx	No	
RecIDIdx	No	

Inheritance Hierarchy

xRecord Class Common Table SysSetbasedHelper Table

SystemSequences

The SystemSequences table holds the next available record ID block for each table.

Fields

FIELD	TYPE	EXTENDED TYPE	ENUMERATION TYPE	DESCRIPTION
cycle	Enum		boolean	
dataAreaId	String	DataAreaId		
id	Int			
maxVal	Int64	RecId		Unique ID for the record in the database
minVal	Int64	RecId		Unique ID for the record in the database
name	String			
nextVal	Int64	RecId		Unique ID for the record in the database
RecId	Int64	RecId		
recVersion	Integer	RecVersion		
tabId	Integer	TableId		ID for the table

Relations

RELATION	TABLE
dataAreaId	DataArea

Indexes

INDEX	ALLOW DUPLICATES	FIELDS
Id	No	

Security Note

Use of this table could lead to an Elevation of Privileges attack or a Denial of Service attack. Therefore, the AOSAuthorization property is set to an enumeration value of CreateUpdateDelete. The Application Object Server authorizes each create, update, and delete action on the table by confirming that the current user has permission to perform the requested operation on that table. If the user who initiates the operation is not authorized to perform the operation, an exception occurs.

Inheritance Hierarchy

xRecord Class Common Table SystemSequences Table

TableCollectionList

The TableCollectionList table stores the mapping between table collections and virtual companies.

Fields

FIELD	TYPE	EXTENDED TYPE	ENUMERATION TYPE	DESCRIPTION
Partition	Int64	Partition		(This field applies only to the following version(s): Microsoft Dynamics AX 2012 R3, Microsoft Dynamics AX 2012 R2 (SYS))
RecId	Int64	RecId		
recVersion	Integer	RecVersion		
tableCollection	String	UtilElementName		Name of the application element.
virtualDataArea	String	VirtualDataArea		ID for a virtual company

Relations

RELATION	TABLE

RELATION	TABLE
Relation_CollectionList1	UtilElements
Relation_CollectionList2	DataArea

Indexes

INDEX	ALLOW DUPLICATES	FIELDS
VirtualDataArea	No	

Security Note

Use of this table could lead to an Elevation of Privileges attack or a Denial of Service attack. Therefore, the AOSAuthorization property is set to an enumeration value of CreateUpdateDelete. The Application Object Server authorizes each create, update, and delete action on the table by confirming that the current user has permission to perform the requested operation on that table. If the user who initiates the operation is not authorized to perform the operation, an exception occurs.

Inheritance Hierarchy

xRecord Class Common Table TableCollectionList Table

TimeZonesList

The TimeZonesList table contains the list of the time zones that are supported.

Fields

FIELD	TYPE	EXTENDED TYPE	ENUMERATION TYPE	DESCRIPTION
EnumName	String			
EnumPosition	Int			
RecId	Int64	RecId		
recVersion	Integer	RecVersion		
TimeZoneKeyName	String			
TzEnum	Enum		Timezone	

Indexes

INDEX	ALLOW DUPLICATES	FIELDS
EnumPosition	No	
TzEnum	No	

Security Note

Use of this table could lead to an Elevation of Privileges attack or a Denial of Service attack. Therefore, the AOSAuthorization property is set to an enumeration value of CreateUpdateDelete. The Application Object

Server authorizes each create, update, and delete action on the table by confirming that the current user has permission to perform the requested operation on that table. If the user who initiates the operation is not authorized to perform the operation, an exception occurs.

Inheritance Hierarchy

xRecord Class Common Table TimeZonesList Table

TimeZonesRulesData

The TimeZonesRulesData table contains the GMT offsets and daylight saving time information for all time zones that are supported.

Fields

FIELD	TYPE	EXTENDED TYPE	ENUMERATION TYPE	DESCRIPTION
Bias	Int			
DBias	Int			
DDay	Int			
DDayOfWeek	Int

Extensibility home page

2/18/2021 • 3 minutes to read • Edit Online

Dynamics 365 Finance, Supply Chain, and Commerce are extensively customized by partners, value added resellers (VARs), and even some customers. The ability to customize the product is a strength that has historically been supported through overlayering of the application code. The move to the cloud, together with more agile servicing and frequent updates, requires a less intrusive customization model, so that updates are less likely to affect custom solutions. This new model is called *extensibility* and has replaced customization through overlayering.

Extensibility is the only customization framework in Finance, Supply Chain, and Commerce. Overlayering isn't supported.

Introduction

These introductory topics contain general information about customization. This information includes information about when the transition occurs from customization through overlayering to a purely extension-based model. These topics also explain how to log extensibility requests to Microsoft, and provide answers to frequently asked questions (FAQ).

- Application extensibility plans
- Extensibility requests
- Extensibility FAQ

What's new

Read What's new or changed for extensibility for extensibility-related updates that have been made since July 2017.

Getting started

The topics in this section will help you start to build extensions. They will also help you migrate solutions that are currently based on overlayered code to extension-based solutions. This section includes hands-on labs that walk you through simple customizations.

- Migrate from overlayering to extensions
- Customize model elements through extension
- Customize through extension and overlayering

Fundamentals on extensions

This section includes fundamentals, principles, and practices for making extensions. The guiding principles in these topics discuss how customization must be approached through extensions. These principles include naming guidelines. Additionally, these topics discuss the foundation framework, such as extensions and chain of command.

- Intrusive customizations
- Class extension model in X++
- Class extension - Method wrapping and Chain of Command
- Naming guidelines for extensions

- Relax model restrictions to refactor overlayering into extensions

How do I create extensions?

This section includes "How do I?" topics that explain how to customize specific object types or code. Most of these topics are brief and to the point. Because there are many topics here, it might be practical to search for a specific topic.

Data types

- Add values to enums through extension
- Modify extended data types (EDTs) through extension

Classes

- Register subclasses for factory methods
- Respond by using EventHandlerResult
- Extend the RunBase class
- Customize application startup by using delegates

Tables

- Modify existing fields in a table through extension
- Add fields to tables through extension
- Add indexes to tables through extension
- Add relations to tables through extension
- Modify table properties through extension
- Add methods to tables through extension
- Perform business actions throughout the lifecycle of table records

Forms

- Add a new data source to a form
- Change the captions of forms through extension
- Modify the properties of form controls through extension

Others

- Extending decimal point precision for selected data types
- Add new inventory dimensions through extension

Reports

- Extend the list of Electronic reporting (ER) functions
- Customize App Suite reports by using extensions

Blog posts

Information about customization is also shared through blogs where various topics are discussed. This section includes reference to some of these blogs.

- Extending Dynamics 365 for Finance and Operations
- Extension methods
- Extensible base enumerations
- Static event subscription
- Subscribing to onValidatingWrite
- Embrace the extensions mindset with Dynamics 365 for Finance and Operations
- Extensible X++ - Method Signatures

How do I create an extensible solution?

This section includes some best practices on how to create/make your solution extensible, so that consumers of your code can extend your solution.

- Write extensible code
- Classes
- Methods
- Forms
- Extended data types
- Extensible enums
- Delegates
- Tables
- Attributes that make methods extensible

Breaking changes

When you make your solution extensible, you also help guarantee that you won't break those extension points later.

- For pointers that can help you avoid breaking your consumers, see Breaking changes.
- The compatibility checker tool can detect metadata breaking changes against a given baseline release or update, helping to ensure backward compatibility.

Application extensibility roadmap

2/18/2021 • 2 minutes to read • Edit Online

Reducing implementation and upgrade effort is a major initiative for the development team. The benefits of this initiative are to enable you to quickly take advantage of new innovations from Microsoft and your partners, reduce the total cost of ownership, and improve quality. A major part of this initiative is to change the customization approach for the product. In Dynamics AX 2012, several extension capabilities were added to the product. For example, the ability to do event-based customization using methods pre-and post-events was introduced. Extension capabilities have continued to grow in the evolution to the new application.

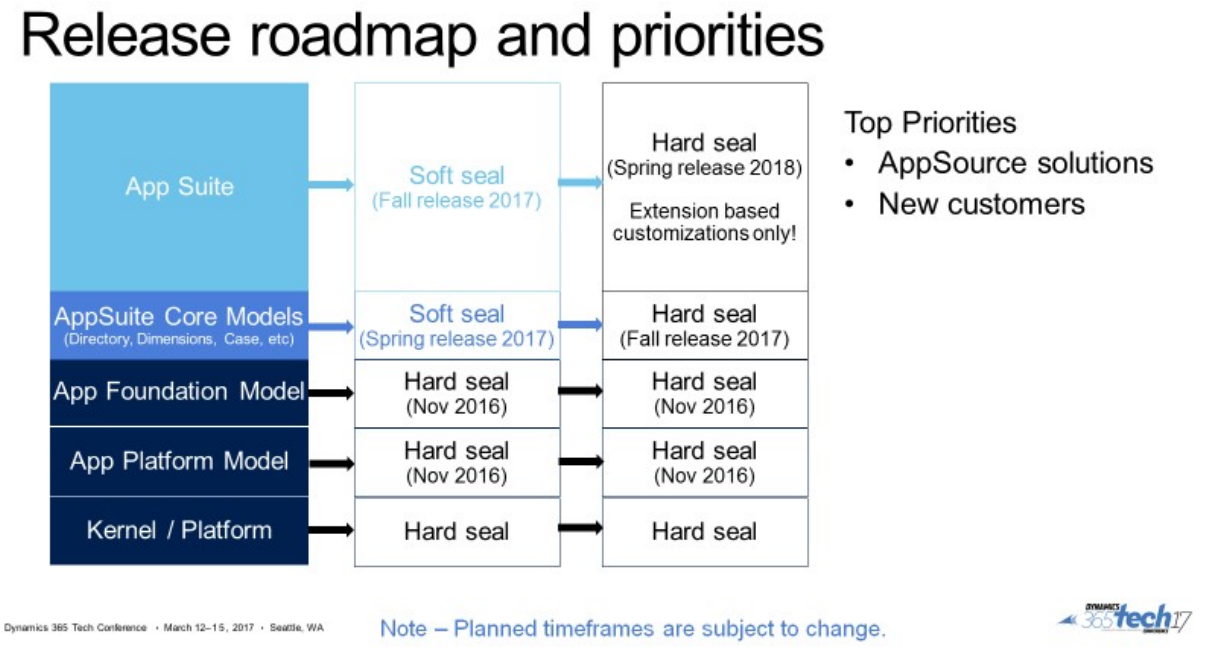
Extension-based customizations have several advantages over the legacy approach of overlayering-based customizations, especially when it comes to reducing implementation and upgrade effort.

- Overlayering-based customizations require code upgrade, recompile time, and extensive testing. This limits the ability to seamlessly apply hot fixes. These costs can be an inhibitor for customers to upgrade to newer versions containing innovations from Microsoft and partners.
- Extension-based customizations also improve the development experience. Models containing overlayered customizations must be in the same package as the base objects. This results in longer compile cycles and larger package distributions. Extensions are also much easier to unit test in isolation from the base object.
- Reducing upgrade costs through extension-based customizations reduces the support matrix for partners as fewer release combinations will need to be supported.

For these reasons, we have gradually been sealing the product models, so they only support extension-based customizations. **AppPlatform** and **AppFoundation** were the first. These models were sealed for overlayering in Platform update 3 (November 2016). Binary updates are now provided to these models on a monthly basis, achieving our goals of reducing upgrade cost and delivering innovation to our customers at a faster cadence.

With Microsoft Dynamics 365 for Finance and Operations release 8.0, we have sealed all product models. Now only extension based customizations are supported.

The following illustration shows the roadmap we followed as we moved to extensions, away from overlayering.



NOTE

A soft seal results in a compiler warning upon overlayering. A hard seal results in a compiler error upon overlayering.

The Modern support policy provides three years of support for a release. Given this, overlayered code will continue to be supported for three years starting November 2017 on the Microsoft Dynamics 365 for Finance and Operations, Enterprise edition 7.3 release. However, this code will not be moved forward to subsequent product releases until the overlayered code is moved to extensions.

There is a substantial amount of work for Microsoft, partners, and customers to accomplish this goal. Workshops, office hours, Help topics, and additional resources are available for training and collaboration in this ecosystem. Internally, we are ready to build more extensibility features in both the core platform and the application. We're working closely with partners with applications on AppSource to define patterns as they migrate to extensions.

The benefits of reducing upgrade friction and enabling innovation uptake will be worth the effort to remove overlayering.

Extensibility requests

2/18/2021 • 6 minutes to read • Edit Online

Finance and Operations applications exclusively use extensions to customize the product. We're aware that this change impacts our entire partner ecosystem. We recommend that you read the resources listed on the Extensibility home page. These resources answer many questions and prepare you for building solutions using extensions.

You will discover that some customizations, which were possible with overlayering, cannot be done through extensions. To enable the same business requirements without overlayering, we have added many extension capabilities and expect to add more going forward. For some customizations that were done with overlayering, you will need to log requests, to make us aware of what you need.

What we are doing

We've been working toward an extension-based customization model for some time. Over the past several releases we have been gradually sealing models. As of Dynamics 365 for Finance and Operations release 8.0, this completes the sealing. From this release forward, only extension-based customizations are allowed.

In future releases, we will be adding even more extensibility capabilities to enable independent software vendors (ISVs) and value-added resellers (VARs) to deliver complete business solutions. We will prioritize these on a customer-by-customer basis with frequent releases.

How do I log extensibility requests?

If you discover a customization that you cannot implement as an extension, you must log a request to Microsoft to ensure appropriate extension support is added to the product for your scenario.

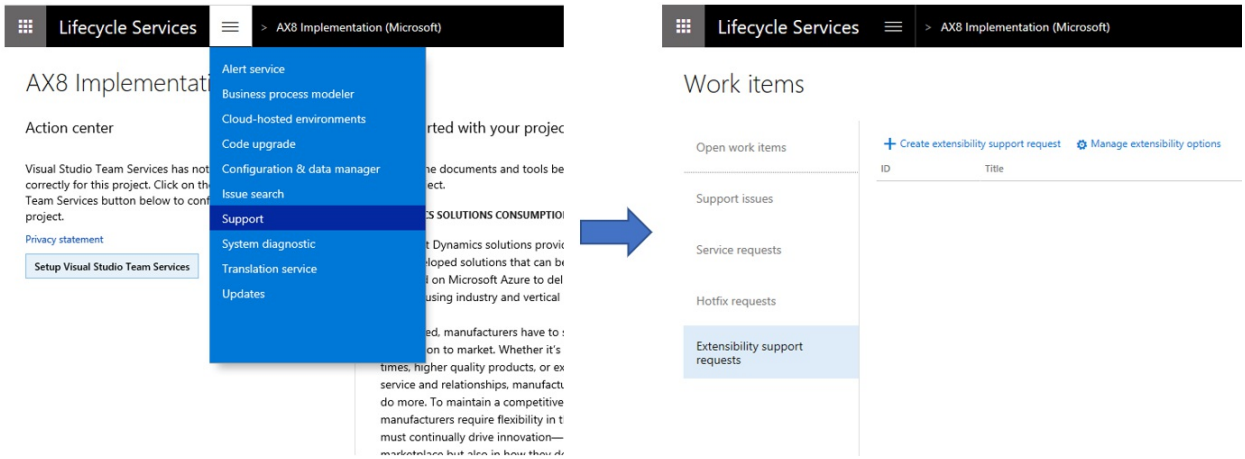
Before logging the request, there are a few things to consider:

- Could the requirement be met with existing extensibility features? Building solutions with extensions requires different design and implementation patterns.
- How important is the requirement to the customer and/or business analyst?
- Will the implementation be upgrade friendly for the long term?

Learn more about extensibility by reading the resources listed on the Extensibility home page and related resources.

Extensibility requests are logged using a specific project in LCS. Logged requests are collected under that same project. We recommend that you log related requests under the same LCS project as this helps maintain a holistic view on all requests for a specific solution or an implementation. Microsoft then further identifies logged requests by the organization name that is associated with the LCS account.

In your LCS project, at the top of the page, select the hamburger icon and then click **Support** menu item.



You can view the list of logged extensibility support requests and their status. Click the request ID to review details of the logged request.

New requests that are logged are briefly assigned a status of **Pending** while the request is copied to the Microsoft tracking databases. Next, an ID is assigned to the request and the status is updated to **Active**. When a request is processed by Microsoft, the status of the request will be updated to **Closed**. Click the request ID to view resolution date and description information. Requests that have been closed are released with monthly application updates.

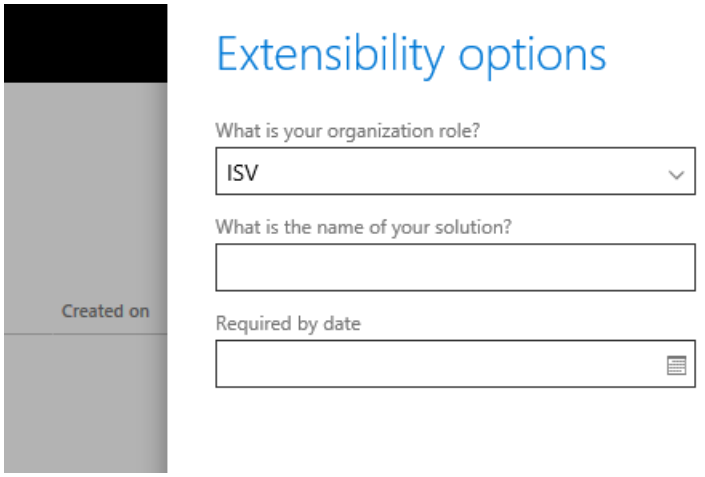
> **NOTE**
>
> At this time, there is no state available to indicate feedback from Microsoft on when requests have been planned.

The **Extensibility support request** form includes two actions:

- **Manage extensibility options**
- **Create extensibility support request**

When you click **Manage extensibility options**, you can view all of the information that is shared between requests. This information includes, requests for either an **ISV** or **VAR** solution and if the requests are specific for a **Customer** implementation project. If the role selected **ISV** or **VAR**, a solution name must be specified. The name should be recognizable and correlate with AppSource solutions. The **Required by date** indicates the last date that requests can be made to be available for your development.

> **IMPORTANT**
>
> Note that Microsoft does not guarantee that all requests will be provided by the date given. However, the required date provides an indication that will be considered when planning for requests at Microsoft.



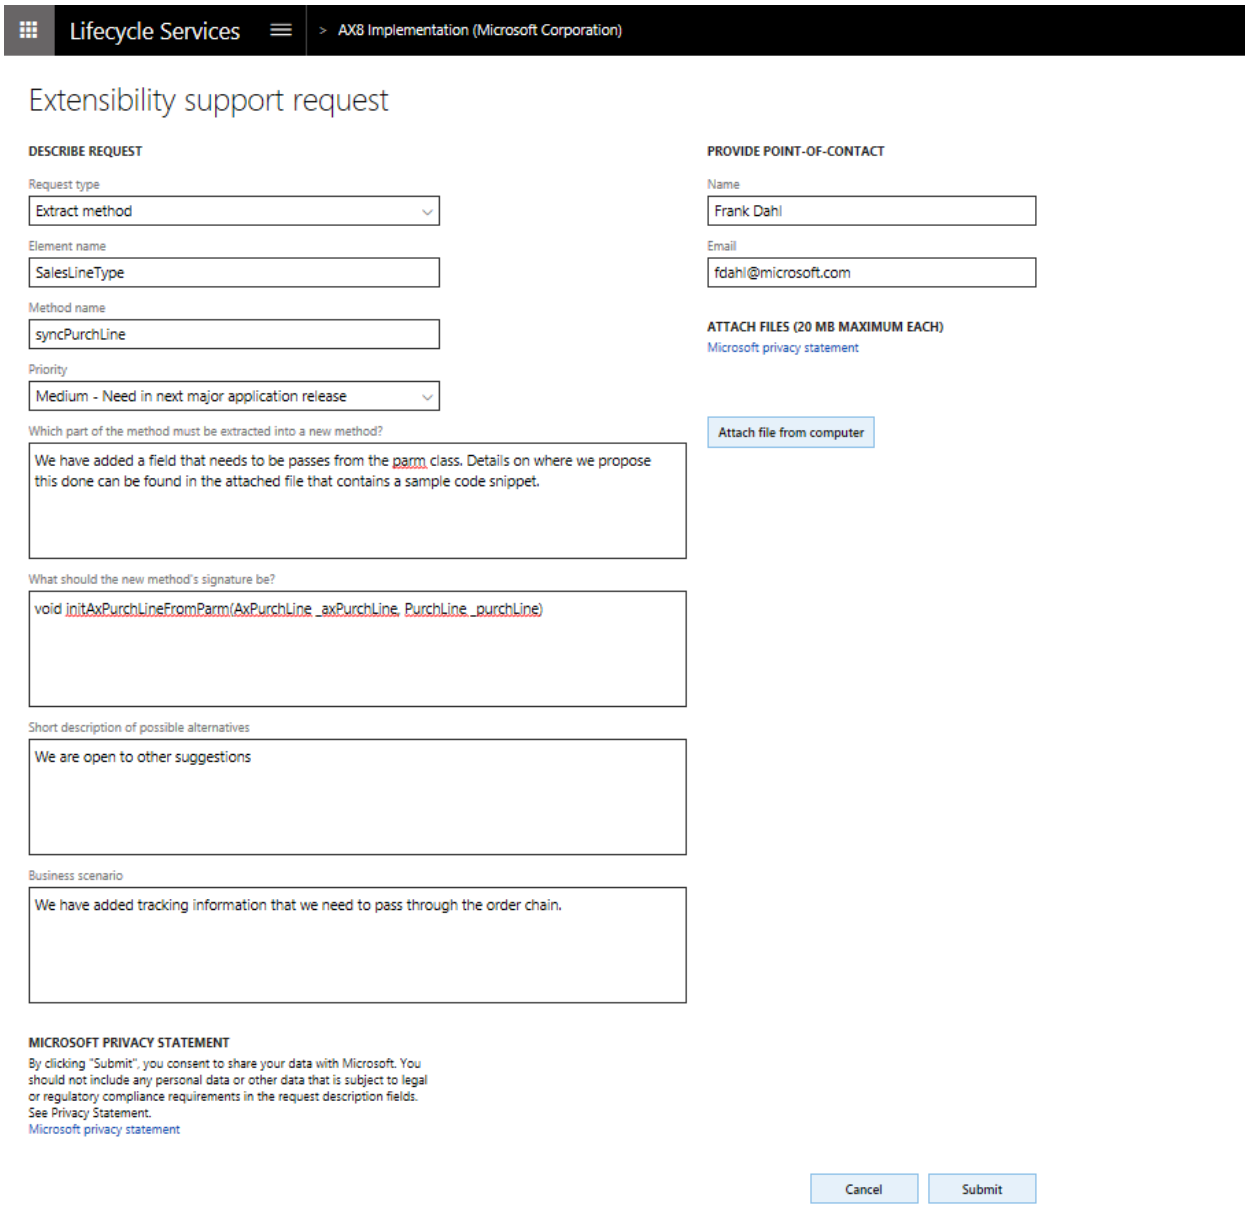
Extensibility support options can be updated to reflect any changes after a request is created. After you have made your updates to the request, click **Update** to notify Microsoft of your changes.

> **NOTE**
> There is currently no option with the tool to record what a Customer implementation includes regarding ISV or VAR solutions.

The action 'Create extensibility support request' is used for creating, or logging, new extensibility requests. When you log an extensibility request, provide detailed information about what you need to become enabled for extensibility, and include information on what it is you need to extend. This will help Microsoft to be efficient in addressing your requests. You are welcome to propose how Microsoft could enable the functionality that you need in the standard application in a way that effectively addresses your needs.

When you select the request type, determine how your request aligns with the request types that Microsoft uses to categorize requests. Each request type changes the form to include specific fields related to the request type. This helps guide the process to make the request actionable for Microsoft. Be sure to provide accurate names when naming elements and methods. Microsoft rarely enables requests by adding inline delegates, so when possible, consider other types of requests. Common application request types include **extract method**, **extensible enum**, **construct with throw**, and **method change**. Additionally, there is **platform request** and **metadata change** for proposing changes, including general platform improvements. The request type **method signature change** is typically for a breaking change. It is unlikely that a breaking change can be accommodated under a monthly update as it will require a more major release version to drive such changes.

Click **Attach file from computer** to upload documents that you can attach to requests. You can use the attachments to supply code snippets that provide additional details for the request. We recommend that you be as specific as possible with your requests.



Log a request for each instance. Do not bundle multiple requests into one. If multiple requests are related, consider adding a document or description that includes request ID's so that any work on the requests is considered in context.

The requests include a point of contact. This is needed for times when the logged extensibility request is not actionable for one reason of another. The requests may require discussion regarding, for example different design options. Microsoft will use this contact information to drive such interactions. Click **Submit** when you are ready to submit the request to Microsoft. Because requests can't be edited after they are submitted, verify the data before you submit. Requests that are accidentally submitted with incomplete or inaccurate date can be removed using the designated action after clicking the ID on the request. Requests that are submitted to Microsoft will temporarily show as **Pending** until the request is created within the Microsoft tracking databases. This will assign an ID to the request and the state will become **Active**. This status update indicates that the request is now visible to Microsoft.

Make sure to read through the privacy statement before you log any requests.

> **NOTE**
>
> We will not release extensibility requests as hotfixes.

Extensibility requests are exclusive for the application. We are not planning to accommodate extensibility requests for Dynamics AX 2012 or earlier releases.

When will my extensibility requests be enabled?

Extensibility requests are logged to a backlog. Microsoft engineers prioritize all requests, and then work on them in priority order. Please note that Microsoft is not ensuring that all requests will be fulfilled. In particular, requests that are intrusive by nature will not be supported, as they will prevent seamless upgrade.

How will extensibility requests be made available to deploy?

After Dynamics 365 for Finance and Operations release 8.0, we plan to release frequent application updates with new extensibility requests. This will follow the same release cadence as platform updates.

Still have questions?

Read the Extensibility FAQ and the other resources listed on the Extensibility home page.

Extensibility FAQ

2/18/2021 • 5 minutes to read • Edit Online

Will source code be available after the hard seal?

Yes, source code will be available after the hard seal. It's required for effective implementation and debugging.

How do I contact Microsoft if I have an extensibility request?

There is a special extensibility request form on the Lifecycle Services (LCS) site.

Where can I ask questions about extensibility patterns?

You can gain access to the Operations Extensibility group in Yammer. Operations Extensibility is an active group that has a significant amount of partner engagement. You get access via the Connect site by signing an NDA.

Where can I find documentation about extensibility patterns?

Documentation about extensibility patterns is available on the Extensibility home page.

Where can I get information about extensibility training?

We will announce training sessions in multiple ways. AppSource partners might receive direct invitations for some sessions. We will also announce workshops in the Operations Extensibility Yammer group and other forums.

What is the goal of sealing the application?

The application is being sealed as a step toward reducing upgrade costs in the ecosystem, so that customers can stay current on new releases. Customers can take advantage of new innovations that come from Microsoft and partners.

Extension packages enable better performance at design time, faster build automation, and unit testing. They also provide more efficient distribution and installation of models from independent software vendors (ISVs) and customers across different systems.

What is Microsoft working on to support this move?

There are several areas where the product team is working to improve the extensibility of the product. This work ranges from platform changes that have broad impact to refactored application code that provides additional hook points. For details, see the Operations Extensibility Yammer group and the product release plans.

After the application is sealed, what should customers do in a critical situation if they must make a quick change?

This scenario is very similar to a scenario where a critical bug fix is required, and the same process should be followed. As a required first step, you must create a case for support.

Can I overlayer an ISV solution after the hard seal of the application

code?

We recommend that ISVs also seal their models. This step helps achieve the broader goal of reducing upgrade costs.

Will I be able to overlayer an on-premises solution?

On-premises solutions will follow the same patterns as cloud solutions. Therefore, no overlayering of Microsoft code will be supported.

How often will Microsoft provide external updates so that partners can see what extensibility enhancements have been made?

We plan to provide monthly updates of platform and application after Microsoft Dynamics 365 for Finance and Operations release 8.0.

Why wasn't my extensibility request accepted?

Some extensibility requests break changes. Some of the more common potentially breaking requests are listed here along with potential workarounds. In addition, read Creating extensions to understand the existing platform extension capabilities and Tips for logging extensibility requests to learn more about how to create solid requests if a capability doesn't exist in the latest release.

Why can't EDT.StringSize be made extensible?

- Request: Make EDT.StringSize changeable via extension.
- Problem: When a table string field (FieldX) is of type "parent EDT" and is associated (through table relations) with another table's field (FieldY) of type EDT2 (EDT2 is derived from "parent EDT"). If FieldY could have a larger string by allowing EDT2.StringSize to increase, FieldX would not be able to handle the new string size.
- Workaround: Create a new EDT and use that for the table field FieldY.

Why can't a unique table index be made extensible?

- Request: Make unique table indexes changeable via extension, for example by allowing an extra field to be added.
- Problem: If a unique table index changes and any data does not conform to the new index, then it would be a breaking change. Also, any query would affect it since it can now retrieve a non-unique record. For example, if a Person table had a key of "Name" and select person where name="Chris" works, but if BirthDate was added to the key, now there could be multiple records returned for "Chris".
- Workaround: Add "soft" constraints in the validateWrite or validateInsert methods.

Why can't CountryRegionCode be made extensible? (*it already is*)

- Request: Make CountryRegionCode changeable via extension.
- Problem: Starting with Platform update 14, changes to CountryRegionCode are supported if the CountryRegionCode property already has a value. Empty CountryRegionCode properties cannot be changed because that change is more restrictive (the element would now only be available for certain countries/regions) and therefore would be a breaking change.
- Workaround: Use the existing CountryRegionCode extension capability when the element is already country/region specific.

Why can't the Table Field properties AllowEdit, AllowEditOnCreate, Mandatory, or IgnoreEDTRelation be made extensible?

- Request: Make Table Field properties AllowEdit, AllowEditOnCreate, Mandatory, and/or IgnoreEDTRelation changeable via extension.
- Problem: The ability to change the "Allow Edit", "Allow Edit On Create", "Mandatory", and "IgnoreEDTRelation"

properties on Table Fields would result in breaking changes. Changing a field to allow editing changes the intent of the field. Not allowing a field to be edited can break existing behavior. Changing a relation breaks the original intent of that relation, which is a breaking change. Making a field mandatory can result in breaking existing behavior.

- Workaround: Add new Table Fields via extension and control those as needed.

Why can't Security Privileges be made extensible?

- Request: Make Security Privilege changeable via extension.
- Problem: The ability to change the Security Privilege would result in breaking changes because this is the lowest level of security metadata.
- Workaround: Create a new Security Privilege if needed and use that.

Why should I avoid calling and extending APIs that are marked with InternalUseOnlyAttribute?

Throughout the application, an effort has been made to avoid breaking changes to APIs made by customers, partners, or ISVs. When a class or method has the **InternalUseOnlyAttribute** applied to it, this means that the API is for internal use only and could change without warning. If customers, partners, or ISVs use or extend an API with **InternalUseOnlyAttribute**, this could create issues because the API could change at any time, which would require changes in their extensions before an update can be applied. This could result in urgent changes and the need to recompile. Developers should not depend on these classes and methods remaining unchanged.

Calls to classes and methods with the **InternalUseOnlyAttribute** will result in compiler warnings. Starting in Platform update 20 to Platform update 24, targeting classes and methods with **InternalUseOnlyAttribute** using Chain of Command will result in compiler errors. In Platform update 25 and later, we plan to continue to issue compiler warnings.

Migrate from overlayering to extensions

2/18/2021 • 10 minutes to read • Edit Online

Introduction

When the application was first released, we strongly recommended that extensions be used instead of overlayering for customization. Overlayering-based customizations have been migrated from release to release through code migrations, and many customizations of application code are still based on the overlayering of code. For most partners, at least some of their solution is still based on overlaying, and some partners will have lots of overlayering across their solutions.

The amount of work that is required to change an implementation from overlayered code to extensions depends on the code itself. Some overlayered code can be changed relatively seamlessly. However, for some changes, you must rethink the customization to find an appropriate way to accomplish it through extension. Therefore, it can be a major undertaking to change complete solutions where multiple places have overlayered code. Such an undertaking requires an investment in the solution. The upside of this investment is a more seamless upgrade process, because customization is now based on application programming interfaces (APIs) through extensions. Additionally, a lengthy code upgrade process is no longer required as it was for overlayered code. More importantly, daily servicing of a running environment offers many benefits. The core application and extensions no longer have to be compiled together, and patching can be done by deploying precompiled assemblies. Therefore, customers can apply patches to their system in a relatively seamless manner, and the amount of downtime is minimized. However, there is work that must be done before this result can be achieved.

Although there are multiple ways to approach this task, we have gained experience through our close work with independent software vendors (ISVs) and value-added resellers (VARs) that have already started to migrate from overlayering to extensions. In this topic, we share some of this experience.

First things first

The task ahead is substantial, and we want to make sure that our shared investment pays dividends. Keep the goal in mind as you work through your customizations. When customization is done correctly, your solution has these qualities:

- It has no intrusive customizations.
- It supports side-by-side deployment with other ISV solutions.
- It's resilient to changes in Microsoft code.
- It's resilient to changes in other ISV solutions.
- It can be upgraded automatically to future versions.

This type of customization represents a fundamental shift of approach. Previously, the primary objective was to implement the functional requirements on the current version. This objective was acceptable, because we knew that manual work was required in order to upgrade the solution. Previously, great engineers minimized the manual upgrade cost. Now, *every* engineer must implement solutions that require *zero effort* to upgrade.

Staying on the right path

Cars are designed to be safe. However, they can't yet prevent accidents. Accident prevention remains the driver's responsibility. Similarly, the development toolset is designed for extensibility. However, the toolset can't yet prevent every type of intrusive customization. As an engineer, it's your responsibility to avoid intrusive customizations.

Sometimes, you might find that you can reach your functional goal only by implementing intrusive customizations. In this case, you should reach out to Microsoft to find a correct solution. You should not force

your way forward. Otherwise, customers who, for example, experience an outage of their service after an automated upgrade might realize that your solution isn't future-proof after all.

Because a future-proof solution represents a competitive advantage, it's worth the extra effort to do it correctly.

Obtain an overview of your code

When you create an overview of your code, first consider analyzing each of your solutions independently instead of analyzing them all together. This approach might be practical even if different teams work on the individual solutions. By choosing one team that you will engage before the other teams, you can gain some experience. Experience is valuable, because it not only helps you analyze and plan the work, but also helps the team ramp up and become familiar with the extensibility model. Therefore, the experience that you and your team gain can become valuable "lessons learned" that you can apply to later solutions.

We have gained practical experience both with ISVs that take each ISV solution in turn, and with ISVs that work as VARs and take customer solutions later.

No matter how the work is pieced together in solutions, you can use the Customization Analysis Report (CAR) to get information about what has been overlayered. This report is generated when you submit your solutions to the Code Migration tool on Microsoft Dynamics Lifecycle Services (LCS). The report is in Microsoft Excel format and includes a list of all the places that have overlayered code. You can use the report to both analyze and categorize all overlayered instances in your solution.

To obtain an overview, you might find it helpful to categorize each overlayered instance. The category that you apply to an overlayered instance should represent the approximate effort that is required in order to change the customization to extensions. Some customizations will be easily changed to extensions. However, for other customizations, the change will be more difficult.

From our experience working with numerous ISVs, we have found that the following categories are a good starting point.

CATEGORY	DESCRIPTION
Extensible enums	You can add new enum values by using extensions. For more information, see Add values to enums through extension.
Construct with throw	Most construct methods are simple and can be extended by using post-event handlers. However, some construct methods are more complex and throw an exception when no class is created.
Exposing members	Member variables that have the **private** access modifier in their definition can't be accessed through extensions unless they become exposed through public methods. You can request that we add access to members through extensions that currently have not been exposed for this. Note that access to protected members is generally enabled through extension classes.
Data manipulation methods that don't raise DataEvents	In some places in the application, data methods such as **insert()** and **update()** don't call **super()**. Therefore, the methods don't raise DataEvents to add extensions to. Microsoft plans to refactor the standard application so that it includes additional methods that enable extensions in these places. If you submit a request for Microsoft to add this, add any of the affected methods that you must currently overlayer, if those methods haven't already been accounted for.

CATEGORY	DESCRIPTION
Extract method	This category is for code changes in the middle of methods, which can't be made through chain of command. When you request a method extraction, be sure to specify which lines of a method to extract, and what the signature of the new method must be.
SQL statement operations	SQL statements that are written directly in the application code don't enable extensions. When you make a request to extend these SQL statements, be sure to explicitly specify what you must extend, such as a field list, **where** clauses, or ordering.
Metadata overlayering	Provide the Application Object Tree (AOT) path of the element where you believe the metadata (property value) must be changed. Metadata changes can't be made through the current extension capabilities.
Method overlayering	This category is for customizations where a method is overlayered. You should consider converting the overlayed method to an extension, so that changes are clean by extension not substitution.
Method signature changes	The capability to change method signatures through overlayering will be discontinued. Other patterns for achieving similar results are required. You can request changes to the standard signature to support extensibility. Be sure to include information about additional parameters that are required.
Inventory dimensions	You can no longer add dimensions by editing the macro and recompiling the standard application. Another approach will be offered that involves predefined dimensions that are deployed at runtime. This approach drives changes to existing customizations where new dimensions are added.
Extensibility platform	Some customizations might not be possible through extensions unless new platform features are added. If you determine that customizations can't currently be done through extensions, open an extensibility request that explains the scenario and what is required.
Reports	Customizations of report designs have limited support for extensibility. In general, a new report must be created. Data provider classes can also be customized so that they include additional information. In some places, the standard application must be changed to enable this type of customization.
Other	This category is for overlayering instances that don't fit into any other category.

By categorizing all overlaying code, you gain an overview of what must be changed.

Analyzing for impact and estimating work

In a typical approach to assessing work impact, you break down tasks into something tangible. This approach also applies to this work. The categories that were discussed in the previous section help frame similar

customizations, and a first pass on estimates can be built by coming up with an overall estimate for each of these categories and similar categories that make up your solution. The group of customizations in a given category often has a few extremes that stand out, and it might be appropriate to establish estimates for these customizations individually.

Consider that some customizations will require either a request to Microsoft to enable extensibility or significant refactoring of the customization so that it can be done through extensibility. Both of these scenarios will increase the estimates for migrating the solution.

Customization that drives what are referred to as intrusive changes is often more complex to convert to extensions. For these changes, you must consider what is the correct way to approach the customization. Here are some examples of these changes:

- Customizations that request inline delegates.
- Customizations of complex classes or methods such as **SalesLinetype**.
- Changes to method signatures.
- Additions of inventory dimensions.
- Changes to report definitions and report data provider classes.
- Intrusive changes to forms.

For changes that require different approaches to make the customizations extension-based, you might have to log requests to Microsoft to enable extensibility. When creating your migration schedule, you'll need to take into account the delay of waiting for updates from Microsoft.

What is supported, and what requires an extensibility request?

When you review a customization, be sure to consider different options for converting it to an extension. Be sure to consider whether a method is hookable, or whether it can be a class extension or form event. Review most of the currently available application code that is available to you.

You might conclude that a change to the standard application is required in order to enable the required extension. In this case, you must log an extensibility request. The request is then put into the backlog at Microsoft so that it can be addressed. Don't log extensibility requests by opening a request for a hotfix, because Microsoft doesn't release extensibility requests as hotfixes.

Be sure to supply enough contextual information in your extensibility requests. For example, a request for an inline delegate might come from the current customization approach. However, to better accommodate extension, the requirement that led to this customization might be better served by a structural change to the standard application. We appreciate suggestions of this type, because they help move the application toward a better platform for building different customizations.

Planning the migration

Be sure to start planning the migration of your solutions early. This planning is important because it helps you make sure that you have room in your schedules to identify and log extensibility requests, and that you have room for the time delay before these requests become available in product releases. Additionally, acknowledge that your developers might have to build new skills, and make sure that you cater to any required learning as part of the migration plan.

Your solution might contain intrusive customizations that aren't easily accommodated through extensions. You should consider whether the business value of these customizations outweighs the effort of building them through extensions. In some cases, partners have decided to discontinue parts of their solutions, because they found that it was impractical to rebuild those parts through extensions, and those parts weren't critical to the solutions.

Some smaller fixes that you're customizing across the application might not be core for your solution, but they are important for the customers that you engage with. In these cases, you must decide whether you prefer to ask Microsoft to implement similar capabilities in the standard application. You can enter an extensibility request for this purpose. For example, if customers want to simplify standard business processes in the system, you might suggest that we add options for disabling steps of the process in the standard application.

Customize model elements through extension

2/18/2021 • 16 minutes to read • Edit Online

In this tutorial, you'll become familiar with the Fleet Management Extension model. This model contains elements that extend the functionality of the Fleet Management application. You can customize model elements by creating *extensions*. Unlike the overlayering capabilities of Microsoft Dynamics AX 2012, extensions don't overlay the baseline model elements. Instead, extensions are compiled as a separate assembly that adds to or customizes the model and the associated business logic. You can extend metadata, for example, by adding a field to a table or adding a control to a form, and also extend or customize business logic by defining event handlers and plug-in classes. You can now author event handlers on several pre-defined events on tables, forms, form data sources, form controls, and others. Plug-ins are also a new extensibility concept that enables replacing or extending the business logic of the application.

Prerequisites

This tutorial requires you to access the environment using Remote Desktop, and that you are provisioned as an administrator on the instance.

Understanding the Fleet Management model

The Fleet Management application provides a rental car company a system for managing vehicles, customers, and vehicle reservations. The application is designed for use by the Fleet Clerk and Fleet Manager personas.

Fleet Clerk

The Clerk is the front desk employee who handles the face-to-face and over-the-phone interactions with customers. The Clerk is primarily concerned with entering customer information into the application, creating vehicle reservations for customers, upselling the reservation by offering vehicle accessories, and processing vehicle returns upon completion of a vehicle rental. The Clerk spends the vast majority of their time using the **Fleet Management Workspace** to prepare for interactions with customers by anticipating their needs and providing a pleasant and memorable experience, while interacting with the customer.

Fleet Manager

The Manager is the back office employee who handles setting business requirements and processes. The Manager is primarily concerned with entering vehicle information, defining the available vehicle accessories, vehicle maintenance, determining pricing, and analyzing business performance measures such as revenue, upsell success, and so on. The application's business logic revolves around the following three primary entities and the relationships between them.

Customers

Customers contact the Fleet Clerk to make vehicle reservations, choose vehicle accessories, check out and return vehicles, and pay for vehicle rentals. Customer-related information is stored in the table named **FMCustomer**.

Vehicles

Vehicles vary primarily in their price, which is proportional to the vehicle *class*. The names of tables that store information about vehicles begin with **FMVehicle**.

Reservations and rentals

Reservations handle the relationship between customers and vehicles. Reservation information includes reservation dates, customer information, vehicle selection and price, and additional charges such as accessories or fees. Reservation and rental information is stored in the **FMRental** and **FMRentalCharge** tables. A

calculation engine handles the transactional information related to the pricing of vehicle reservations. Using this data model the Fleet Management application provides a basic car rental experience.

Extending the Fleet Management model

The basic Fleet Management application has been customized with additional capabilities that enable a rental car company to provide pricing incentives to its customers through discounts. The additional business logic and data that enables these discount capabilities is stored in the Fleet Management Extension model. The discount capabilities add value to the Fleet management application through three primary customizations.

The Fleet Management Extension data model

Two new tables have been added that store discount-related information. **FEDiscounts** stores the list of all discounts and their rates. **FERentalDiscountRelationTable** keeps track of the reservations that the discounts are applied to. Existing tables have been extended to account for the addition of discounts to the pricing scheme. The table that keeps track of the vehicle rate for a particular reservation, named **FMRental**, has been extended to accommodate discounts to the vehicle rate. The table that keeps track of the accessories for a reservation, named **FMRentalCharge**, has been extended to accommodate discounts applied to accessories.

The Fleet Management Extension Calculation Engine

The basic calculation engine has been customized to add the various pricing schemes defined by the new discounts. A plug-in class has replaced the functionality of the base calculation engine. When a vehicle is reserved for more than 7 days, the vehicle Fleet Management model calculates savings based on the difference between a vehicle's daily rate and a lower weekly rate. The plug-in removes the weekly rate calculation because this same behavior can be accomplished by using discounts.

The Fleet Management User Interface Extensions

The Rental, which is contained by the form named **FMRental**, has been extended to enable the Clerk to apply discounts to a reservation. The on-screen price summary is updated in real time with savings information related to discounts that can be applied to vehicles and accessories related to the reservation. In the following steps, you'll explore the customizations that have been made in the Fleet management Extension model, as well as re-implement a portion of the customizations for yourself.

Setup

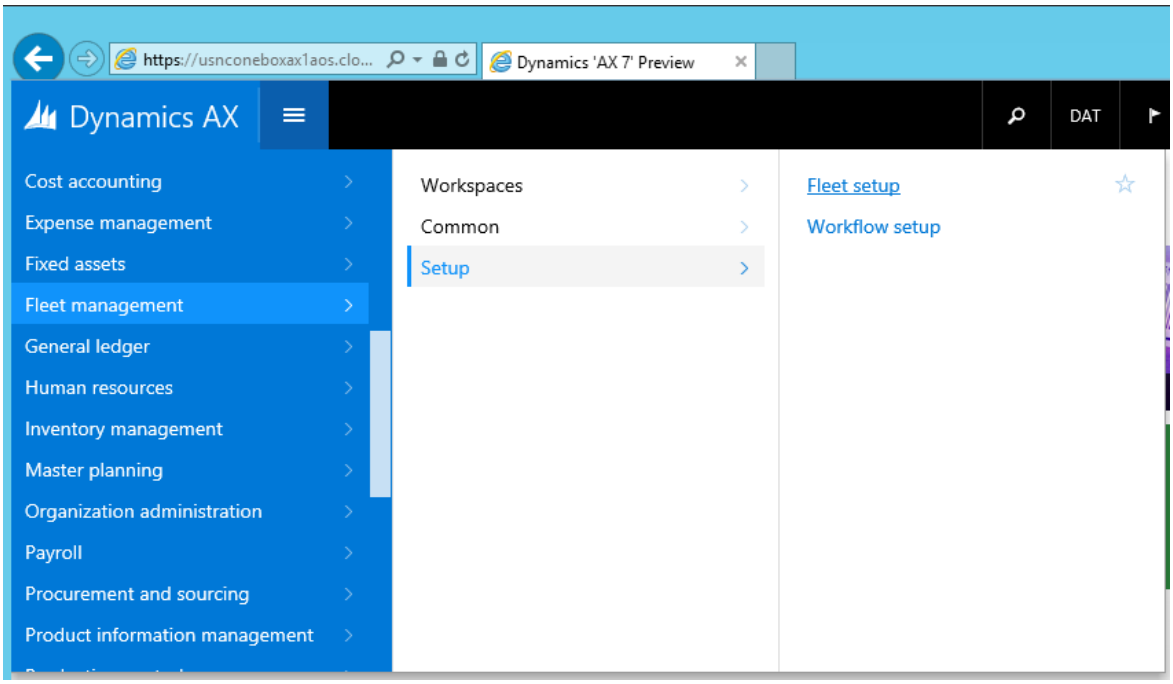
If you haven't opened the Fleet Management Solution in a previous tutorial, follow these steps. The fleet management solution file is available on the Dynamics AX downloadable VM.

1. On the **Desktop**, double-click the **Visual Studio** shortcut to open the development environment.
2. Open the **FleetManagement** solution. On the **File** menu, point to **Open**, and then select **Project/Solution**.
3. Browse to the desktop and open the **FleetManagement** folder. If the solution file is not on your computer, the steps to create it are listed in Tutorial: Create a Fleet Management solution file out of the Fleet Management models in the AOT.
4. Select the solution file named **FleetManagement**. The file type listed is Microsoft Visual Studio Solution.
5. Select **Open**. The solution may take some time to open.

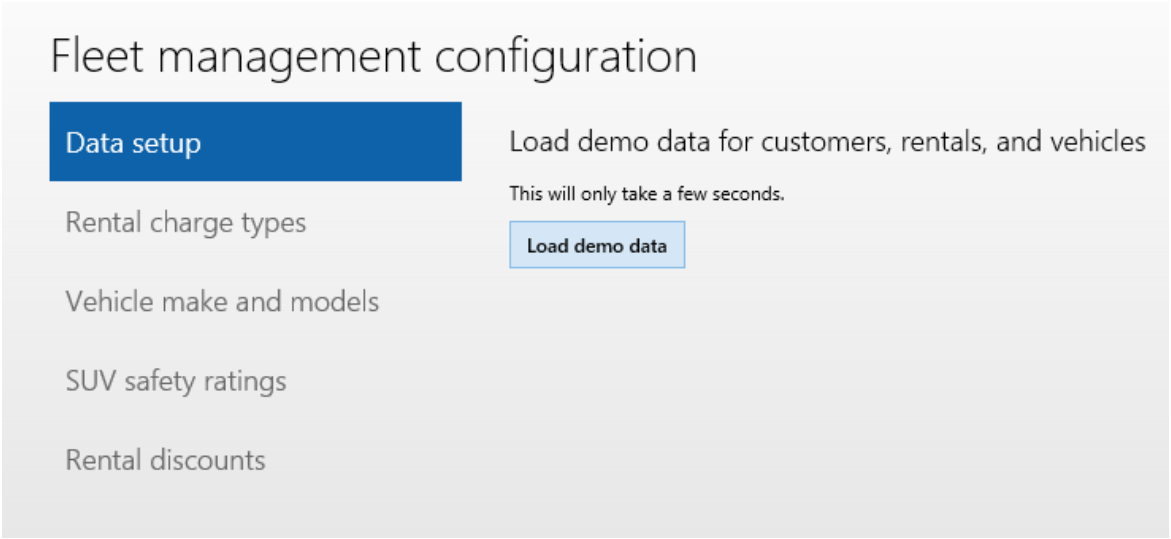
Installing the demo data

If you've already installed the demo data, you can skip to the next section.

1. In the VM, open Internet Explorer and navigate to the application's base URL.
2. Sign in.
3. On the dashboard, open the navigation pane and navigate to **Fleet Management > Setup > Fleet Setup**.



4. Click **Setup Demo Data**.

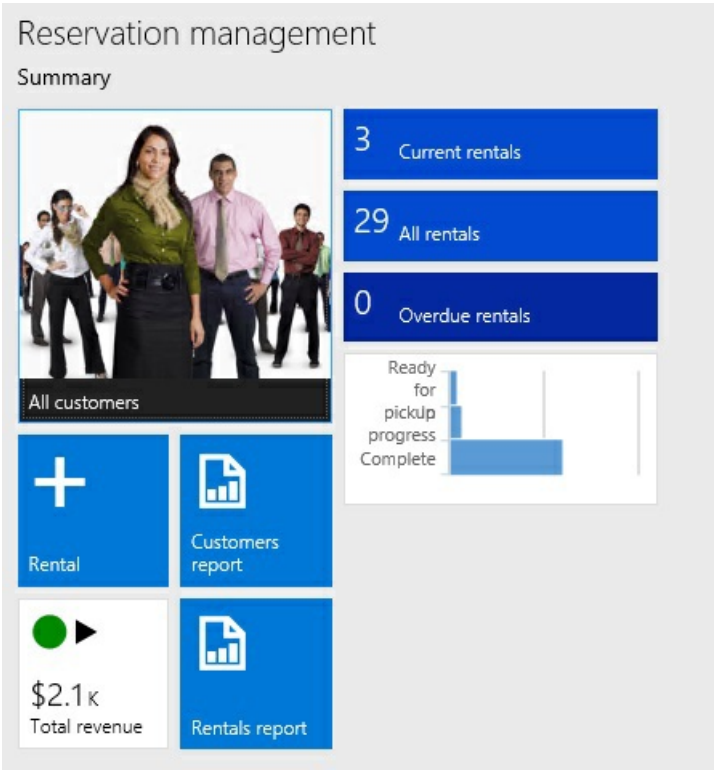


5. If you're prompted to reload the demo data, select **Yes**.
6. When the data is finished loading, select **Close**.
7. On the dashboard, open the navigation bar and navigate to **System Administration > Common > Maintain aggregate measurements**. (Steps 7 to 9 are not applicable on newer releases.)
8. Select **FMAggregateMeasurements**, and on the Action Pane, select **Refresh now**.
9. Wait until the processing completes. The ongoing processing is indicated at the top of the page by a series of moving dots. The processing is completed when the indicator disappears and the **Time Last Processed** field is updated.

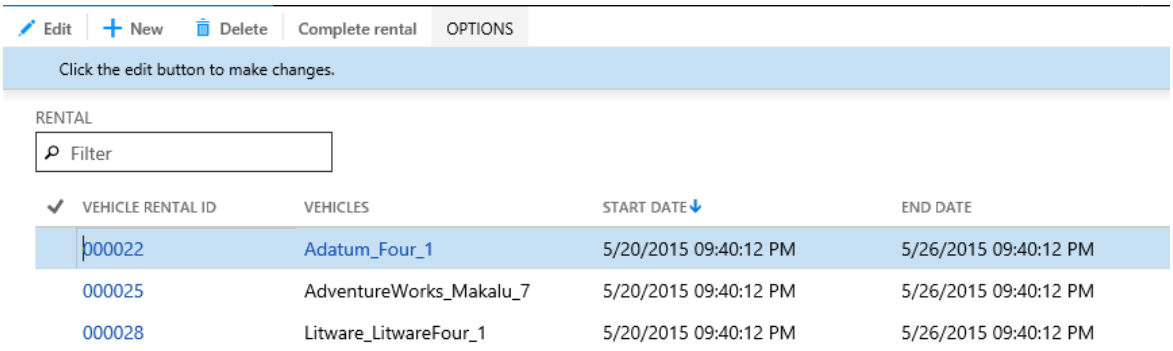
Open the FMRental form on the one-box environment

1. In the VM, open Internet Explorer and navigate to the base URL of your Dynamics AX application. For more information, see Deploy and access development environments.
2. Sign in, if prompted.
3. Find the **Reservation Management** tile and select it to open the Reservation Management workspace.

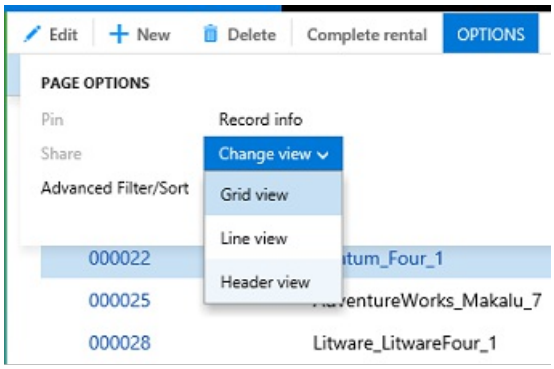
4. When the **Reservation Management** workspace opens, select **Current rentals**.



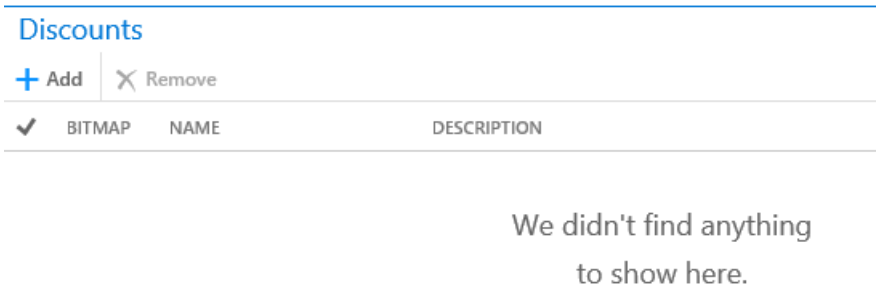
5. The **Rental** form opens in grid view.



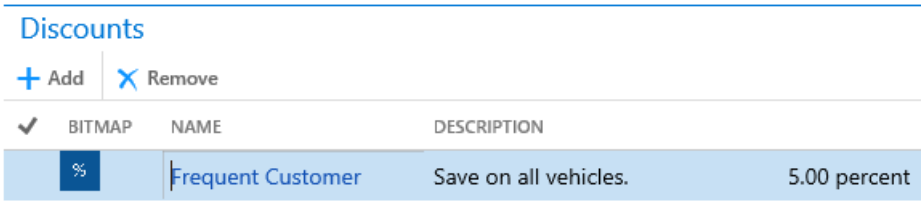
6. After the **Rental** form loads, select **Options** > **Change view** > **Header** to open the **Header view**.



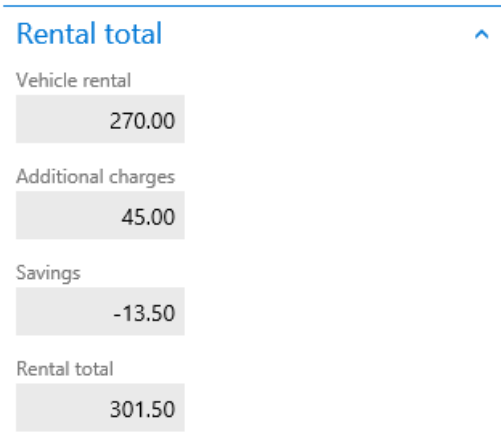
7. When the **Header view** form loads, scroll to the bottom and expand the **Discounts** tab. This tab isn't part of the Fleet Management model. It has been modeled in the Fleet Management Extension Model as an extension to the **FMRental** form.



8. Select **Add** to add a discount.
9. Select the **Frequent Customer** discount, and then select **OK**. The selected discount is added to the **Discounts** grid.



10. Use the shortcut key, **Alt+F2** to open the FactBox.
11. Expand the **Rental total** FactBox on the right and view the discount savings that are applied.



Overview of the Fleet management discount extension project

In this tutorial, the **FleetManagementDiscounts** Project contains the model elements that belong to the model named **Fleet Management Extension**. Here, you'll explore and learn about the project elements.

Navigate to FMRental.Extension in the Tree Designer

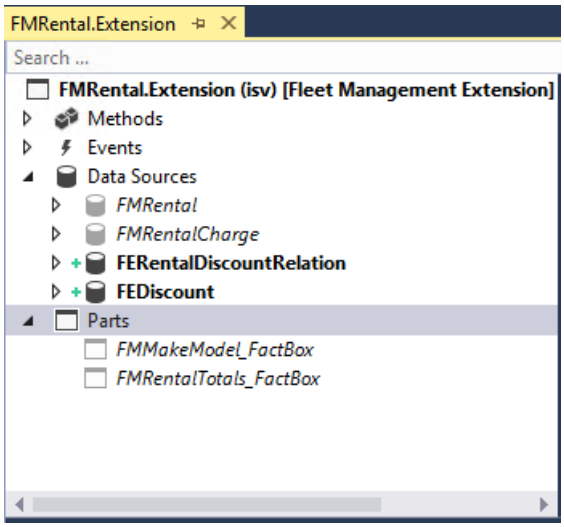
1. In the Visual Studio, in **Solution Explorer**, in the **FleetManagement Discounts** project, expand **User Interface > Form Extensions**.

   The **FMRental.Extension** element is an extension element that extends the functionality of the **FMRental** form by adding two new data sources and a new tab control.

2. In **Solution Explorer**, double-click **FMRental.Extension** to open the designer. As the following image shows:

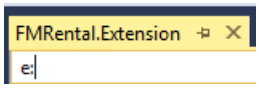
   - The data sources shown in *italic* text are data sources defined in the baseline form.
   - The data sources shown in **bold** are the ones defined in the current extension.

   The designer presents an integrated view of the model element, including its extensions. Read-only nodes are shown in italic text, while nodes that belong to the current extension are shown in bold, with other visual cues that indicate the type of customization.

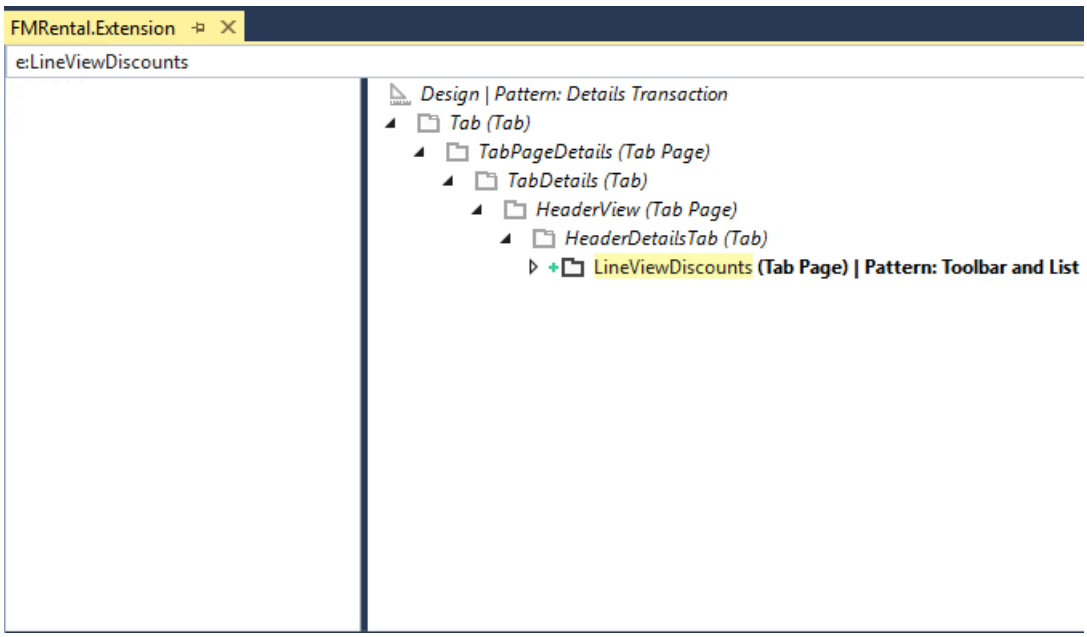


3. In the designer's search box, type 'e:' as shown in the image below. This filters the current designer to

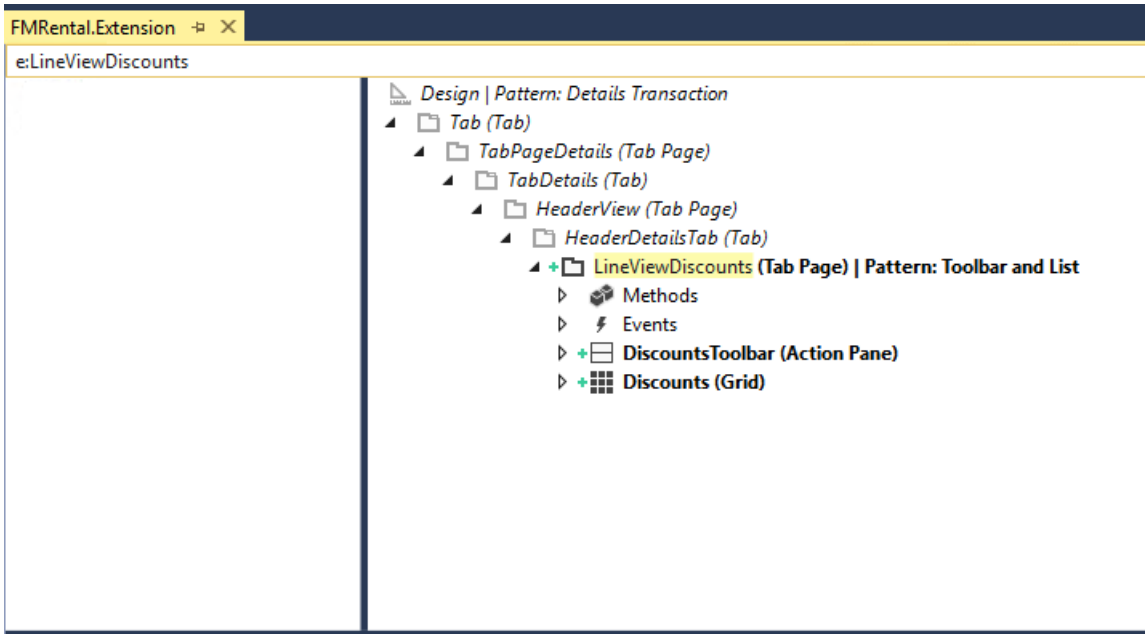
only show nodes that belong to the current extension.



4. You can also type 'e:LineViewDiscounts' to filter the designer to show nodes that match the name **LineViewDiscounts** and that belong to the current extension.

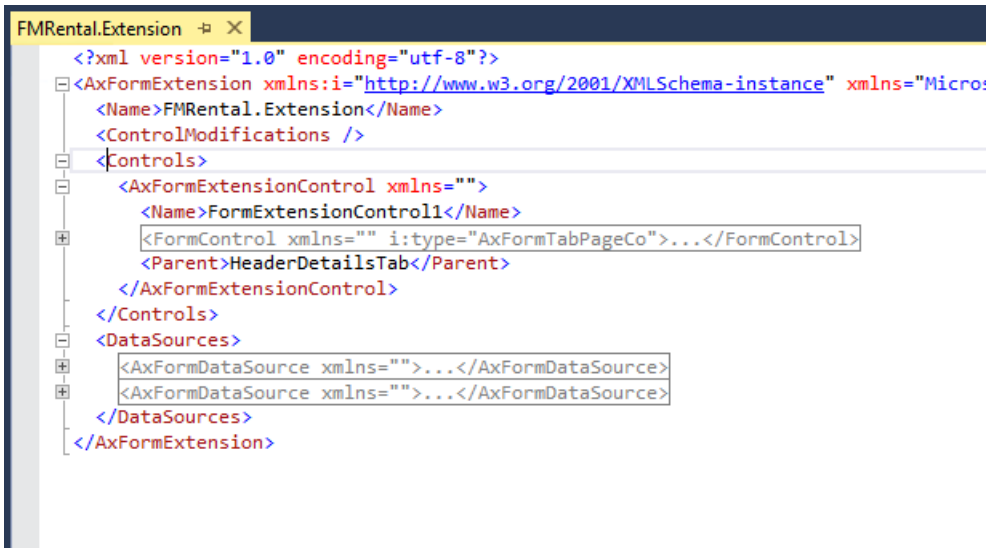


5. Expand the **LineViewDiscounts** node to see its contents.



Open the FMRental.Extension XML file to view the metadata

1. In the **Solution Explorer**, right-click FMRental.Extension form extension, and then click **Open with**.
2. In the **Open with** dialog box, select **XML (Text) Editor**, and then click **OK**.
3. When prompted to close the designer, click **Yes**.
4. Click the corresponding minus signs to collapse the child nodes of the **Controls** and **DataSources** nodes. Refer to the following image for the correct result.



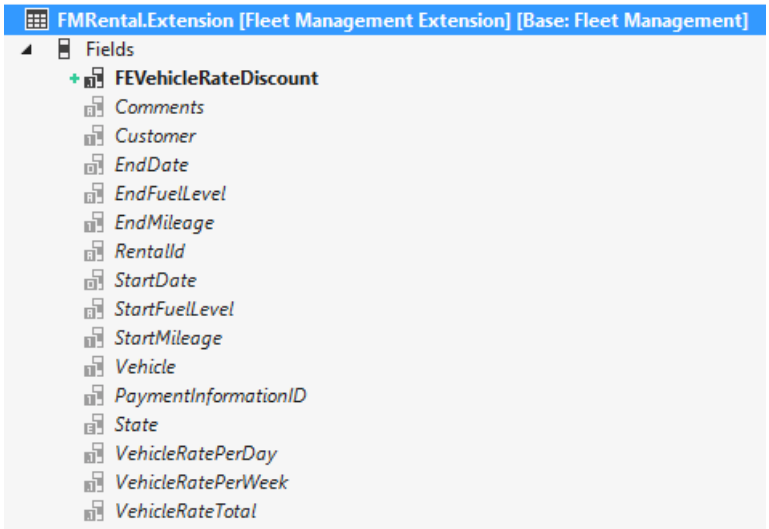
The XML file contains the metadata associated with the **FMRental.Extension** element. You can see that this file contains metadata that describes only one tab page control and two data sources that are part of the extension. You can also see that it doesn't contain any metadata from the base form.

View other elements in the Fleet Management discount extension project

The **FleetManagement Discounts** project contains two new tables, **FEDiscount** and **FERentalDiscountRelationTable**, and two extensions to existing Fleet Management tables, **FMRental** and **FMRentalCharge**.

1. In **Solution Explorer**, in FleetManagement Discounts, double-click **Data Model > Table Extensions > FMRental.Extension** to open the designer.

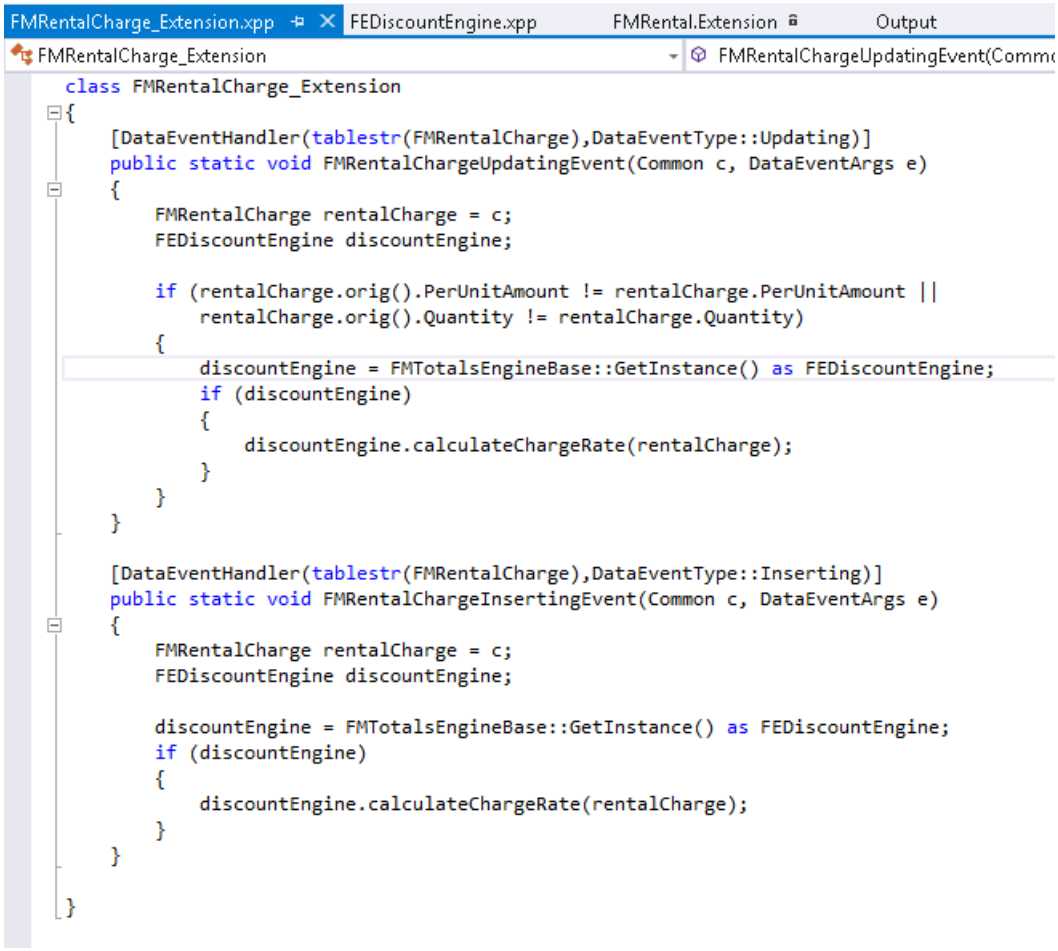
2. Expand the **Fields** node to see that this extension contains one added field, FEVehicleRateDiscount, to the base FMRental table.



3. Similarly, open the **FMRentalChange.Extension** element in the designer to explore its contents.

Inspect the data event handlers

In **Solution Explorer**, in the FleetManagement Discounts project, double-click **Code > Classes > FMRentalCharge_Extension** to open the code editor.



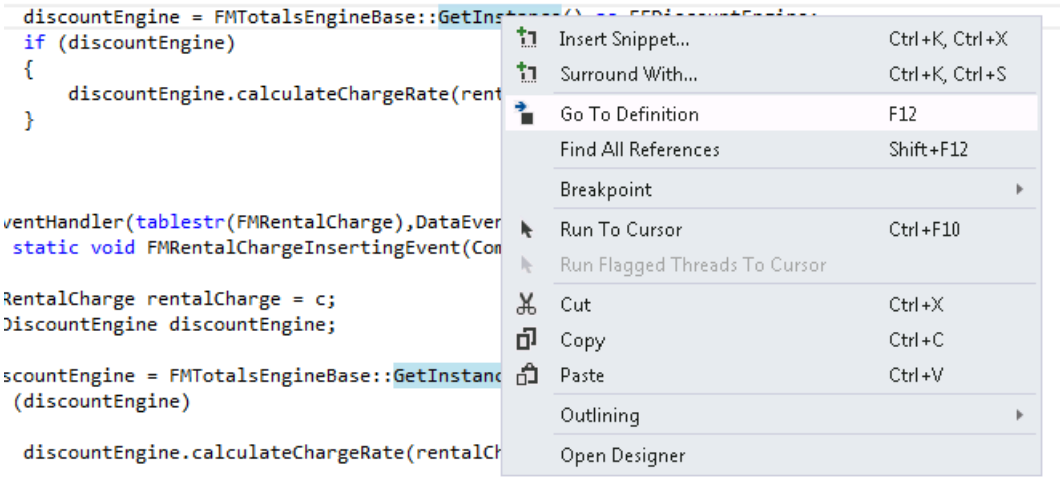
This class contains event handler implementations that subscribe to the **Updating** and **Inserting** events of the **FMRentalCharge** table. Microsoft Dynamics AX introduces data events that can occur on tables and other types. You can subscribe to data events of a table, enabling your application to extend business logic without overlayering base X++ code. Later in this tutorial, you'll see how easy it is to subscribe to table events.

> **NOTE**
>
> Notice that this class is an extension class (indicated by the _Extension suffix). You can author event handlers in any class, this class does not need to be an extension class. Extension classes are needed in order to create extension methods. For more details on extension methods, refer to the "Extension methods" section of the X++ debugger features article.

View the plug-in classes

In the event handler code of the **FMRentalCharge_Extension** class shown in the previous section, notice that both event handlers call **FMTotalsEngineBase::GetInstance** to retrieve the current instance of the Fleet Management calculation engine. The calculation engines are implemented by using plug-in classes. A class factory creates the appropriate instances of a plug-in class based on configuration or business data.

1. In the code editor window that displays FMRentalCharge_Extension.xpp, right-click **GetInstance**, and then select **Go To Definition**. The code editor opens with the abstract class **FMTotalsEngineBase**. This abstract class is called a **plugin point** and it's associated with the following attribute: [Microsoft.Dynamics.AX.Platform.ExportInterfaceAttribute()]



Plug-in classes represent extensions or implementations of abstract classes or interfaces. Plug-in classes are associated with attributes defining their metadata and the plug-in point. In this example, there are two plug-in classes associated with the **FMTotalsEngineBase** plug-in point. The base calculation engine is defined by the plug-in class **FMTotalsEngine**. You can find it in the project **FleetManagement Migrated > Code > Classes**.

```
[System.ComponentModel.Composition.ExportMetadataAttribute("TotalsEngine", "Default"),
System.ComponentModel.Composition.ExportAttribute("Dynamics.AX.Application.FMTotalsEngineBase")]
class FMTotalsEngine extends FMTotalsEngineBase
{
```

The discount calculation engine is defined by the plug-in class **FEDiscountEngine**. You can find it in the project **FleetManagement Discounts > Code > Classes**.

```
[System.ComponentModel.Composition.ExportMetadataAttribute("TotalsEngine", "Discount"),
System.ComponentModel.Composition.ExportAttribute("Dynamics.AX.Application.FMTotalsEngineBase")]
class FEDiscountEngine extends FMTotalsEngine
{
```

2. Look at the **GetInstance** method. It uses the plug-in factory **SysPluginFactory::Instance** to instantiate the current calculation engine based on current plug-in metadata. The plug-in metadata is specified in the global configuration table, **FMParameters**.

```
// the {key,value} pair from the SetManagedValue call should match the {key,value} pair from the attribute on the plugin class
meta.SetManagedValue("TotalsEngine", FMParam.TotalsEngine);

_instance = SysPluginFactory::Instance("Dynamics.AX.Application", classStr(FMTotalsEngineBase), meta) as FMTotalsEngineBase;
if (!_instance)
{
    warning('SysPluginFactory could not initialize totals engine - using default. Consider running fleet setup.');
    _instance = FMTotalsEngine::construct();
}
```

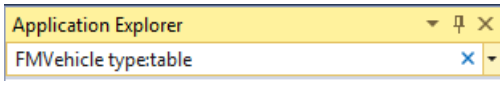
The Finance and Operations apps also support configurable plug-in classes where the plug-in metadata associate with the class isn't known at development time and is configurable at runtime by an administrator. This tutorial doesn't cover that feature.

Create additional Fleet Management extensions

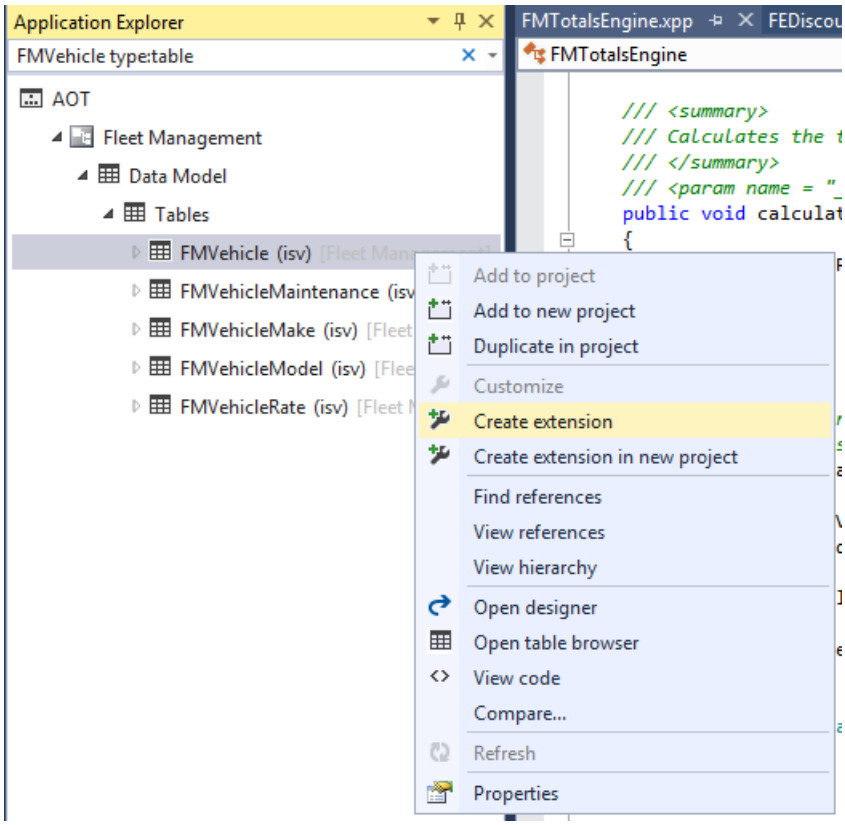
This section shows how you can use the Visual Studio tools to create and interact with extensions.

Extend the FMVehicle Table

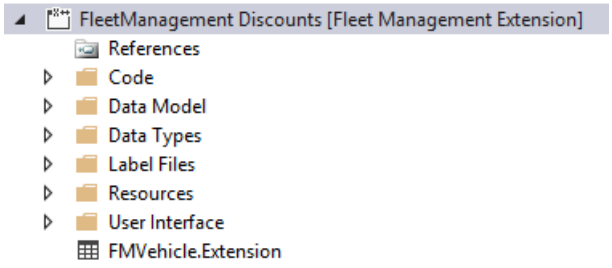
1. In **Solution Explorer**, select the **FleetManagement Discounts** project.
2. In Visual studio, in **Application Explorer,** select **View > Application Explorer**, and search for the table named FMVehicle. Type `FMVehicle type:Table` in the filter bar and press **Enter**.



3. Right-click **FMVehicle**, and then select **Create extension**.



An extension of the **FMVehicle** table is created in the **FleetManagement Discounts** project named **FMVehicle.Extension**.

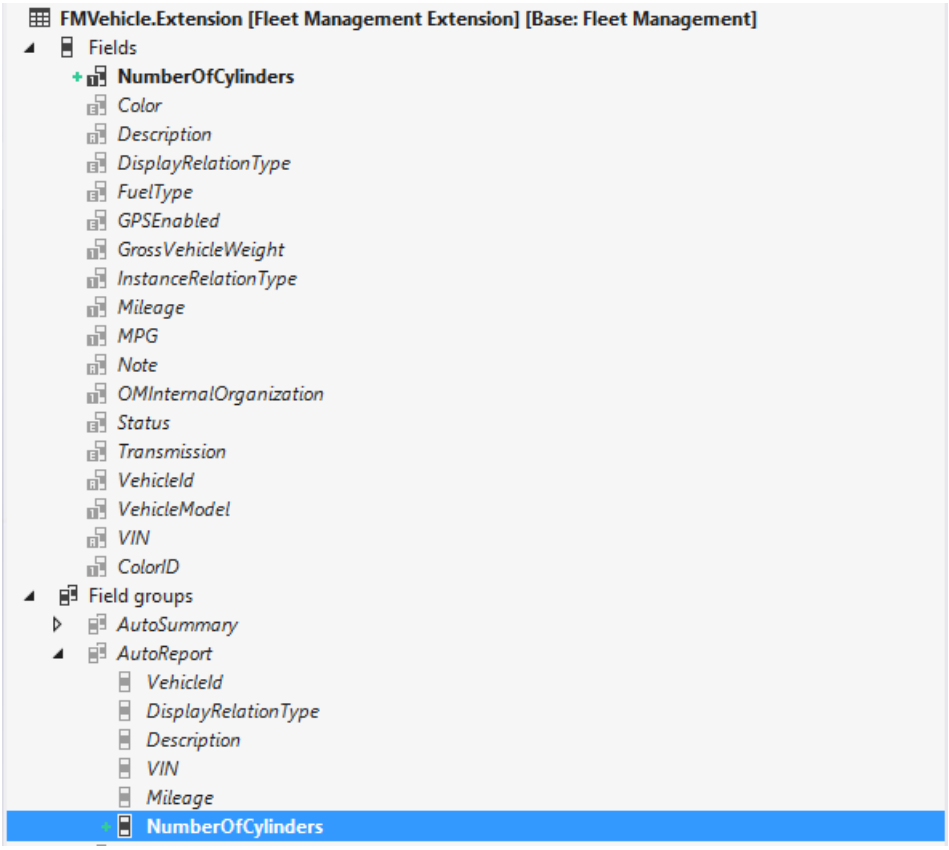


4. In **Solution Explorer**, right-click **FMVehicle.Extension**, and then select **Open with**. In the dialog box, select **XML (Text) Editor**, and then select **OK**. **Note**: This extension file is simply a template that doesn't contain metadata from the base **FMVehicle** table. An extension file will always contain only the metadata that defines the extension and nothing from the base model element.

```
<?xml version="1.0" encoding="utf-8"?>
<AxTableExtension xmlns:i="http://www.w3.org/2001/XMLSchema-instance">
  <Name>FMVehicle.Extension</Name>
  <FieldGroupExtensions />
  <FieldGroups />
  <Fields />
  <Indexes />
  <Relations />
</AxTableExtension>
```

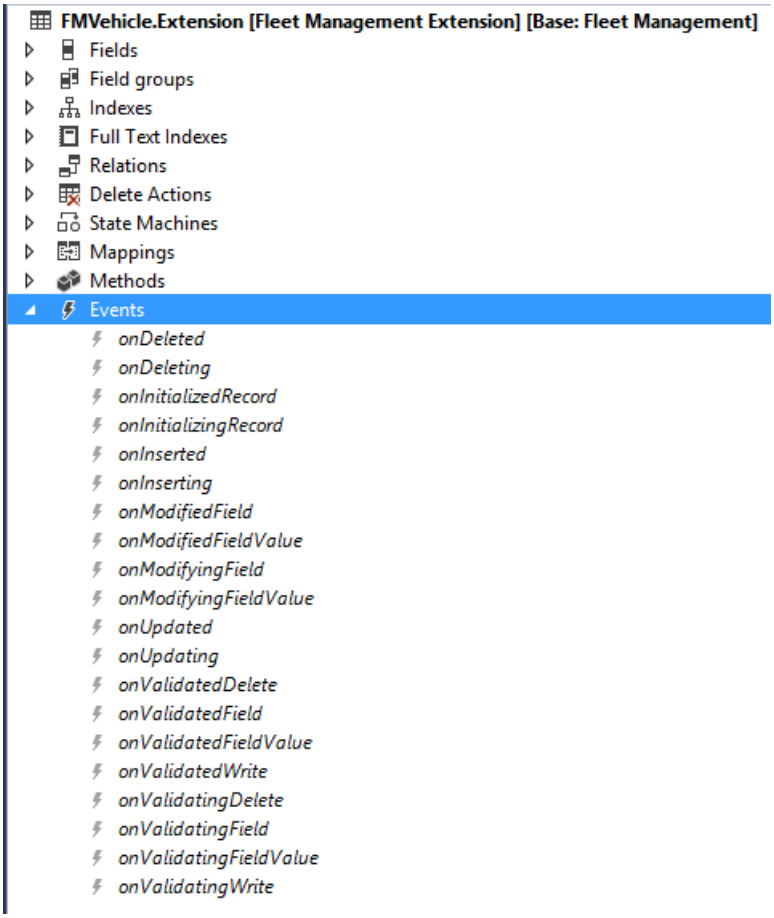
5. Close the XML editor.
6. In **Solution Explorer**, double-click **FMVehicle.Extension** to open the designer.
7. Right-click **Fields** and add a new integer field. Change the name of the field to **NumberOfCylinders**.
8. In the **Properties** window, set the **Label** property of the new field to **NumberofCylinders**.
9. Drag-and-drop the **NumberOfCylinders** field into the **AutoReport** field group to extend the field

group of the base table.



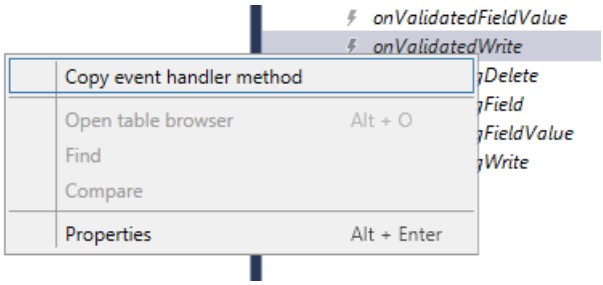
10. Save FMVehicle.Extension.

11. Expand the **Events** node. The **Events** node lists all events that the table exposes. This list includes events that are defined by the framework, and delegate methods that are defined by application developers.



> **NOTE**
>
> Different framework events are exposed on the designers of many types of element and sub-elements, like table events, form events, form data source events, and form control events.

12. Right-click onValidatedWrite, and then select **Copy event handler method**.



This step copies the event handler method signature to the clipboard.

13. Add a new class named **FMVehicleEventHandlers** to the **FleetManagement Discounts** project.
14. In **Solution Explorer**, double-click **FEVehicleEventHandlers** to open the code editor.
15. Right-click and paste the event handler method that you copied in step 12.

```
Class FMVehicleEventHandlers
{
    /// <summary>
    ///
    /// </summary>
    /// <param name="sender"></param>
    /// <param name="e"></param>
    [DataEventHandler(tableStr(FMVehicle), DataEventType::ValidatedWrite)]
    public static void FMVehicle_onValidatedWrite(Common sender, DataEventArgs e)
    {
    }
}
```

16. Insert the following code into the **FMVehicle_onValidatedWrite** event handler. This code validates that the number of cylinders can't be greater than 8.

```
[DataEventHandler(tableStr(FMVehicle), DataEventType::ValidatedWrite)]
public static void FMVehicle_onValidatedWrite(Common sender, DataEventArgs e)
    {
        ValidateEventArgs validateArgs = e as ValidateEventArgs;
        FMVehicle vehicle = sender as FMVehicle;
        boolean result = validateArgs.parmValidateResult();

        if (vehicle.NumberOfCylinders > 8)
        {
            result = checkFailed("Invalid number of cylinders.");
            validateArgs.parmValidateResult(result);
        }
    }
```

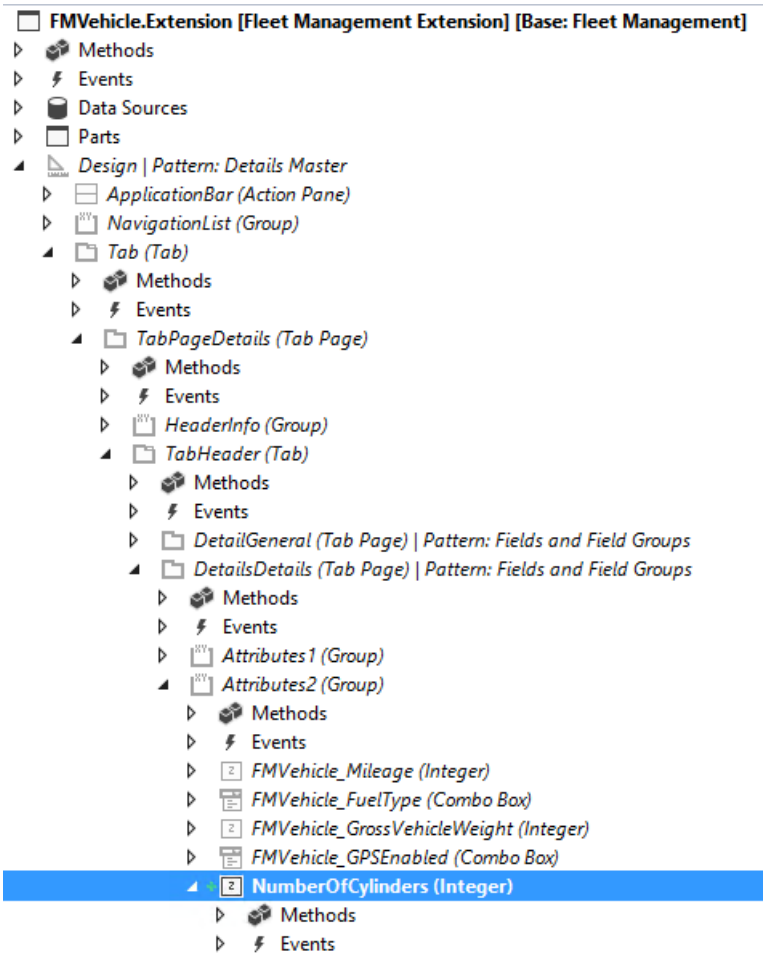
17. Save FMVehicleEventHandlers class

> **TIP**
>
> You can paste and define your event handlers in any class of your model. The class FMVehicleEventHandlers is used only as an example.

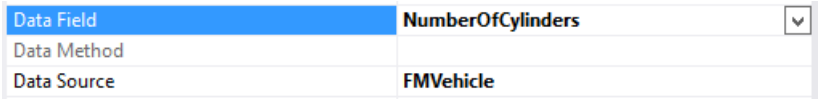
Extend the FMVehicle Form

Next, add an extension to the **FMVehicle** form in the **FleetManagement Discounts** project. First, be sure to select this project in **Solution Explorer**.

1. Use **Application Explorer** to find the form named **FMVehicle**, and in the **Application Explorer** filter bar, enter `FMVehicle type:form`.
2. Right-click the form, and then click **Create extension**.
3. Add a new integer control named **NumberOfCylinders** to the **Attributes2** group control as shown below. You can find this control by expanding **Design** > **Tab** > **TabPageDetails** > **TabHeader** > **DetailsDetails** > **Attributes2**.



4. Bind the new control to the **NumberOfCylinders** data field in the properties window as follows.

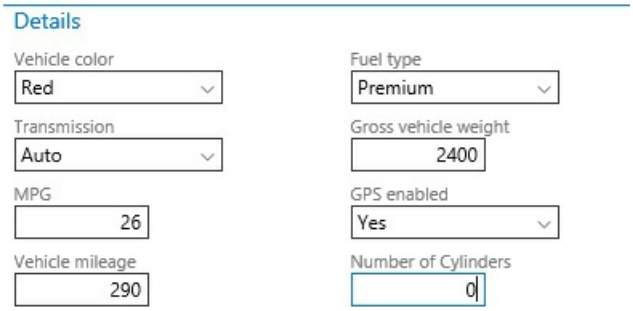


5. Save FMVehicle.Extension and build the project.

Test your extensions

1. In **Solution Explorer**, right-click **FleetManagement Discounts**, and then click **Set as StartUp project**.

2. Similarly, in FleetManagement Discounts, set the **FMVehicle.Extension** form as the startup object.
3. Press **Ctrl+F5** to start without debugging, or use the **Debug** menu.
4. After the **Vehicles** form opens, select a vehicle to view its details.
5. Expand the **Details** tab and notice the new **Number of Cylinders** field.

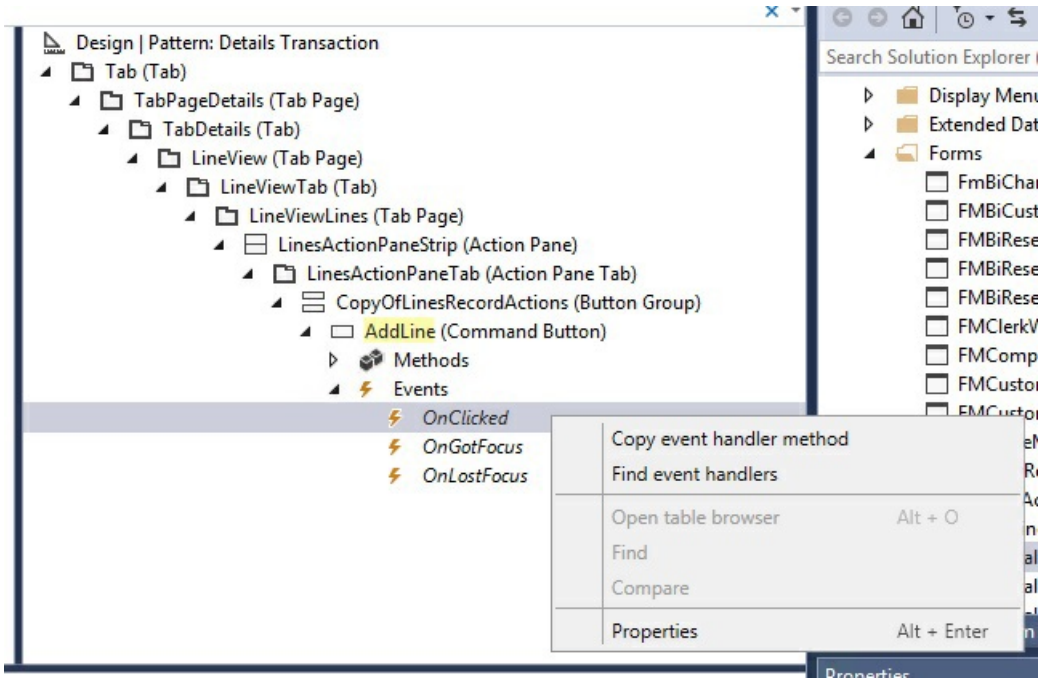


6. In the Action Pane, click **Edit**, and change the value in the **Number of cylinders** field to 12.
7. In the Action Pane, click **Save**.
8. Notice the validation error.
9. Enter a valid number of cylinders, less than 9, and then save the new value.

Experiment with event handlers on form controls

You can add event handler methods on existing controls.

1. Find the **AddLine** command button control in the **FMRental** form designer, right-click the **OnClicked** event, and select **Copy event handler method**.



2. Paste the event handler method in a class of the Fleet Management Extension model and add X++ code to implement it.

```
/// <summary>
///
/// </summary>
/// <param name="sender"></param>
/// <param name="e"></param>
[FormControlEventHandler(formControlStr(FMRental, AddLine), FormControlEventType::Clicked)]
public static void AddLine_OnClicked(FormControl sender, FormControlEventArgs e)
{
}
```

When implementing the AddLine_OnClicked event handler, you can access the button control instance using the **sender** parameter.

```
FormButtonControl button = sender as FormButtonControl;
```

If you need to access the parent form or any of its variables, this example shows how to access the **FormRun** instance and one of its data sources.

```
FormRun fr;
fr = sender.formRun();
var frDs = fr.dataSource("FMRental");
```

Experiment with event handlers on form data sources

Just like tables, form controls and other element types, form data sources and form data source fields provide framework-level events. The following example shows how you can use the ValidatingWrite event on a form data source or the Validating event on a form data source field to validate user input on the FMRental form. This functionality is available as of Platform Update 7.

```
/// <summary>
/// When saving a new rental, prevent setting the start mileage on the FMRental form to a value that is
equal to 1
/// </summary>
[FormDataSourceEventHandler(formDataSourceStr(FMRental, FMRental),
FormDataSourceEventType::ValidatingWrite)]
public static void FMRental_OnValidatingWrite(FormDataSource sender, FormDataSourceEventArgs e)
{
    var datasource = sender as FormDataSource;
    var args = e as FormDataSourceCancelEventArgs;
    if (args != null && datasource != null)
    {
        FMRental record = datasource.cursor() as FMRental;
        if (record.recId == 0)
        {
            if(record.startmileage == 1)
            {
                boolean doCancel = !checkFailed("Start Mileage = 1 is not allowed");
                args.cancel(doCancel);
            }
        }
    }
}
```

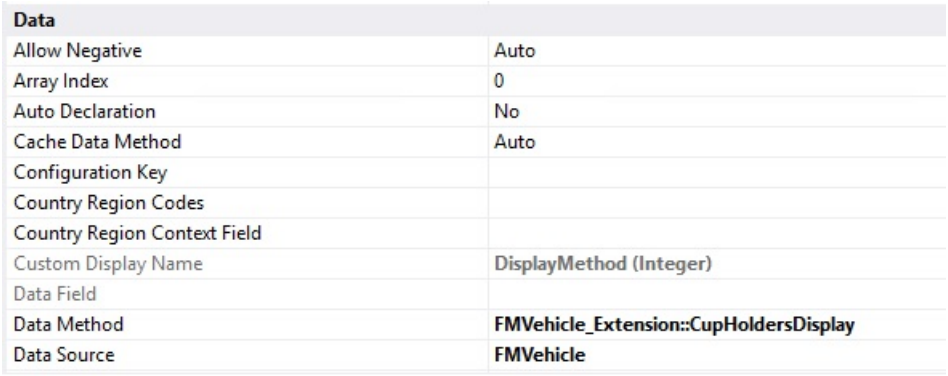
```
/// <summary>
/// Prevent changing the start mileage field on the FMRental form to a value that is equal to 1
/// </summary>
[FormDataFieldEventHandler(formDataFieldStr(FMRental, FMRental, StartMileage),
FormDataFieldEventType::Validating)]
public static void StartMileage_OnValidating(FormDataObject sender, FormDataFieldEventArgs e)
{
    var dataObject = sender as FormDataObject;
    var args = e as FormDataFieldCancelEventArgs;
    if (args != null && dataObject != null)
    {
        var datasource = dataObject.datasource() as FormDataSource;
        if (datasource != null)
        {
            FMRental record = datasource.cursor() as FMRental;
            if (record.RecId > 0)
            {
                if (record.StartMileage == 1 )
                {
                    boolean doCancel = !checkFailed("Start Mileage = 1 is not allowed");
                    args.cancel(doCancel);
                }
            }
        }
    }
}
```

Experiment with table extension display and edit methods

Extension methods enable you to extend tables by creating new display and edit methods on these tables without over-layering X++ code (Extension method must belong to a class named with an _Extension suffix). For example, this class shows how you can extend the FMVehicle table with an extension display method named CupHoldersDisplay.

```
public static class FMVehicle_Extension
{
    public static display int CupHoldersDisplay(FMVehicle vehicle)
    {
        return 7;
    }
}
```

On a form or form extension, you can bind a control to this display method by setting "Data Source = FMVehicle" and "Data method = "FMVehicle_Extension::CupHoldersDisplay" as the image below shows.



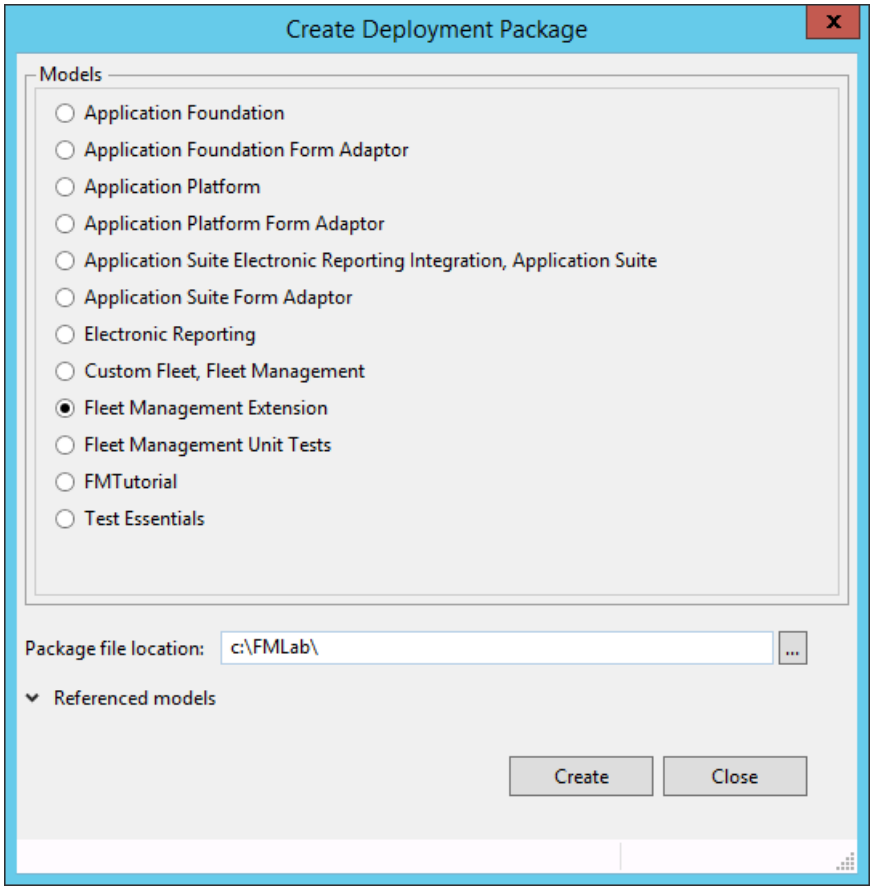
Data	
Allow Negative	Auto
Array Index	0
Auto Declaration	No
Cache Data Method	Auto
Configuration Key	
Country Region Codes	
Country Region Context Field	
Custom Display Name	DisplayMethod (Integer)
Data Field	
Data Method	**FMVehicle_Extension::CupHoldersDisplay**
Data Source	**FMVehicle**

Create a Fleet extension package for deployment

To deploy your extension to another environment, for example, a test, pre-production or production

environment, you must create a deployment package.

1. In Visual Studio, on the **Dynamics AX** menu, point to **Deploy**, and then select **Create Deployment Package**.



2. Select the **Fleet Management Extension** check box.
3. In the **Package file location** text box, enter "c:\FMLab".
4. Select **Create**. A deployment package that contains the Fleet management Extension package is created.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Customize through extension and overlayering

2/18/2021 • 12 minutes to read • Edit Online

This topic discusses the two methods of customizing source code and metadata of model elements - overlayering and extensions and details supported extension capabilities.

Overlayering

You can customize source code and metadata of model elements that are shipped by Microsoft or third-party Microsoft partners. In order to customize metadata and source code of a model, the developer must create a new model that overlays the model they want to customize. For example, solution developers can provide code in the SLN layer, independent software vendors can use the ISV layer, and value-added resellers can use the VAR layer. Functionality defined in higher layers (VAR layer in this example) can override the functionality of lower layers. The overlaying model must belong to the same **Package** as the source model and belong to a layer that is higher than the source model. Overlayering is a powerful tool to perform advanced customizations of metadata and source code, but may increase the cost of upgrading a solution to a new version.

Extensions

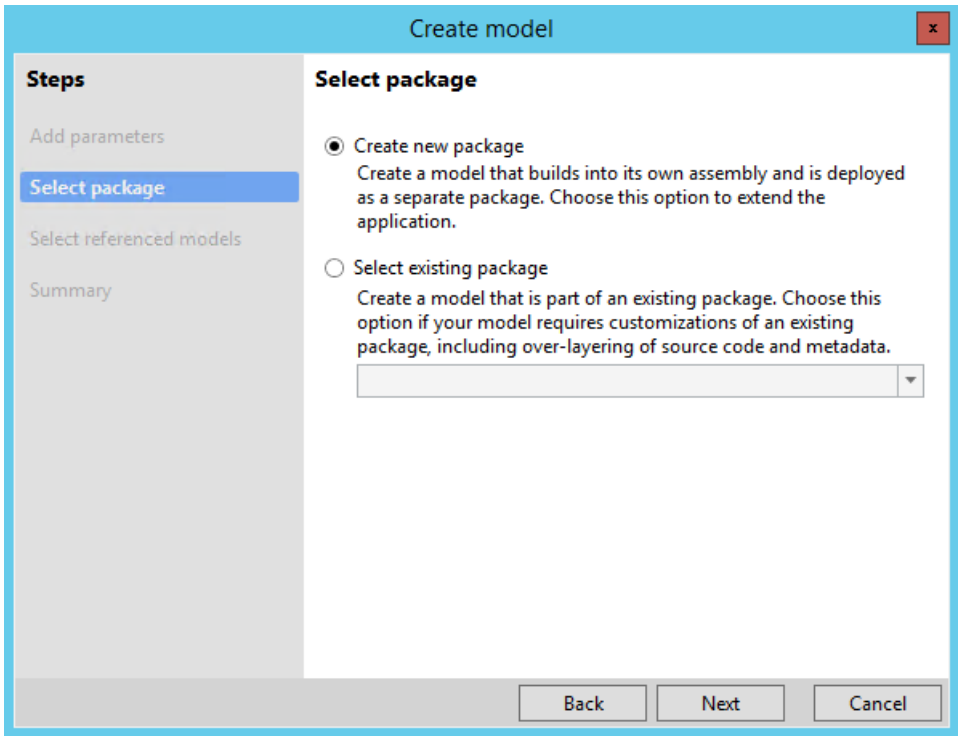
You can customize an application by using *extensions*. An extension enables you to add functionality to existing model elements and source code. Extensions provide the following capabilities:

- Creating new model elements.
- Extending existing model elements.
- Extending source code using class extensions.
- Customizing business logic. Ways to customize business logic include:
  - Creating event handlers to respond to framework events, such as data events.
  - Creating event handlers to respond to event delegates that are defined by the application.
  - Creating new plug-ins.

To get started, review or complete this tutorial: Customize model elements through extension.

Extension models and packages

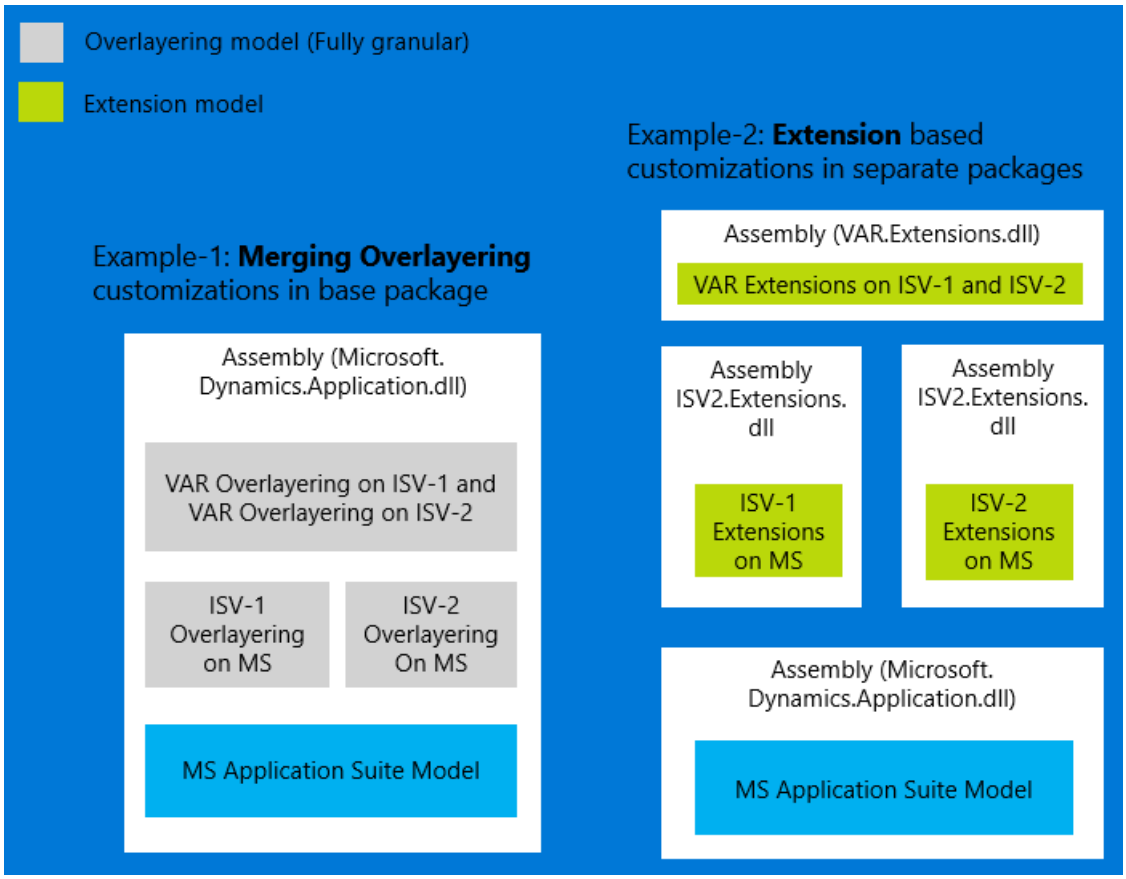
You can create a model that contains only new model elements, new code, or extensions. This model is compiled into its own separate assembly. These assemblies, along with related metadata and runtime artifacts can be packaged (as a deployable package file) and deployed on runtime sandbox or production environment. To create an extension model, go through the Create model wizard and select **Create new package** on the second step.



Extension models have several advantages, including:

- **Application lifecycle management (ALM):** Extension models simplify and improve the performance of deployments, builds, test automation and delivery to customers.
- **Design time performance:** Building your model or project doesn't require you to recompile the entire application.
- **Servicing:** In the cloud, Microsoft can install, patch, upgrade, and change internal APIs without affecting your customizations.
- **Upgrades:** Unlike overlayering, extensions reduce the cost of upgrading to a new version, as this approach eliminates costly code and metadata conflicts.

The following diagram illustrates how extensions get isolated in their assemblies.



Code extensions

You can extend source code in 3 ways:

- By subscribing to events (framework events and delegates)
- By writing plug-ins.
- By creating class extensions (aka class Augmentation), see section below.

You should understand the following characteristics of framework events:

- Events are implemented as multi-cast delegates, which means that more than one event handler can be subscribed to any particular event.
- Events are broadcast; there's no sequencing of calls to event handlers.
- Event handlers execute within the transaction scope of the base methods.

Events

Events are raised as preceding and succeeding operations around the base methods. This means that you have the opportunity to run code before a base method is called and after it has completed. Microsoft Dynamics AX 2012 introduced XPP events, which are also available in this release and can be subscribed to in your extensions.

Plug-ins

Plug-ins are extension points that are defined by the base application. By using a class-factory pattern, plug-ins enable you to replace the base functionality. You can see how to implement a plug-in in the tutorial, Customize model elements through extension.

Class Extensions

Class extensions enable you to augment a class by adding methods and variables to existing classes, tables and forms. For more details, refer to the topic Class extension model in X++.

Form extensions

You can extend the functionality of a form by extending its controls and data sources. For example, in a form extension, you can:

- Add a new control.
- Enable or disable a control.
- Change the text or label property of a control.
- Change a control's visibility.
- Change a form's help text.
- Change a form's caption.
- Add a new data source.
- Add a form part.

Other ways to customize a form, such as reordering controls in the form are planned to be included in a future release. In Microsoft Dynamics AX 2012, you could override form methods. In the current version, you use extensions to implement event handlers that are called from the base implementations of form methods. The following table lists each method and its associated events.

PUBLISHED FORM DATASOURCE METHOD	PRECEDING EVENT	SUCCEEDING EVENT
active	N/A	Activated
delete	Deleting	Deleted
validateWrite	ValidatingWriting	ValidatedWrite
write	Writing	Written
create	Creating	Created
executeQuery	N/A	QueryExecuted
linkActive	N/A	PostLinkActive
init	N/A	Initialized
validateDelete	ValidatingDelete	ValidatedDelete
reread	N/A	Reread
selectionChanged	N/A	SelectionChanged
markChanged	N/A	MarkChanged
leaveRecord	LeavingRecord	LeftRecord

PUBLISHED FORM OBJECT METHOD	PRECEDING EVENT	SUCCEEDING EVENT
init	Initializing	Initialized
close	Closing	N/A

PUBLISHED FORM OBJECT METHOD	PRECEDING EVENT	SUCCEEDING EVENT
run	N/A	PostRun
activate	N/A	Activated

PUBLISHED FORM CONTROL METHOD	PRECEDING EVENT	SUCCEEDING EVENT
modified	N/A	Modified
validate	Validating	Validated
leave	Leaving	LostFocus
enter	N/A	Enter
gotFocus	N/A	GotFocus
clicked	N/A	Clicked
selectionChange	SelectionChanging	N/A
pageActivated	N/A	PageActivated
allowPageDeactivate	AllowPageDeactivate	N/A
expand	Expanding	Expanded
tabChanged	N/A	TabChanged
dialogClosed	N/A	DialogClosed

Code behind extension forms

You can use class extensions to author X++Â logic associated with form extensions. This allows the definition of state variables accessible to form and control event handlers. It also allows overriding form methods without overlayering code. Refer to this blog article for an example.

Table extensions

You can create a table extension to extend a table's design and logic. You can add new fields, field groups, indexes, mappings and relations. You can also add new fields to existing field groups, change the label of a table field, change the Created By, Created Date Time, Modified By, Modified Date Time properties. Using table extensions, you can also change the Extended Data Type property on fields and set it to an EDT that is derived from the current EDT (*This is available as of platform update 8*).

In Microsoft Dynamics AX 2012, you could override the virtual methods of a table's base class to control the behavior that occurred during table operations, such as when creating, reading, updating, or deleting. In the current version, you instead use extensions to implement event handlers that are called from the base implementations of the table methods. The following table lists each table method and its events.

PUBLISHED TABLE METHOD	PRECEDING EVENT	SUCCEEDING EVENT
validateWrite	ValidatingWrite	ValidatedWrite
validateDelete	ValidatingDelete	ValidatedDelete
validateField	ValidatingField	ValidatedField
validateFieldValue	ValidatingFieldValue	ValidatedFieldValue
modifiedField	ModifyingField	ModifiedField
modifiedFieldValue	ModifyingFieldValue	ModifiedFieldValue
Insert	Inserting	Inserted
Update	Updating	Updated
Delete	Deleting	Deleted
Initvalue	InitializingRecord	InitializedRecord
FinalDeleteValidation	Executed when a delete operation is performed on a table object, before the operation is committed to the underlying database table	N/A
FinalInsertValidation	Executed when an insert operation is performed on a table object, before the operation is committed to the underlying database table	N/A
FinalReadValidation	Executed when a read operation is performed on a table object.	N/A
FinalUpdateValidation	Executed when an update operation is performed on a table object, before the operation is committed to the underlying database table.	N/A

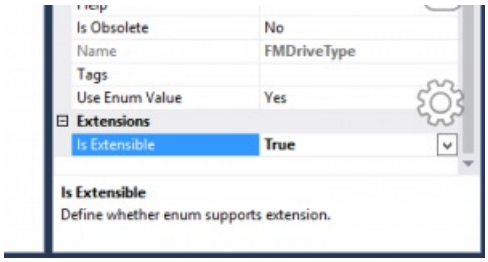
Validation events capture and return results by using the **DataEventArgs** parameter. The display and edit method modifiers are supported on table extensions.

View and Data entity extensions

You can extend a View or Data entity to achieve much of the functionality available with table extensions.

Enum extensions

You can extend any Enum that is marked extensible (IsExtensible=True).



By extending an Enum, you can add new Enum values to it. It is important to keep the following in mind when dealing with extensible Enums:

1. You cannot have X++ logic that depends on the integer value of Enum values (For example. *If (Enum1.v1 > Enum1.v2) ...* is not supported for extensible enums)
2. When Enum values of extensible Enums are synchronized into the database:
   - Integer values that belong to the baseline enum are deterministic, they come from the metadata.
   - Integer values that are an extension are generated during the synchronization process and are not deterministic.

EDT extensions

You can extend an EDT element in order to modify any of the following properties:

- Form help
- Label
- String size
- Help text

Query extensions

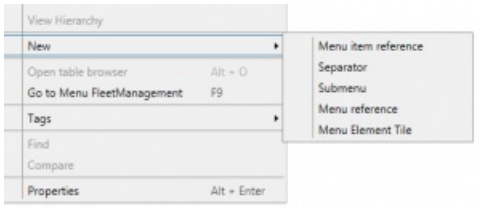
You can extend a Query element to achieve the following:

- Add ranges to an existing data source.
- Add new (embedded) data sources to an existing data source.
- Add new fields to an existing data source.

Menu extensions

You can extend a Menu element to achieve the following:

1. Add new menu items, submenus, menu references and tile references to an existing menu.
2. Hide an existing menu item, tile, or sub-menu in a menu by setting the **Visible** property to No.



Security role and duty extensions

You can extend a Security Role or a Security Duty to add new duties/privileges to these elements.

Report extensions

You can customize reports and business docs using extensions, below is a list of tutorials that help you learn more.

Customize App Suite reports by using extensions: Customizations to reporting solutions in the standard application are fully supported using a pure 'Extension' model. This article offers guidance on how to add the most common customizations to standard application reports without over-layering Application Suite artifacts. Here are some...

Create custom designs for business documents: This article focuses on the steps involved in crafting a custom report design for an existing application business document using a 'pure' extension model. Follow the steps below to associate a custom report design with an application document instance....

Expand Application Suite report data sets: This article focuses on the expansion of an existing report data set produced using X++ business logic in a Report Data Provider (RDP) class. Use custom delegate handlers and table extensions to include additional field data and/or calculations without...

Extend report menu items to redirect user navigation: This article focuses on the process of extending existing application menu items to redirect navigations with minimal code changes. Using this technique you will avoid the hassle of tracking down and replacing all references to an existing application...

Label extensions

You can create label extension files in order to modify the string value of a label, add new labels to the same label file or add new languages. To create a label extension file you must name it with a _extension suffix. For example, to extend the **FLM** labels of the Fleet Management model, do the following:

1. Create a project that belongs to a model that references Fleet Management (The model Fleet Management Extension is an example).
2. Add a new label file to the project and name it **FLM_Extension**.
3. Within the FLM_Extension label file, you can create new labels or modify the value of labels that are defined in the **FLM** label file of the Fleet Management model. Use the standard label editor to define new labels or redefine labels that already exist in the original FLM label file.
4. If your goal is to create translations of the FLM label, right-click on the FLM_Extension element in your project and select **Add new languages**. Follow the wizard to add translation files to the FLM labels.

> **NOTE**
> If the FLM_Extension file already exists in another model, you can name your file **FLM_ExtensionN** where N is any integer (For example FLM_Extension2, FLM_Extension3, ...etc)

Extension of Country/Region Codes

> **NOTE**
> This functionality is available as of Platform update 7.

The **Country Region Codes** property enables developers to restrict functionality to certain regions or countries based on the current legal entity's primary address. Developers can extend this functionality by setting the Country Region Codes property on the following extension element types: Menu extension, Menu Item extension, Table extension (and fields), Form extensions (form controls), EDT extensions, Enum extensions, and View extensions.

You can specify additional country/region codes in their extension. The effective country/regions (at runtime) associated with an element will be the union of all codes from the baseline element and all its extensions.

Event argument types

When an event takes place, the delegates described in the sections above get triggered. In this section, we provide the details of the types of the arguments that are passed as the event arguments. Some of the entries in the table below have a null in the column designating the event args; this means that no arguments are passed - the relevant information is in the first argument (typically called sender) in this case.

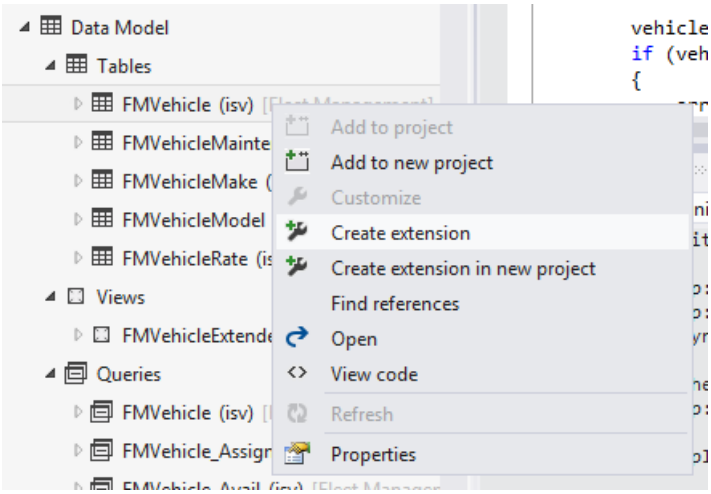
EVENT	ARGUMENT TYPE
onDefaultedField	DefaultFieldEventArgs
onDefaultedRow	null
onDefaultingField	DefaultFieldEventArgs
onDefaultingRow	null
onDeleted	null
onDeletedEntityDataSource	DataEntityContextResultEventArgs
onDeleting	null
onDeletingEntityDataSource	DataEntityContextResultEventArgs
onFindingEntityDataSource	DataValidationEventArgs
onFoundEntityDataSource	DataEntityContextRecordEventArgs
onGettingDefaultingDependencies	DefaultingDependenciesEventArgs
onGotDefaultingDependencies	DefaultingDependenciesEventArgs
onInitializedEntityDataSource	DataEntityContextEventArgs
onInitializedRecord	null
onInitializingEntityDataSource	DataEntityContextEventArgs
onInitializingRecord	null
onInserted	null
onInsertedEntityDataSource	DataEntityContextResultEventArgs
onInserting	null
onInsertingEntityDataSource	DataEntityContextResultEventArgs
onMappedDatasourceToEntity	DataEntityContextEventArgs
onMappedEntityToDataSource	DataEntityContextEventArgs

EVENT	ARGUMENT TYPE
onMappingDatasourceToEntity	DataEntityContextEventArgs
onMappingEntityToDataSource	DataEntityContextEventArgs
onModifiedField	ModifyFieldEventArgs
onModifiedFieldValue	ModifyFieldValueEventArgs
onModifyingField	ModifyFieldEventArgs
onModifyingFieldValue	ModifyFieldValueEventArgs
onPersistedEntity	DataEntityContextEventArgs
onPersistingEntity	DataEntityContextEventArgs
onPostedLoad	null
onPostingLoad	null
onUpdated	null
onUpdatedEntityDataSource	DataEntityContextResultEventArgs
onUpdating	null
onUpdatingEntityDataSource	DataEntityContextResultEventArgs
onValidatedDelete	ValidateEventArgs
onValidatedField	ValidateFieldEventArgs
onValidatedFieldValue	ValidateFieldValueEventArgs
onValidatedWrite	ValidateEventArgs
onValidatingDelete	ValidateEventArgs
onValidatingField	ValidateFieldEventArgs
onValidattingFieldValue	ValidateFieldValueEventArgs
onValidatingWrite	ValidateEventArgs

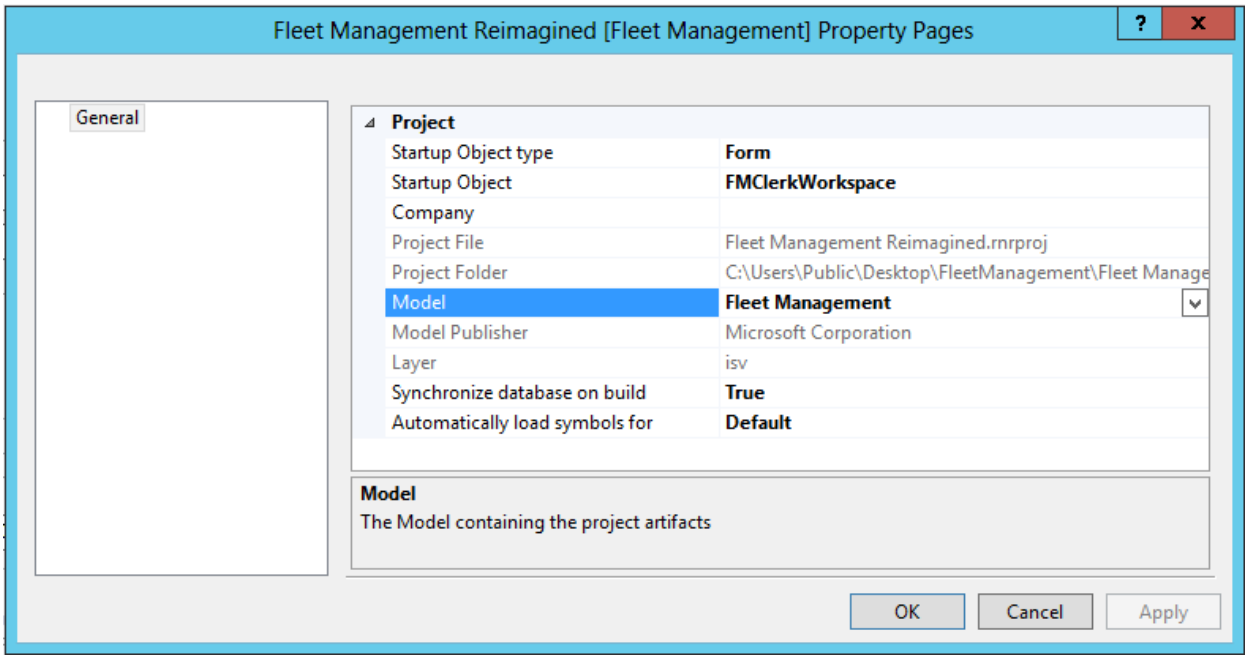
Development tools support

The development tools in Visual Studio provide integrated features to help you create and work with extensions. For example, when you right-click an element name in **Application Explorer**, you can create an extension for

that element.



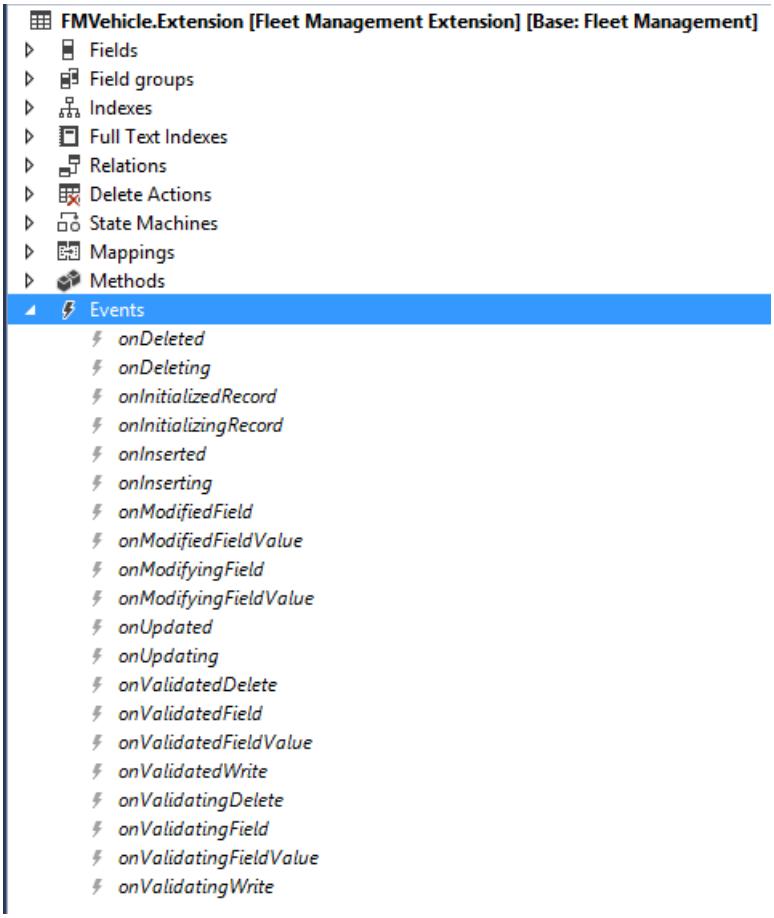
To create an extension, the current project in **Solution Explorer** must belong to a model that references the model of the selected element in **Application Explorer**. To view the model for a particular project, view the project properties.



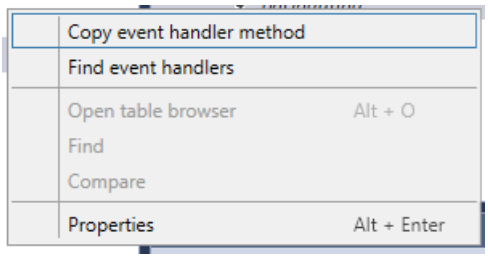
Visual Studio creates the extension file for you, either in the current project or in a new project. You can then work with the extension file either as source code or by using a designer. You package a code-extension model for deployment exactly like you would package any other model. On the **Dynamics 365** menu, point to **Deploy**, click **Create Deployment Package**, and then select the check box for the package name.

Framework events

Tables, form data sources, form controls, and other element types that support extension events list the available events (and delegates) under an **Events** collection node. For example, viewing the **Events** node of a table extension shows events that are defined by the framework, and delegate methods that are defined by application developers.



Note: Events are exposed on the designer on different element and sub-element types, like table events, form events, form data source events, form control events, and others. Open the context menu of an event node to interact with events:



- **Copy event handler method**: This option copies a method signature to the clipboard. You can paste it in any X++ code editor to define a method that subscribes to the selected event.
- **Find event handlers**: Searches and lists all methods subscribed to the selected event.

Extensibility changes in Dynamics 365 for Finance and Operations version 10.0.3

2/18/2021 • 2 minutes to read • Edit Online

This topic lists the extensibility features that were implemented in Microsoft Dynamics 365 for Finance and Operations version 10.0.3. For more information about the schedule of changes that support extensibility, see Application extensibility plans.

Enumerations made extensible

The following enumerations have been made extensible in this update:

- LedgerJournalWFApprovalModule
- RetailReceiptTransaction

SQL operations made extensible

The following SQL operations have been made extensible in this update:

- CustVendTrans support for an extensible map pattern

Metadata changes

The following metadata changes have been made in this update:

- CostSheetAmount.NoOfDecimalsIsExtensible
- SalesLinePercent.NoOfDecimalsIsExtensible

Refactored methods

The following methods have been refactored to support extensibility:

- BankReconciliationDataInitializer.initDocumentOpenTmp
- BankReconciliationDataInitializer.initStatementOpenTmp
- Class\BomCalcJob_All.processSingleTask
- Class\KanbanEventQuantityMap.newStandard
- Class\MCRFullTextSearchRefresh.run
- Class\PdsRebateAgreementValidate.validate
- Class\PurchRFQFormLetter.main
- Class\ReqTransPoMarkFirm.getPurchIdSingleThread
- Class\TAMVendRebateCorrectClaims.correctClaims
- Class\TAMVendRebateCorrectClaims.createClaimCorrection
- Class\TAMVendRebateCorrectClaims.rebateAmountPerUnit
- Class\WhsReleaseToWarehouseForm.buttonRelease_clicked
- Classes\LedgerAllocationRules.ValidateDimension
- Classes\ProjJournalCheckPost.checkFeeJournalDimensions
- Commission_Sales.run
- CreditcardPaymentCardTokenize.getFromDialog

- CustInPaymDialog.openDialog
- CustVendDisputeHelper.canDeleteDispute
- EcoResCategoryTreeDatasource.new
- EcoResProductRelationtable.validateWrite
- Form\EcoResProductCreate.updateCallers
- Form\InventOnhandReserve\DataSource\InventSum.reserveNow
- Form\PdsRebateAgreement\DataSource\PdsRebateAgreement.executeQuery
- Form\ProcCategoryHierarchyManagement\FormDesign\CategoryTreeGroup\CategoryTreeCtrl.selection
- Form\ReqSupplyDemandSchedule.updateDesign
- Form\SalesTable\DataSource\MCRSalesLineDropShipment\field\DropShipment.modified
- Form\SalesTable\DataSource\SalesTable.create
- FormletterService.removeProforma
- InventJournalTrans.validateWrite
- InventJournalTrans_Tag.validateWrite
- InventMovement.addLedgerPhysicalAmount
- InventMovement.canAutoReserveQuantity
- InventTransSerialNumberCreate.checkFormat
- InventUpd_Reservation.updateReserveLess
- LedgerJournalEngine.onSegmentChangedForPrimaryAccount
- LedgerJournalTransCustPaym.enableDisableMandate
- LedgerTransStatementDP.processOffsetAccountInStaging
- PdsBatchAttribReserveForm.checkReserveLine
- PriceDisc.findDiscAgreement
- PriceDiscAdmCheckPost.postJournal
- PriceDiscHeading.updateDiscQty
- PriceDiscHeading.updateMultiLineDiscTmp
- PriceDiscPolicyFindOrCreate.run
- ProjInvoiceControl.projInvoiceControl
- ProjPostCostJournal.new
- PurchLineType.validateWrite
- ReqTransFormExplosion.tmpReqExplosionOnhandBuildServer
- ReqTransPoMarkFirm.createPurchTable
- ReqTransPoMarkFirm.updatePurchBuyerGroup
- RequisitionPurchaseOrderGeneration.createPurchaseOrder
- RetailBarCodeManagement.CreateBarCodeNoDim
- RetailTransactionServiceOrders.createCustomerOrder
- RetailTransactionTransformer.readTransactionSalesTrans
- SalesLine.createLine
- SalesLine.initFromPriceDisc
- SalesLine.insert
- SalesLine.update
- SalesLine.validateDelete
- SalesLine.writeRetailSalesLine
- SalesTable.updateMultiLineDisc
- SmaServiceFunctionLine_transfer.Run
- SmmOpportunityStatusUpdate.updateFromQuote

- Table\MCRCustpaymTable.salesTableByPassCreditLimit, displayOrderID, getCurrency, and mcrCustPaym\getCustomerPostingProfile
- Table\ReqPO.findAnySalesLineForReqPO
- TaxUncommitted.createTaxUncommitted, added local method createTaxUncommittedFromTmpTaxWorkTrans
- TmpTaxReport_IT.create
- TrvExpTrans.defaultTaxGroupFromWorker
- WHSBillOfLadingDP.insertWHSBillOfLadingTmp
- WHSControlItemId.populate
- WhsWarehouseRelease.creditLimitCheck
- WhsWorkCreate.addRangesToWorkTemplateQuery
- WHSWorkExecute.CreateTransferJournalLine
- WhsWorkTypePrintHandler.buildLabelAndConfirm

Other extensibility enhancements

- The PriceDiscHeading map was made extensible.
- **Retail channel:** Pre-triggers were added for Shipped, PackingSlip, and MarkAsPacked.
- **Retail channel:** The Cancellation charge dialog box can be overridden.
- **Retail channel:** Recall order default parameter value extension for the search order dialog box.

Extensibility changes in Dynamics 365 for Finance and Operations version 10.0.2

2/18/2021 • 2 minutes to read • Edit Online

This topic lists the extensibility features that were implemented in Microsoft Dynamics 365 for Finance and Operations version 10.0.2. For more information about the schedule of changes that support extensibility, see Application extensibility plans.

Enumerations made extensible

The following enumerations have been made extensible in this update:

- MarkupModuleType
- MCRCustPaymType
- PaymSchedBy

SQL operations made extensible

The following SQL operations have been made extensible in this update:

- JmgPayAdjustment.payAdjustLoop
- ProjPosting.ExtensionHash.New field
- WmsArrivalOverviewGeneration.buildPurch
- WmsArrivalOverviewGeneration.buildTransferOrder

Metadata changes

The following metadata changes have been made in this update:

- CostSheetPercent.NoOfDecimalsIsExtensible
- WHSCycleCountingWarehouseWorkLineEntity.IsPublic

Refactored methods

The following methods have been refactored to support extensibility:

- /Forms/ProjJournalTable/datasource/ProjJournalTable.initValue
- /Forms/PurchReqTable.instantiatePurchReqTableForm
- /Forms/PurchReqTable/DataSource/PurchReqTable.init
- /Forms/SalesQuotationProjLinkWizard/Controls/ProjInvoiceId.lookup
- /Tables/SalesTable.lastQuotation
- AccPolicyProductReceipt.isAccountingRequiredForSourceDocLine
- AssetFixedAssetEntity.overrideDataSource
- AssetProposalDepreciation.run
- AssetTableMethod.init
- BankAccountReconcile.validate
- Class\BomCalcCost.calcCostModel
- Class\MCRLoadContinuityCustInfo.insertLineData

- Class\McrPriceHistoryUpdate.insertNewlyFoundReferences
- Class\McrPriceHistoryUpdate.update
- Class\McrPriceHistoryUpdate.updatePriceHistoryLineReferences
- Class\ProjCopyItemEstimates.copyToItemRequirment
- Class\PurchAutoCreate_RFQ.createPurchOrderRFQLineReference
- Class\ReqEventProcessDeleteUnusedKanban.deleteUnusedKanban
- Class\ReqEventProcessDeleteUnusedKanban.run
- Class\ReqTransUpdate.updateLogAddQty
- Class\SalesCancelOrder.run
- Class\SalesCreateOrderFromCustomer.main
- Class\TAMVendRebateCorrectClaims.rebateAlreadyGiven
- Class\tamVendRebateTableStatusType_Approved.runPayment
- Class\TamVendRebateTableStatusType_Calculated.inserted
- Class\TamVendRebateTableStatusType_Calculated.runPayment
- Classes\TaxWithhold.createAllTaxWithholdTrans
- Classes\TaxWithhold.isCalculateTaxWithholdingNeeded_TH
- Classes\TaxWithhold.postTaxWithhold
- Classes\TaxWithhold.totalInvoiceLineAmountSettled_TH
- CustDirectDebitMandate.setDefaultMandate
- CustDueReportDetailDP.class declaration
- CustDueReportDetailDP.insertCustDueReportDetailTmp
- CustQuotationConfirmJour.printJournal
- CustVendCreatePaymJournal.pack
- CustVendCreatePaymJournal.parmHasBatchBeenSplit
- CustVendEditTaxBranch_TH.init
- CustVendSumForPaym.run
- CustVendTransSettlement.post
- DimDerDistRuleSalesComplInvoice_BR.createDimAllocForProjRevenue
- EcoResProductCreateExtended.SetAllowEditField
- EcoResProductVariantEntity.findDataSource
- FBSpedFileCreator_Fiscal_BR.createRecordC195
- Form\ProdTableCreate.canContinueWithEmptyDim
- Form\PurchCreateFromSalesOrder\DataSource\SalesLine.included
- Form\PurchCreateFromSalesOrder\DataSource\SalesLine.specifyVendAccount
- Forms\TaxWithholdTable.init
- FreeTextInvoiceDP.setSysDocuBrandDetails
- InventItemOrderSetupMap.checkNotStopped
- InventNonConformanceTable.InventNonConformanceTable.Create
- InventUpd_Estimated.updateAutoDimBatchId
- InventUpdateReserveMore.InventUpdateReserveMore
- InventValueReportPopulateItem.updateReportLinePL
- JmgCalcApproveDateView.viewDate member
- JmgCalcApproveWeekView.viewDate member
- JmgPayAdjustment.payAdjustLoop
- LedgerJournalPeriodicCopy.journalTransCopy
- LedgerTransStatementDP.populateTempTableLedgerInStaging

- MCRCustpaym.validateWrite
- MCRFullTextSearch.buildSearchText
- MCRFullTextSearch.truncate
- MCRHoldCodeTrans.insert
- MCRHoldCodeTrans.setOrderStoppedFlag
- MCRHoldCodeTrans.unreserve
- McrPriceHistoryForm.calcPotential
- McrPriceHistoryForm.insertPotentialTradeAgreements
- PaymTerm.validateWrite
- PdsRebateAgreement.checkLineBreaks
- PdsRebateAgreement.groupChangeCheckValid
- PdsRebateAgreement.lineAmountHasGapOrOverlap
- PdsRebateAgreement.lineQuantityHasGapOrOverlap
- PdsRebateAgreementLine.selectRebateAgreementLineMax
- PriceDisc.mcrCalcPostageDisc
- PriceDiscLinePolicyRule.retrieveSystemPolicyFieldList
- ProdUpdCostEstimation.updateSubPurchLine
- ProjBudgetManager.createBudgetLineDetail
- ProjBudgetManager.getQuery
- ProjForecastCost.validateWrite
- ProjForecastEmpl.validateWrite
- ProjForecastRevenue.validateWrite
- ProjLedgerUpdate.insert
- ProjPlanVersionsManager.importHierarchy
- ProjPlanVersionsManager.importProjPlanVersionRecords
- ProjPost.PostCost
- ProjPost.PostCost
- ProjWorkBreakdownStructureHelper.addQuotationRelatedRecordsForTask
- ProjWorkBreakdownStructureHelper.Addtask
- ProjWorkBreakdownStructureHelper.Addtask
- ProjWorkBreakdownStructureHelper.Addtask
- ProjWorkBreakdownStructureV2FormHelper.IndentTaskV2
- ProjWorkBreakdownStructureV2FormHelper.MoveTasks
- PurchFormletterParmDataInvoice.createParmLinesAndTable
- PurchLine.delete
- PurchLine.distributionUpdateNeeded
- PurchLine.initFromPriceDisc
- PurchLine.insert
- PurchLine.update
- PurchLineType.statusChangeAllowed
- ReqEventProcessKanban.newStandard
- ReqTransNeutralTracker.trackReqTrans
- ReqTransPoMarkFirm.create
- Retail channel: CartWorkflowHelper.AllowAggregation
- RetailEcoResProductReleaseManager_Extension.setAndSaveRetailProductProperties
- RetailMassUpdateUploadDBManager.insertIntoProductProperty

- RetailPeriodicDiscount.validatePriceGroup
- RetailTransactionServiceCustomer.newCustomer
- RetailTransactionTransformer.ReadDiscountLines
- SalesInvoiceDP.setSysDocuBrandDetails
- SalesInvoiceJournalPost.run
- SalesInvoiceJournalPostBase.run
- SalesLine.CheckItemId
- Table\InventTable.purchPriceAgreement
- Tables\TaxWithholdTrans.copyTaxWithholdTrans, initFromTaxWithholdTable, insert, validateWrite, amountTotalWHT, existPeriod_TH
- TAMVendRebatePaymentPost.main
- TAMVendRebateTableProcess.runProcess
- TrvPostExpenseHeader.postCustVendTransactions
- TrvPostExpenseHeader.postCustVendTransactions
- WhsControlLicensePlateId.process
- WhsLicensePlateLabelBuild.insertSingleLabelMenuItem
- WhsLicensePlateLabelBuild.insertSingleLabelPrintLine
- WhsrfControlData.processLegacyControl
- WhsWorkCreateProdPut.createReportFinishedParameters
- WhsWorkCreateProdPut.insertProdParmforCoByProduct
- WhsWorkCreateProdPut.insertProdParmForProdItem
- WhsWorkCreateProdPut.setAcceptError
- WHSWorkCreateReplenishment.checkExistingReplenWork
- WhsWorkExecuteDisplay.buildPick
- whsWorkExecuteDisplayInquiryLocation.buildLocationInquiry
- WmsArrivalOverviewGeneration.buildInventTransId
- WmsOrderTransType_OutputDontPostTransfer.decreaseQty
- WmsOrderTransType_OutputDontPostTransfer.increaseQtyOverdelivery

Other extensibility enhancements

- The accessModifier of Classes\BankPositivePayExport.Class changed from private to protected.
- The InventItemOrderSetupMap map was made extensible.
- **Retail channel:** Custom columns in RetailTransactionView.
- **Retail channel:** The sign-in request can be overridden.
- **Retail channel:** Shipping view extension controller class.
- **Retail channel:** Support for the AppBar button in AddressAddEditView.
- **Retail channel:** Support for overriding the Bank deposit amount key in the dialog box.

Extensibility changes in Dynamics 365 for Finance and Operations version 10.0.1

2/18/2021 • 2 minutes to read • Edit Online

This topic lists the extensibility features that were implemented in Microsoft Dynamics 365 for Finance and Operations version 10.0.1. For more information about the schedule of changes that support extensibility, see Application extensibility plans.

Enumerations made extensible

The following enumerations have been made extensible in this update:

- ACOCostStatus_BR
- ACOCostType_BR
- ACOJournalType_BR
- BankModuloCheck_NO
- InventTransferOrderType_BR
- ProdJourType
- ProjTransStatus
- RetailLabelTypeBase
- RetailLedgerBank
- RetailTenderFunction
- SalesPurchTrntype_BR
- SMAGetPriceFrom
- SMASubscriptionIndexChange

SQL operations made extensible

The following SQL operations have been made extensible in this update:

- InventSumDelta.findInventSumDeltaInventSumFieldsAll.
- LedgerFiscalJournal was changed so that it uses QueryObject.
- TaxTransDP.

Metadata changes

The following metadata changes have been made in this update:

- Data Entities/WMSItemArrivalJournalLineEntity.IsPublic, PublicCollectionName, PublicEntityName.
- DataEntities/LedgerJournalNameEntity/Fields/voucherSeriesCode.Allow Edit, Allow Edit on Create.
- DataEntities/LedgerJournalNameEntity/Fields/VoucherSeriesCompanyId.AllowEdit.
- Enums\SalesStatus::Backorder, Delivered.Label.
- Extended Data Types/WeightBase.Scale.
- InventTransferOrders added a form control group in the grid.

Refactored methods

The following methods have been refactored to support extensibility:

- AssetProposalDepreciation.run
- BankStatementValidate.validateDate
- Class\BankDocumentBankAccountTrans.loadSourceBuffer
- Class\BankReconMatchingRuleAutoProcessor.doProcessMatchRule
- Class\ProjJournalTransMapForm.initFromProjTable
- Class\RetailEodStatementPaymentJournal.createPaymentJournalLine
- Class\RetailKitAssemblyOrder.CreateOrUpdateBOMJournal
- Class\RetailTransactionServiceOrders.createOrUpdateRetailOrderLines
- Class\SalesInvoiceController.initReportName_IN
- Class\SalesInvoiceJournalPost.endUpdate
- Class\WrkCtrScheduler.loadRoute
- CreditCard.mcrInitFromCustPaymTable
- CreditcardProcess.mcrDoCapture
- CreditCardProcess.mcrDoRefund
- CreditCardProviderProcess.Submit
- CustCollectionLetterCreate.skipCustomer
- CustVendCheque.output
- CustVendSumForPaym.run
- EFDOCDanfe_BR.additionalInformationPageBreak
- EfDocDANFEDP_BR.additionalInformationBox
- ERDocuManagement.insertFile
- ERFileDestinationAttachment.saveFile
- ERFileDestinationBrowser.saveFile
- Form\BankReconciliationWorksheet.Init
- FreeTextInvoiceController.initReportName_IN
- HcmWorkerTransition.createHcmWorker
- InventCostClosingCancel_Init.createTasks
- InventDimCtrl_Frm_OnHand.initFromCaller
- InventMov_Jour_BOM.journalPostTrans
- InventProcessGuideDisplayLicensePlateDetailsPageBuilder.generateItemInfoForLicensePlate
- InventProcessGuideDisplayLocationDetailsPageBuilder.generateItemInfoForLocation
- InventStockCardDP.createInventStockCardTmpLineDetail
- InventTable.checkProjCategoryId
- InventUpd_WHSReservation.updateReserveMore
- JmgCalcApproveWeekView.initializeData
- LedgerConsolidate.Run and getSelectedDimensionAttributes
- LedgerFiscalJournalDP_IT.addStarsToTmpTable
- LedgerFiscalJournalDP_IT.insertLedgerFiscalJournalTmp_IT
- LedgerFiscalJournalDP_IT.insertLedgerFiscalJournalTmp_IT
- LedgerFiscalJournalDP_IT.processReport
- LedgerJournalTrans.checkAllowEditWhenCheckPrinted
- LedgerJournalTransUpdateVend.pdateNow
- LedgerVoucherTransList.First
- LedgerVoucherTransList.next
- MCRFullTextIndexField.tableIdFromEnum

- MCRFullTextIndexField.viewFromTable
- MCRInventSearch.searchProduct
- McrPriceHistoryLine_Purch.initAndInsertRebate
- PartyProvider.operatingUnitTypeToName
- PdsRebateAgreementValidate.construct
- POS_IssueLoyaltyCardView.NA
- PriceDiscAdmCheckPostPriceDiscTableUpdater.formattedQueryValue
- PriceDiscAdmTrans.checkItemRelation
- ProjBudgetManager.deleteProjBudgetLinesWhenZeroAmount
- ProjBudgetManager.updateProjBudgetLinesWithAmt
- ProjHourCostPrice.psaFindCostPrice
- ProjInvoiceProposalListPageInteraction.initializeQuery
- ProjPostEmplProposalSale.new
- ProjPostRevenueProposalSale.new
- ProjTable.initProjectFromCustomerAndInvoice
- ProjTransferPrice.findByContractResourceCategory, findTransferPrice, find
- ProjValElementServer.addProjToResource
- ProjValElementServer.deleteProjFromResource
- PurchPackingSlipJournalPost.postMarkupOnTrans
- PurchReqLine.setProjSalesPrice
- PurchRFQSendJournalCreate.createOrUpdateRFQLine
- ReqCalc.covCalcDim
- ReqCalc.covCalcDim
- ReqCalc.covCalcDim
- RequisitionPurchaseOrderGeneration.create
- RequisitionPurchaseOrderGeneration.create
- Retail extension point in the Commerce runtime (CRT) to override the ValidateCartLineQuantityAndPriceSymbol method
- RetailCatalogProductAttributeFormHelper.addProductAttributeControls
- RetailCreateSpecificLabel.makeLabel
- RetailEodStatementCustomerOrderInvoiceController.run
- RetailEodStatementPaymentJournal.ledgerBank2LedgerJournalACType
- RetailEodStatementPaymentJournal.postPaymentJournalForOthers, postPaymentJournalForSales, createTenderedPaymentLines, createPaymentJournalLine
- RetailEodTransactionTransformer.ReadTransactionHeader
- RetailEodTransactionTransformer.setExtensionProperty
- RetailEventNotificationAction.packingSlipCompletion
- RetailMediaAssociationHelper.associateProduct
- RetailProductPropertyManager.validateWriteOnInventModelGroupItem
- RetailSMBSeedGenerator.AccountReceivable
- RetailStatementPost.createPaymentLedgerTrans
- RetailTransactionSalesTransMark.MarkTransactions
- RetailTransactionServiceOrder.settleCustomerOrder
- RetailTransactionServiceOrders.cancelCustomerOrder
- RetailTransactionServiceOrders.createCustomerOrder
- RetailTransactionServiceOrders.createLedgerJournalForStore
- RetailTransactionServiceOrders.createOrUpdateRetailOrderHeader

- RetailTransactionServiceOrders.createOrUpdateRetailOrderLines
- RetailTransactionServiceTransactions.fillPaymentTransDetails
- RetailTransactionServiceTransactions.fillRetailTransactionDetails
- RetailTransactionServiceTransactions.fillSalesTransDetails
- RetailTransactionServiceTransactions.getJournalListQuery
- SalesCreateOrder.updateDeliveryAddress
- SubledgerJournalizer.loadAccountingdistributionTmp
- SubledgerJournalizer.recordSubledgerJourAccEntriesForRounding
- SubledgerJournalizer.recordSubledgerJournalAccountEntries
- Table\MCRContinuityScheduleLine.UpdateOtherLines
- Tax1099SummaryHelper.populateTaxSummaryFromVendSettlementTax
- TrvCreditCardTransactionEntity.validateWrite
- TrvExpenses.initializePersonalAmount
- TrvExpenses.updateFormVisibilityOnCategoryChange
- TrvExpenses.updateItemizationControls
- TrvExpTrans.copyValueToChildLines
- TrvExpTrans.defaultTaxGroupFromWorker
- TrvExpTrans.modifiedField
- TsTimesheetSignOffDP.insertTmpTSTimesheetSignOff
- WHSBillOfLadingDataUtil.populateCarrierInformation
- WHSBillOfLadingDataUtil.populateCustomerOrderInfo
- WHSLoadPlanningWorkbenchServerForm.addLoadLinesToLoad
- WHSLocationDirective.getValidSellableDaysQty
- WHSMobileAppAttachedImageDetails.getImageTypeFromSymbol
- WhsPostPackingSlip.updatePurchaseLoadLines
- WhsPostPackingSlip.updatePurchParmLineQuantityData
- WhsWarehouseRelease.main
- WhsWorkManualComplete.executeWorkLines
- WhsWorkManualComplete.performValidation
- WorkTimeCheckClassWorkCalendarDateLineTableWorkTimeLineTable class, validateWrite()
- WorkTimeLine.createWorkTimeCheck

Other extensibility enhancements

- **Retail channel:** Allow for extensions to support Select all and Clear all in OrderFulfillmentView.
- **Retail channel:** Expose Add return line to cart from the transaction application programming interface (API) by line ID.
- **Retail channel:** Line item locations can be viewed in OrderFulfillmentView.
- **Retail channel:** OrderFulfillmentView adds ICustomListColumn to allow for more information.
- Retail statement posting method adds another aggregation view by using the new RetailTransactionAggregationFieldList table that adds additional fields.

Extensibility changes in Dynamics 365 for Finance and Operations version 10.0

2/18/2021 • 2 minutes to read • Edit Online

This is a list of extensibility features that were implemented in Dynamics 365 for Finance and Operations version 10.0. For more information about the schedule of changes that support extensibility, see Application extensibility plans.

Enumerations made extensible

These enumerations have been made extensible in this update.

ENUMERATION
AssetAccrualCalendar
AssetYear
BankReconciliationReportType
BudgetPlanColumnPeriodLength
BudgetPlanHCMReportGroupOption
CurrencyTypeBrief_RU
EInvoiceStatus_IT
EInvoiceStatus_IT
HRPAuthorityBasis
HuExchOutflowType
InventJournalTagStatus
InvoiceAssociationType
MCRClaimType
MCRMerchandisingEventCategory
PaymAttribute
PaymProposalReportedBy
PayrollCategory

ENUMERATION
projActualVsBudget
ProjListStateId
ProjTransLayout
ProjType
RCashCheckContract
RCashDocRepresType
RCashDocType
RCashRemainLimitType
RCashTableAll
RCashTransStatus
SMARelationType
smmActivityTaskTimeType
TaxIdType
TrvAirlineServiceClassEnum
TrvFieldVisibility
TSPeriodFrequency
TSPerWeekMth
VendPaymentValidate

SQL operations made extensible

These SQL operations have been made extensible in this update.

OPERATION
JmgStampJournalTable.makeLines
MCRDropShipStatusUpdate_PurchLine.updatePurchDropShipStatusOnRecord
MCRDropShipStatusUpdate_PurchTable.updatePurchDropShipStatusOnRecord
SalesInvoiceJournalCreate.checkDocumentData_PL

OPERATION
SalesInvoiceJournalPost.postFailed

Metadata changes

These metadata changes have been made in this update.

OPERATION
/Data Model/Data Entities/BOMBillOfMaterialsVersionV2Entity.IsPublic
/Data Model/Data Entities/InventItemBatchEntity.IsPublic

"No of Decimals is Extensible" property on several EDTs
RetailLoyaltyRewardPoint.Replacement Key
Tables/CustTrans/Relations/ThirdPartyBankAccountId.Validate
Tables/EInvoicePropertyTable/Relations/EInvoicePropertyTypeTable.RelationshipType
Tables/ResourceSetup.FormRef
Tables/WHSTmpWorkExecuteListBoxItems/Fields/Elements.EDT

Refactored methods

These methods have been refactored to support extensibility.

REFACTORED METHODS
AdvancedLedgerEntryLine.setProjInvoiceLineLedgerDimension
AgreementConfirmationDP.getSalesAgreementHeader
AgreementConfirmationDP.getSalesAgreementHeaderHistory
PurchAutoCreate_Sales.createPurchLine
PurchCreateFromSalesOrder.run
InventItemPrice.insert
InventJournalTrans.setCostPrice
PurchLine.initFromReqPO
AssetBook.initDepreciationProfile
AssetDepreciationProfile.validateStraightLine
AssetProposalDepreciation.run
BankPaymAdvicePrint.BankPaymAdvicePrint (variable)
BankReconciliationMatchingMatchProcessor.constructMatch
BankReconMatchingMatchStmtReversalDoc.Multiple
BankStatementDocumentEntity.postGetStagingData
BankVoucher.post
BomCalcItemLine.mustExplodePrice
BOMCopyToProd.delete
BOMCreateDialog.promptCreateBOMDialog
BomRouteCopyJob.initFromItemId
BudgetPlanningConfiguration.displayYearOffset
BudgetPlanningConfiguration.updateColumnPeriodLengthValueLabel
CatVendorCatalogProductApproval.getApprovedProductForRetail
LedgerJournalTransType.validateAccountType
LedgerTransferOpening.processQuery

REFACTORED METHODS
BankPositivePayExport.generatePositivePayFile
BankPositivePayExport.updateBankPositivePay
CaseSendEmail.getEmailMessage
ContactPerson.insert
CostSheetModeStrategyStaging.createCostSheetNodes
CreditCard.recordAuthorization
CreditCard.recordCapture
CreditCardPaymentJournal.createJournal
CreditCardPaymentJournal.Init
CreditCardPaymentJournal.run
CustAgingReportContract.Validate
CustAgingReportDP.CustAgingReportTmp
CustAgingReportDPclass.insertCustAgingReportTmp
CustAgingReportDPclass.setCustAgingReportTmpInReverse
CustBalanceList.insertIntoTmpAccountSumV2
CustBillOfExchangePostRemit.postSettlingStep
CustCollectionsSetTransactionStatusHelper.createActions
CustCustomerBaseEntity/CustCustomerEntity/CustCustomerV2Entity/CustCustomerV3Entity.processChangesForApproval
CustCustomerDetailEntity/CustCustomerDetailV2Entity.processChangesForApproval
CustInvoiceJour.setInvoiceAddress
CustInvoiceLine.getCustBillingCodeLedgerAccount
CustInvoiceLine.setProjInvoiceLineLedgerDimension
CustInvoiceLine.setProjInvoiceLineLedgerDimensionBase
CustInvoiceLine.shouldDefaultLedgerDimensionFromProject

REFACTORED METHODS
CustOutPaymRecord_Cheque.checkValues
CustPostInvoiceJob.custPostInvoiceUpdate
CustVendAgingCalculation.process
CustVendChequeSlipTextCalculator.getChequeDocLength
CustVendChequeSlipTextCalculator.getMinimumSlipLines
CustVendChequeSlipTextCalculator.fillSlipText
CustVendChequeSlipTextCalculator.Property
CustVendEditTaxBranch_TH.init
CustVendOutPaym.getSumByCurrency
CustVendPaymInvoiceWithJournal.createJournal
CustVendPaymInvoiceWithJournal.createPayment
CustVendPaymProposal.resolvePaymAccountAndType
CustVendPaymProposalLine.paymTransactionAmountMST
CustVendPaymProposalTransferToJournal.getVoucherNum
CustVendReversePosting.restoreCustVendTransOpen
CustVendSettle.postDueToAndFromCreateTrans
CustVendSettle.postExchRateLedgerTrans
CustVendSettle.settleNow
CustVendSettle.updateCustTaxInvoice_TH
CustVendSumUpJournal.createTrans
CustVendSumUpJournal.createVoucher
CustVendTransreorg.end
CustVoucher.updateProjTransPosting
DimDerDistRuleProjectRevenueExt.processRegularTransactions
DimDerDistRuleProjectRevenueExt.processIntercompanyTransCustInvoice

REFACTORED METHODS
DimDerDistRuleProjectRevenueExt.processIntercompanyTransExpense
DimDerDistRuleProjectRevenueExt.processIntercompanyTransTimesheet
DimDerJourRuleProjectTimesheetsExt.getDefaultDimensionAllocation
EcoResEnumerationAttributeTypeValue.createAttributeValuesFromEnum
EcoResProductReleaseForm.addProductsToRelease
EInvoice_IT.newCustInvoice
EInvoice_IT.newProjInvoice
EUSalesListReportingEngine.Construct
FiscalDocument_BR.lastIssueDateForSeries
FormletterJournalPost.docuRefCopyByRecId
ForecastSales.Update
HcmActionState.lookupReferenceActionTypeSetup
HcmWorker.init
HcmWorker.updateEmploymentControls
HcmWorkerActionHireCompletion.getHrmApplication
HcmWorkerTransition.createHcmEmployment
HRCCompGridView.initCompRecord
HRMCompFixedEmpl.enforcePayRateTolerance
HRPDefaultSigningLimitRule.insertFormDataSourceJobDetail
HRPDefaultSigningLimitRule.populateDetailGrid
HRPDefaultSigningLimitRule.SaveValidation
HRPDefaultSigningLimitRule.insertOrUpdateFormDataSource
HRPDefaultSigningLimitRuleCompensation.getSelectedCompensation
HRPDefaultSigningLimitRuleCompensation.getAvailableCompensation
HRPDefaultSigningLimitRuleCompensation.selectRecords

REFACTORED METHODS
HRPDefaultSigningLimitRuleCompensation.unselectRecords
HrpWorkerLimit.getActiveDefaultSLRule,
HrpWorkerLimit.getDefaultSigningLimits
HrpWorkerLimit.getWorkerSigningLimit
HrpWorkerLimitr.getSigningLimitsIfRequestNotRequired
InterCompanyTransferInventDim.Entire class
InterCompanyTransferInventDim.transfer
InventBatch.update
InventCountCreate_Base.createInventJournalTrans
InventInventoryDimensionEntityFieldsMapping.resolveInventDim
InventMov_Jour_BOM.journalCheckTrans
InventMov_Jour_Loss_Project.checkAccountOperations
InventMov_Journal.journalSetItemId
InventMov_Statement.pdsCWRemainPhysical
InventMovement.performFinancialLedgerUpdate
InventProcessGuideAdjustInController.initialStepName
InventQualityManagementBlock.run
InventQualityManagementCreateHandler.purchFormLetterBeforeHelper
InventQualityOrderTableValidator.checkQty
InventSum.retrieveMatchingInventSumDeltaForTTSId()
InventTrackingRegisterTransForm.construct
InventTransAdjust.updateNow
InventTransferUpdReceive.updateInventTransferLine
InventTransWms_Register.updateInventFromMovementServer
InventUpd_ChildReference updateLess* methods

REFACTORED METHODS
InventUpd_ChildReference.updateMoreIssue
InventUpd_Estimated.updateAutoDimMovement
InventUpd_Physical.UpdatePhysicalReturnedIssue
InventUpd_Physical.updatePhysicalReturnedReceipt
InventUpd_WHSReservation.continueInventTransUpdateReserveMoveLoop
InventUpdateOnhand.checkOnhand()
InventUpdateReserveMore.buildQueries
JmgMESDocuHandling.openFile
JmgProfiles.insertTimeGapsPlannedAbs
JmgStampJournalCalculate.run
JmgStampJournalTransfer.cancelExecute
JmgStampJournalTransfer.cancelExecute
LeanCost_Init.execute
LedgerAllocationController.allocateAmounts
LedgerAllocationProcessRequest.createVoucherDestinations
LedgerJournalCheckPost.replaceTmpVoucher
LedgerJournalDeleteTransaction.deleteLedgerJournalTransRelated
LedgerJournalEngine.currencyModified
LedgerJournalPeriodicCopy.journalVoucherCopy
LedgerJournalTrans.initForCurrency
LedgerJournalTrans.validateWrite_Server
LedgerTransModule.insertTransactionList
LedgerTrialBalanceContract.DataMemberAttribute
LedgerVoucherObject.allocateTransaction
LedgerAllocationController.allocateRecursive

REFACTORED METHODS
MCRCheckHoldWB\Release.clicked
MCROrderEventSetup.find
MCRSalesOrderRecap.Control:SubmitButton.clicked
MCRSalesQuickQuote.Modified
MCRTmpPickingWorkbenchTrans.initFromSessionCriteria
MultilineString.POSDeveloperSupport
OriginalDocuments.insertDocument
PaymSchedCalc_Amount.createTransaction
PdsRebateFindAndCreate.findPdsRebateAgreementAndCreateClaim
PdsRebateFindAndCreate.findPdsRebateAgreementAndCreateClaim()
PdsRebatePaymentPost.insertRebateEntryForGrouping
PmfFormCtrl_BOM_BOMVersion.modifiedFormulaSize
PriceDiscAdmCheckPost.postJournal
ProdJournalCheckPostProd.postTransLedger
ProdJournalTransBOM.inventBatchId.validate
ProdMultiReportFinished.insert
ProdUPDCostEstimation.CreateProdBOM
ProdUpdReportFinished.updateBOMConsumption
ProdUpdStartUp.createJournals
ProjBegBalJournalTrans_CostSales.validateField, validateWrite
ProjBudgetManager.deleteBudgetLinesBeforeImportForRevs
ProjBudgetManager.getQuery
ProjBudgetRevisionManager.createBudgetLines
ProjBudgetTransactionManager.isOverrunAllowed
ProjectCommitmentFacade.updateProjectCommitmentsMap

REFACTORED METHODS
ProjectMainAccDimensionListProvider.populateMainAccountDimensionList
ProjForecastBudgetCopy.do_Cost
ProjForecastBudgetCopy.do_empl
ProjForecastBudgetCopy.do_onAcc
ProjForecastBudgetCopy.do_sales
ProjGroupChange.checkPostedTrxAccounts
ProjIntercompanyCustomerInvoiceCreator.createInvoiceLine
ProjInvoiceJournalPost.postCustVend
ProjInvoiceJournalPost.validateNoTax
ProjInvoiceProposalInsertLines.run
ProjJournalTrans.validateWrite

Other changes

The following additional changes have been made for extensibility.

- Convert queries where InventSumFields is used to SysDa.

Extensibility changes in Dynamics 365 for Finance and Operations version 8.1.3

2/18/2021 • 2 minutes to read • Edit Online

This is a list of extensibility features that were implemented in Dynamics 365 for Finance and Operations version 8.1.3. For more information about the schedule of changes that support extensibility, see Application extensibility plans.

Enumerations made extensible

These enumerations have been made extensible in this update.

ENUMERATION
AttributeDataType
BankDocumentBookType
BudgetPlanHCMReportGroupOption
CommitmentType
CommitmentType
CustVendNegInstStatus
CzAdvanceInvoiceStatus
DateTransactionDuedate
LedgerAllocationMethod
LedgerCovDocumentType
MCRFraudType
PercentHours
PerDayWeekMthQtYr
PrepaymentHandlingLayout_W
ProdStatusAll
TaxDirection
TaxType_IT

ENUMERATION
WHSWaveTemplateType

SQL operations made extensible

These SQL operations have been made extensible in this update.

OPERATION
InventTrans.deleteReturnTransOrigin
InventUpd_ChangeDimension.updateForceInventTrans
PriceDiscAdmCheckPost.updatePriceDiscTableRecords
ProdJournalCleanUp.deleteJournals
ProjBudgetManager.createBudgetCostForecast
ProjBudgetManager.createBudgetEmplForecast
ProjBudgetManager.createBudgetRevenueForecast
ProjBudgetManager.createBudgetSalesForecast
SubledgerJourFinalNetAmtEntryProvider.getFinalRelievingEntriesWithNetAmounts
SubledgerJourFinalRelieveEntryProvider.populateEntriesBySide
SubledgerJournalAccountEntryRelievingTmp.mergeJournalizationEntries
SubledgerJournalFinalReliever.findEntriesAlreadyRelieved
SubledgerJournalFinalReliever.findEntriesToRelieve
SubledgerJournalizer.loadFinalizeSubledgerJournalTmpDetail
SubledgerJournalizer.loadInterCompanyNonOffsetSubledgerJournalTmpDetail
SubledgerJournalizer.loadInterCompanyOffsetSubledgerJournalTmpDetail
SubledgerJournalizer.loadRelievingSubledgerJournalTmpDetail
SubledgerJournalizer.loadReversingSubledgerJournalTmpDetail
SubledgerJournalizer.loadYearEndSubledgerJournalTmpDetail
SubledgerJournalizer.summarizeJourAccountEntryDetailForRound

Metadata changes

These metadata changes have been made in this update.

OPERATION
Classes/CustVendSettle/classDeclaration.field modifier
Classes/LedgerPostingGeneralJournalController/transferLines.HookableAttribute
Classes/VendPaymentJournalDP.none
EcoResProductAttributeTranslationEntity.IsPublic
EcoResProductBarcodeEntity.Property.IsPublic
Enum/RDeferralsCalculatePeriod.Country region code
Enum/RDeferralsInitRetirementDate.Country region codes

Tables/VendSettlement/Relations/VendTrans.RelationshipType
Tables/WHSDocumentRoutingLine/Indexes/DocumentRoutingTablePrinterNameIdx

OPERATION

Refactored methods

These methods have been refactored to support extensibility.

REFACTORED METHODS
AssetJournal.populateLedgerJournalTrans
AssetPost.postToGeneralLedger
AssetProposalDepreciation.run
AssetTransfer.addLedgerVoucherTransObjects
AxSalesLine.setDefaultDimension
BankChequeCopy.fillTmpChequePrintout
BankChequeLayout.updateDesign
BankDepositSlip.modifyBankAccountTrans
BankJournalHeaderEntity.ValidateField
BankPositivePayExport.sendFileToUser
BankStatementValidate.validateDate
BankStmtISOAccountStatement.deleteStatement
BOM.defaultField
BOM.validateField
BOM.validateWrite
BomCalcItem.insertBOMCalcTable
BomCalcItem.insertBOMCalcTrans
BomCalcProd.calcCostSheet
BOMReportFinishMax.retrieveInventTable
BudgetCaculateBalance.getActualLedgerAmountsQuery
BudgetCaculateBalance.getOriginalBudgetQuery

REFACTORED METHODS
BudgetCaculateBalance.getRevisedBudgetQuery
BudgetSourceCollectionIntegrator.newBudgetSourceCollectionIntegrator
BudgetSourceIntegrator.newBudgetSourceIntegrator
ChequeController.ClassDeclaration
ChequeController.init
ContactPersonApplicationSuiteEventHandlers.initializedFromCommonEventHandler
CustBillOfExchangePostRemit.postSettlingStep
CustDirectDebitMandate.checkBankIBAN
CustDueReportDetailDP.updateCustDueReportDetailTmp
CustPostInvoiceJob.custPostInvoiceUpdate
CustSettleJournalizingEntries.createGeneratedEntries
CustSettleJournalizingEntries.getInterestOriginatingEntries
CustSettleJournalizingEntries.getOriginatingEntries
CustTransDetails.new
CustTransListDP.insertCustTransListTmp
CustTransOpenCashFlow.generateCashFlow
CustVendCheque.output
CustVendCreatePaymJournal_Vend.shouldAddCustVendTransOpen
CustVendEditTaxBranchHelper_TH.init
CustVendExchAdjTrans.initLedgerVoucher
CustVendSettle.reverseTax
CustVendTransReorg.paymentSchedSplit
CustVendTransReorg.post
CustVendTransReorg.reorganize
CustVendVoucher.setTransactionTxt

REFACTORED METHODS
CustWriteOff.createTaxJournalLines
DimDerJourRuleProjectTimesheetsExt.getDefaultDimensionAllocation
DirPartyRoleIsExternallyMaintained.setFieldRestrictions
EcoResDocumentAttachmentEntity.insertDatasourceDocuRef
EcoResProductNumberBuilderVariant.getEnumeratorForEnabledOrderedProductDimensions
EFDocMsgFormat_XmlSubmit_BR.createXmlDocumentFromEFDocument
EFDocumentXpath_BR.Not applied
ERclasses - class signature
FiscalDocParmDataCreatorInvTransfer_BR.initHeaderParmData
FiscalDocParmDataCreatorInvTransfer_BR.setinventTransferTableFiscalInfo
FiscalDocumentParmDataCreator_BR.initTaxTransParmDataFromTaxTrans
FiscalDocumentParmDataCreator_BR.setAccountingAmountOnFiscalDocumentLines
FiscalDocumentPost_BR.initFiscalDocument
FreeTextInvoiceDP.insertIntoFreeTextInvoiceHeaderFooterTmp
HcmWorkerTransition.createHcmEmployment
HrpExpireWorkerLimits.expireLimitRequest,expireApprovedLimit,getAuthorityBasis
InventMov_Sales.accountBalanceSheet
InventReleaseOrderPickingForm_Sales.bldInventReleaseOrderPickingTmp
InventTestAssociationTable.checkExecutionTime
InventTrans.insertReturnTransOrigin
InventTrans.updateMarkReqTransCov
InventTransferOrderCopying_BR.createTransferLines
InventTransferOrderCopying_BR.createTransferOrder
InventTransferUpdShip.updateInventTransferLine
InventUnusedDimCleanup.isCandidateInventDimIdTable

REFACTORED METHODS
InventUpd_ChangeDimension.updateTransSwitchDim
InventUpd_ChildReference.updateLessReceipt
InventUpd_ChildReference.UpdateMoreReceipt
InventUpd_Financial.updateFinancialIssue
InventUpd_Financial.updateStdCostPrice
InventUpd_Picked.updatePickMore
InventUpd_Registered.updateRegisterLess
InventUpd_Registered.updateRegisterMore
InventUpd_Reservation.updateReserveLess
InventUpdate.initializeInventTransToIssueListFromDatabase
InventUpdate.initInventTransToReceiveList

WhsWorkExecuteDisplayValidateUserDirect.validateUserDirectWorkExists
WHSWorkTable.executeWorkLinesInit
WmsJournalCheckPostReception.returnOrderUpdate
WmsPickingList_OrderPickDP.initQueryWMSOrderTrans

REFACTORED METHODS
WmsPickingList_OrderPickDP.insertIntoTempTable
WmsPickingList_OrderPickDP.orderQty
WmsPickingList_OrderPickDP.orderUnit
WmsPickingList_OrderPickDP.printDocumentHeader
WmsPickingList_OrderPickDP.setWMSPickingList_OrderPickTmpTemplate

Other changes

The following additional changes have been made for extensibility.

- Updated aging and balance list classes and forms to support the ability for customizations to increase the number of calculated aging buckets.

Other changes

The following table lists additional changes that have been made for extensibility.

CHANGE

- Create a SysQueryUpdateRecordSet class in AppCommon.
- Enable percent controlled for a catch weight item.

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Extensibility changes in Dynamics 365 for Finance and Operations version 8.1.1

2/18/2021 • 2 minutes to read • Edit Online

This is a list of extensibility features that were implemented in Dynamics 365 for Finance and Operations version 8.1.1. For more information about the schedule of changes that support extensibility, see Application extensibility plans.

Enumerations made extensible

These enumerations have been made extensible in this update.

ENUMERATION
BankCodeType
CountryRegionType
MainAccountDimensionListProviderType
ProdSchedulingSortType
ProjAccountTypeSales
ProjBudgetBalancesGroupByOptions
ProjListStateType
ProjStatementType
SalesDeliveryDateControlType

Refactored methods

These methods have been refactored to support extensibility.

REFACTORED METHODS
[Extensibility] Method signature change: WHSWorkExecuteDisplayListWork.displayListWorkStep
[Extensibility] Refactor WhsWorkExecuteDisplayAdjustOut to ProcessGuide framework
AssetJournal
AXSalesQuotationTable.setQuotationId
BankStatementBankAccountIdentify.searchBankAccountTable

REFACTORED METHODS
BankStatementValidate.doValidate
BankStatementValidate.validateDate
BankStatementValidate.validatePeriodGap
BankStatementValidate.validatePeriodOverlap
BOM.validateWrite
BomCalcDialog.updateBomRoute
BOMCalcItem.createBomCalcItemAndAddToListBom
BOMCalcTable.transferToSalesLine
BOMCalcTable.transferToSalesQuotationLine
BomConsistOf.init
BomLevelCalc.loadDependencies
BOMReportFinishMax.init
BOMReportFinishMax.update
BOMReportFinishMax.updateBOMId
BudgetTransactionManager.checkBudgetTransactionNumberSequence
Commission.run
Cust/VendTableChangeProposalApply.apply
CustAccountStatementExtController.runPrintMgmt
CustDebitCreditNoteDP.insertForQuantity
CustDebitCreditNoteDP.insertForValue
CustInterestJour.findCustUnPostedInterestNote
CustOpenTrans.editMarkTrans
CustPackingSlipJour.PrintJounal
CustTable.openInvoiceBalanceMST
CustTable.openinvoiceBalanceMSTDoc

REFACTORED METHODS
CustTable.openPaymentBalanceMST
CustTable.openPaymentBalanceMSTDoc
CustTable.openPaymentBalanceMSTDue
CustVendCreatePaymJournal_Vend.searchTransactions
CustVendDisputeHelper.update
CustVendPaymProposalTransferToJournal.ClassDeclaration
CustVendPaymProposalTransferToJournal.updateSpecTransSet
CustVendPaymProposalTransferToJournal.updateSpecTransSingle
CustVendPrePaymentReversal.construct
CustVendSettle.settleForDifferentProfilesOrPrepayment
CustVendSumForPaym.run
CzCustPostAdvanceInvoice.run
DirPartyFormHandler.manageFields
EcoResProductCreate.close
EcoResProductCreate.templateRecords2Controls
EcoResProductDetailsExtended.InventTable.validateWrite
EssPersonSigningLimits/FormDataSourceRoot/HRPLimitRequestApproved.executeQuery
FormletterJournalPost.postLineDiscount
FormLetterParmData.updateQueryDocumentRanges
FormletterService.run
FormletterServiceBatchTaskManager.createFormletterParmDataTasks
FormletterServiceBatchTaskManager.createFormletterServiceTasks
FormletterServiceMultithread.newFormletterServiceMultiThread
FreeTextInvoiceController.preRunModifyContract
FreeTextInvoiceController.runPrintMgmt

REFACTORED METHODS
GeneralLedgerExtension.validateReferenceNumber
InterCompanyPost.formLetterCollect
InterCompanyPost.formLetterCollect
InterCompanySyncPurchLineType.createOrUpdateSalesLine
InterCompanySyncPurchLineType.synchronizeInTradeCompany
InterCompanySyncSalesLineType.classDeclaration
IntrastatTransfer.updateQuery

Additional extensibility enhancements

In addition to the refactored methods, the following extensibility enhancements have been made.

- Bug request: "CustCollectionLetterTrans -> CollectionLetterNum" Relation properties
- Enable increase of decimal precision through extensiblity for prices
- Enable increase of decimal precision through extensiblity for weights
- Map Extension: LogisticsEntityLocationMap
- OMOperatingUnit should provide user friendly and defined value for DimAttributeOMDepartment.Value
- Redesign how InventPosting finds LedgerDimension
- Refactor WhsWorkExecuteDisplayAdjustIn to ProcessGuide framework
- Refactor WHSWorkExecuteDisplayChangeWarehouse to ProcessGuide framework
- Refactor WhsWorkExecuteDisplayInquiryItem to ProcessGuide framework
- Refactor WhsWorkExecuteDisplayInquiryLocation to ProcessGuide framework
- Refactor WhsWorkExecuteDisplayInquiryLP to ProcessGuide framework
- Refactor whsWorkExecuteDisplayReprintLabel to ProcessGuide framework
- Retail channel: Support BankDropOperationRequest

Extensibility changes in Dynamics 365 for Finance and Operations update 8.0.4

2/18/2021 • 2 minutes to read • Edit Online

This is a list of extensibility features that were implemented in Dynamics 365 for Finance and Operations update 8.0.4. For more information about the schedule of changes that support extensibility, see Application extensibility plans.

Refactored methods to support extensibility

These methods have been refactored to support extensibility through chain of command, delegates, or by providing access to members.

METHOD
AgreementHeader.getModuleType
AssetSplit.construct
BankDepositSlipController.main
BankPositivePayExport.sendFileToUser
CaseDetailForm.getRecordsFromDataSource
CostSheetDesigner.DataSource:CostSheetCalculationFactor.validateWrite
CostSheetNodeCalculation.validate
CostSheetNodeCalculationRate.calcLowestLevel
CostSheetNodeCalculationSurcharge.equal
CustAccountStatementExtController.processParty
CustAccountStatementExtDP.insertNewRecords
CustAccountStatementExtDP.setSysDocuBrandDetails
CustBillOfExchangePost.postNextStep
CustBillOfExchangePostProtestHonored.postNextStep
CustCollectionJourController.runPrintMgmt
CustCollectionLetterCreate.createJournal

Additional extensibility enhancements

In addition to the refactored methods, the following extensibility enhancements have been made.

- CustVendSettle: set variables protected instead of private.
- Data manipulation method not raising event: WHSLocationDirective.loopLocDirLines.
- Data manipulation method not raising event: WhsWorkCreate.createTempLine.
- Map extension: LogisticsPostalAddressMap.
- Map extension: PurchReqLineMap.
- Metadata change: DataEntityView/ProjWBSActivityEstimatesEntity.Is Public = Yes.
- Metadata change: DataEntityView/ProjWBSActivityEstimatesEntity.Public Collection Name = ProjWBSActivityEstimates.
- Metadata change: DataEntityView/ProjWBSActivityEstimatesEntity.Public Entity Name = ProjWBSActivityEstimates
- Metadata change: /Data Model/Data Entities/EcoResProductAttributeValueEntity.IsPublic = Yes.
- Metadata change: Form/WHSLoadPlanningListPage/FormDesign/FormDesign/FormActionPaneTabControl/ActionPaneTabShipReceive.Neede permission.
- Metadata change: WHSContainerLine, Relations WHSLoadLine & WHSShipmentTable.On Delete.
- Metadata change: WHSContainerTable, Relation WHSShipmentTable.On Delete.
- Project pricing: complete uptake of new pricing find methods.

Extensibility changes in Dynamics 365 for Finance and Operations update 8.0.3

2/18/2021 • 2 minutes to read • Edit Online

This is a list of extensibility features that were implemented in Dynamics 365 for Finance and Operations update 8.0.3. For more information about the schedule of changes that support extensibility, see Application extensibility plans.

Refactored methods to support extensibility

These methods have been refactored to support extensibility through chain of command, delegates, or by providing access to members.

METHOD	
AccountingSourceExplorerProcessor.filterEntries	
AgreementClassification.init

Additional extensibility enhancements

In addition to the refactored methods, the following extensibility enhancements have been made.

- Increase EDT string size for EcoResProductSearchName
- Change CacheLookup property to NotInTTS for AssetLedgerAccounts
- Change CacheLookup property to Found on TaxOnItem, TaxJurisdiction, TaxGroupData, and TaxData, and AssetLedgerAcounts

Extensibility changes in Dynamics 365 for Finance and Operations update 8.0.2

2/18/2021 • 2 minutes to read • Edit Online

This is a list of extensibility features that were implemented in Dynamics 365 for Finance and Operations update 8.0.2. For more information about the schedule of changes that support extensibility, see Application extensibility plans.

Refactored methods to support extensibility

These methods have been refactored to support extensibility through chain of command, delegates, or by providing access to members.

METHOD
AccDistProcessorProjectExtension.allocateExistingDistribution
AccDistProcessorProjectExtension.createDistributionLists
AccDistProcessorProjectExtension.ledgerDimensionAllocationList
AgreementConfirmationDP.processReport
Bank_FR.checkControlText
Bank_IT.checkCIN
Bank_IT.checkRegistrationNum
CustVendCheque.initTmpChequePrintout
FBSpedFileCreator_Contabil_BR.createRecordI052
HierarchyTemplateCopying_proj.createFromHierarchySource
HierarchyTreeLookup.datasource smmActivities.init
InventDim.validateFieldCombination
InventTransWMS_Register

Extensibility changes in Finance and Operations update 8.0.1

2/18/2021 • 2 minutes to read • Edit Online

This is a list of extensibility features that were implemented in Dynamics 365 for Finance and Operations update 8.0.1. For more information about the schedule of changes that support extensibility, see Application extensibility plans.

Refactored methods to support extensibility

These methods have been refactored to support extensibility through chain of command, delegates, or by providing access to members.

METHOD
Class ProjControlPeriod::PeriodInsert
Class ProjInvoiceChoose::doSalesLine
Class CustInvoiceJour::printFreeTextJournal
Class ProjCostControl.createEmptyTransactionType
Class ProjEstimate::autoGenerateEstimateLinesFromTask
Class ProjEstimateDataContract.updateEstimates
Class ProjForecastBudget.Run
Class ProjHierarchyProvider.preDeleteHierarchy
Class ProjPlanVersionsManager::CopyTasks
Class ProjPlanVersionsManager.createDraftFromPublishedVersion
Class ProjPlanVersionsManager.PublishQuotationSubHierarchy
Class ProjPlanVersionsManager.CreateDraftVersion
Class ProjTask.addTask
Class ProjInvoiceProposalCreateLines.performTransTypeSelectionCtrlLookup
Class VendOpenTrans.editMarkTrans
Class CustVendReversePosting.reverseTaxWithholdTrans
Class CustVendSettle.postPennyDiff

METHOD
Class CustVendSettle.processStillOpenTransactions
Class InventTransferOrderOverviewDP.insertTmp
Class LedgerJournalTransCost.LedgerJournalTrans.Create
Class ProjAdjustmentSelect.dialog
Class ProjEstimate.syncEstimateLinesFromTask
Class ProjEstimateDataContract.UpdateEstimates
Class ProjForecastTransferFromWbs.transferToForecast
Class ProjWizardActivityCtrl.insertDBOnServer
Class ProjTaskEstimatesSynchronizer.calcTotalEstimateLineHours
Class ProjTaskEstimatesSynchronizer.countNumberOfHourEstimateLines
Class ProjTaskEstimatesSynchronizer.syncExistingHourEstimatesWithTask
Class ProjTaskEstimatesSynchronizer.syncHourEstimatesWithTaskEffort
Class ProjWbsCostPlanningServerActions.executeDataRetrievalAction
Class ProjWbsCostPlanningServerActions.getProjectCategoryTypes
Class ProjWbsSchedulePlanningServerActions.executeAction
Class ProjWbsSchedulePlanningServerActions.executeDataRetrievalAction
Class ProjStatisticCalc.validate
Class WHSInventReserve.insert
Class WHSInventReserveDelta.insert
Class ProjInvoiceProposalCreateLines.performTransTypeSelectionCtrlLookup
Class ProjJournalTransEmpl - Datasource: ProjJournalTrans.Validate
Class LedgerJournalEngine.initTaxItemGroup
Class LedgerJournalEngine.initValue
Class ProjJournalTrans.mergeResourceDimensionDefault
Class ProjTask.setTaskinfo

METHOD
Class ProjJournalName.standardJournalName
Form ProjInvoiceProposalCreateLines.performTransTypeSelectionCtrlLookup

Other extensibility enhancements

In addition to the refactored methods, the following extensibility enhancements have been made.

- Support variable number of decimals - InventTestLowerLimit
- Support variable number of decimals - InventTestLowerTolerance
- Support variable number of decimals - InventTestStandardValue
- Support variable number of decimals - InventTestUpperLimit
- Support variable number of decimals - InventTestUpperTolerance
- Support to skip prompt on transaction reversal
- Enable extension of PSAProjQuotationApproval workflow

Extensibility changes in the Finance and Operations version 8.0

2/18/2021 • 9 minutes to read • Edit Online

Hard-sealed application models

In Dynamics 365 for Finance and Operations version 8.0, all of Microsoft's application models have been hard-sealed. Overlayered code in these models will now produce compilation errors. The only supported customization model is through extensions. If you cannot customize these models through extension, then you will have to make a request to Microsoft to enable extensibility by changing the standard application.

The following table includes a list of models that are now hard-sealed with this release.

MODULE	MODEL
ApplicationCommon	ApplicationCommon
ApplicationSuite	Electronic Reporting Application Suite Integration
ApplicationSuite	Foundation Upgrade
ApplicationSuite	Foundation
ApplicationSuite	SCMControls
ApplicationSuite	Tax Books Application Suite Integration
ApplicationSuite	Tax Engine Application Suite Integration
CaseManagement	CaseManagement
Currency	Currency
DataImpExpApplication	DataImpExpApplication
DataUpgrade	DataUpgrade
Directory	Directory
Directory	SecurityReports
GeneralLedger	GeneralLedger
Ledger	Ledger
PersonnelManagement	PersonnelManagement
ProcessGuide	ProcessGuide

MODULE	MODEL
Retail	Retail
SourceDocumentation	SourceDocumentation
SourceDocumentationTypes	SourceDocumentationTypes
Subledger	Subledger
Tax	Tax

Enumerations that have been made extensible

The following changes were made to support extending enumerations:

- Many enumerations in the standard application have been made extensible. An enumeration is made extensible by setting two properties on the enumeration. The **IsExtensible** property is set to **Yes**, and the **UseEnumValue** property is set to **No**.
- Some enumerations represent state. New façade methods have been added to help enable adding enumeration values by extension. For information about how to extend an enumeration, see Add values to enums through extension.
- Some application code that uses enumerations was changed to support extensibility. Common changes include:
  - Removing **throw** exception statements in the default case of a switch to allow post-event subscription.
  - Adding **SysExtension** support for extension.
  - Adding explicit delegates.

Data manipulation methods that do not raise DataEvents or missing insert, update, delete pre- and post-data events

As a general practice, you use data methods on tables to raise events that can be used for extending the application. The code base has not always followed this practice. For example, the **doInsert**, **doUpdate**, and **doDelete** data methods and certain table implementations did not make a call to **super()** in the data method.

The **insert**, **update**, and **delete** methods on the type classes have been refactored. Changes were made so that **super()** is called more consistently in data methods. These changes enable extensions to be added to these methods, so that pre- and post-events are now available for extension. The tables where the **insert**, **update**, and **delete** events were enabled for extension are listed in the following table.

TYPE, NAME, DATA SOURCE, AND METHOD
Form ProjTableCreate.ProjTable.write
Form ReturnTable.ReturnTable.leaveRecord
Form SalesQuotationProjTable.SalesQuotationTable.leaveRecord
Form SalesQuotationTable.SalesQuotationTable.leaveRecord
Form SalesTable.SalesTable.leaveRecord

Refactored methods to support extensibility

These methods have been refactored to support extensibility through chain of command, delegates, or by providing access to members.

Maps enabled for extensibility

New patterns have been introduced for maps implementation that will allow you to add fields and methods by extensions. Details on how this is done is available in the documentation both with maps that are used as interfaces and for versioning implementations.

The following table lists the maps and related tables where changes have been applied for enabling extensibility.

MAPS
CustVendSettlement
JmgStampTransMap
PriceDiscResultFields
SalesPurchLine

Inventory dimensions

This release made minor improvements to the new model for adding inventory dimensions, all targeted at supporting more scenarios through extensions.

CHANGE

Extensibility changes in Finance and Operations, Enterprise edition 7.3

2/18/2021 • 16 minutes to read • Edit Online

This topic lists the extensibility features that were released in Dynamics 365 for Finance and Operations, Enterprise edition 7.3. For more information about the schedule of changes that support extensibility, see Application extensibility plans.

Soft-sealed application models

This release marks the last release before all models will become hard-sealed, and as a step toward this all application models are now soft-sealed. Soft-sealed models still allow for making overlayered code, but warnings will be generated when you compile the overlayered code.

> **NOTE**
> You can still overlayer code, but extension is the recommended approach.

The following table includes a list of the models that are soft-sealed with this release.

MODULE	MODEL
ApplicationCommon	ApplicationCommon
ApplicationSuite	Electronic Reporting Application Suite Integration
ApplicationSuite	Foundation Upgrade
ApplicationSuite	Foundation
ApplicationSuite	SCMControls
ApplicationSuite	Tax Books Application Suite Integration
ApplicationSuite	Tax Engine Application Suite Integration
CaseManagement	CaseManagement
Currency	Currency

Directory	SecurityReports

MODULE	MODEL
GeneralLedger	GeneralLedger
Ledger	Ledger
PersonnelManagement	PersonnelManagement
Retail	Retail
SourceDocumentation	SourceDocumentation
SourceDocumentationTypes	SourceDocumentationTypes
Subledger	Subledger
Tax	Tax

Hard-sealed application models

With this release, almost all application core models have been hard-sealed. Overlayered code in these models will now produce compilation errors. The only supported customization model is through extensions. If you cannot customize these models through extension, then you will have to make a request to Microsoft to enable extensibility by changing the standard application.

TThe following table includes a list of models that are now hard-sealed with this release.

MODULE	MODEL
AccountsPayableMobile	AccountsPayableMobile
ApplicationWorkspaces	ApplicationWorkspaces

UnitOfMeasure	UnitOfMeasure
WMSAdvancedMigration	WMSAdvancedMigration

Enumerations that have been made extensible

The following changes were made to support extending enumerations:

- Many enumerations in the standard application have been made extensible. An enumeration is made extensible by setting two properties on the enumeration. The **IsExtensible** property is set to **Yes**, and the **UseEnumValue** property is set to **No**.
- Some enumerations represent state. New façade methods have been added to help enable adding enumeration values by extension. For information about how to extend an enumeration, see Add values to enums through extension.
- Some application code that uses enumerations was changed to support extensibility. Common changes include:
  - Removing **throw** exception statements in the default case of a switch to allow post-event subscription.
  - Adding **SysExtension** support for extension.
  - Adding explicit delegates.

Foundation changes were made to improve support for extensible enumerations. The **SysPlugin** framework was enabled for enumerations where **IsExtensible** is set to **Yes**. Views were enabled with new name-based syntax for enumerations.

Data manipulation methods that do not raise DataEvents or missing insert, update, delete pre- and post-data events

As a general practice, you use data methods on tables to raise events that can be used for extending the application. The code base has not always followed this practice. For example, the **doInsert**, **doUpdate**, and **doDelete** data methods and certain table implementations did not make a call to **super()** in the data method.

The **insert**, **update**, and **delete** methods on the type classes have been refactored. Changes were made so that **super()** is called more consistently in data methods. These changes enable extensions to be added to these methods, so that pre- and post-events are now available for extension. The tables where the **insert**, **update**, and **delete** events were enabled for extension are listed in the following table.

Exposing class members

Additional private members are now available for customization as a result of changes to access modifiers and parm methods. The chain of command platform feature enables extension class access to protected methods and members. For more information about chain of command, see Extensible X++: Chain of Command.

Construct methods with throw statements

Some **construct** methods were implemented with **throw** statements if there was a missing implementation for a given type. This doesn't work well with extensibility, so to mitigate this, **construct** methods were changed so that they do not throw exceptions. These methods are now to open for extensibility through class augmentation or by post-event subscription.

Find methods with throw statements

Some **find** methods were implemented with **throw** statements if there was a missing implementation for a given type. This does not work well with extensibility, so to mitigate this, **find** methods were changed so that they do not throw exceptions. These methods are now to open for extensibility through class augmentation or by post-event subscription.

METHODS
TradePostalAddress.partyTable

Extracted method to open for class extensions

The **Chain of Command** feature lets you create extension classes. Extensions classes offer a stronger way of extending than other options because they allow access to both protected and public methods and members. This provides more flexibility than extending through delegates or by pre or post event.

Within this group of changes, longer methods are extracted into smaller methods. The new methods have a more specific focus and you have more control over the scope of your extensions.

After the introduction of the **Chain of Command** feature, we suggest using extensibility by extracting methods instead of adding delegates because this approach provides a more versatile solution.

The following table lists the new methods that have been extracted and opened for building extension classes.

Changes using other methods to support extensibility

The group of changes in this section includes several different approaches to extensibility and represents the extensibilty changes made before **Chain of Command** was introduced. Some of the approaches used are extracting methods, adding "stub" methods, adding delegates, changing access modifiers on methods, and using the SysExtension framework. Please consult the implementation in places required for your customization to determine if the approach taken will work for your customization. In future releases, this group will be small, because we will primarily be using **Chain of Command**.

SQL operations made extensible

Application code with embedded SQL statements cannot be modified through extensions. Changes have been made to the standard application to enable extensibility in the methods listed in the following table. This has commonly been enabled by transforming embedded SQL statements into query objects that support extending how SQL statements are built in these methods.

METHOD
CustCollectionLetterCreate.updateAllExisting
CustCollectionLetterCreate.updateExisting
CustProvisionalBalanceDP.insertCustProvisionalBalanceTmp
CustProvisionalBalanceDP.processReport
CustSettlementPriorityProcessing.createTempData
DirPartyTable.getLocationFromRole

METHOD
InventQualityOrderTable.createInventQualityOrderLines
InventTransIdSum::calcSum
InventTransIdSum_InventLocation::calcSum
InventTransReference::setRefTrans
Markup.insertMarkupTrans
Markup.mcrCopyForReturn
PriceDisc.findDisc
PriceDisc.findPriceAgreement
PurchFormLetterParmDataInvoice.createLineProject
ReqPlanCopy.copyReqTransAndReqTransCov
ReqPlanCopy.copyReqTransKeep
ReqPlanCopy.copyWrkCtrCapRes
ReqPlanCopy.copyWrkCtrCapResForReqPO
SalesCopying.deleteLines
SalesLineType::deliveredInTotal
SalesTableType.parmPickingListRegistrationEnumerable
SalesTableType_Sales.canPickingListBeUpdated
SalesUpdateRemain.canclRemainderOnOpenSalesLines
SubledgerJournalizer.createSummaryFromJournalAccountEntry
SubledgerJournalizer.loadAccountingDistributionTmpJournalize
SubledgerJournalizer.loadFinalizeSubledgerJournalTmpDetail
SubledgerJournalizer.loadStandardSubledgerLedgerJournalTmpDetail
SubledgerJournalizer.loadSubledgerJourTmpDetailWithRelieving
SubledgerJournalizer.recordSubledgerJourAccEntriesForRounding
SubledgerJournalizer.summarizeJourAccountEntryDetailForRound

METHOD
SubledgerJournalTransferCommand.insertGeneralJournalAccountEntryRelatedDetail
TmsProcessXML_Base.writeShipDeliveryAccessorials
VendProvisionalBalanceDP.insertVendProvisionalBalanceTmp
VersioningPurchaseOrder.archivePurchLine
WhsLoadPostEngineBase::createShipments
WHSPackForm.getShipmentId
WHSPostEngineBase.executeWaveSteps
WhsPostPackingSlip.preparePackingSlipPosting
WhsWarehouseRelease.createShipments
WhsWarehouseRelease::createOrConsolidateShipmentForSalesOrder

Maps enabled for extensibility

New patterns have been introduced for maps implementation that will allow you to add field and methods by extensions. Details on how this is done is available in the documentation both with maps that are used as interfaces and for versioning implementations.

The following table lists the maps and related tables where changes have been applied for enabling extensibility.

MAPS AND TABLES
Map CustVendInvoiceTrans
Map SalesPurchLine extensions or inheritance
Map SalesPurchTable
Map VendDocumentLineMap
Table PurchLine mappings
Table PurchLineHistory mappings

Inventory dimensions

This release introduces a new model for adding inventory dimensions. In previous releases it was not practical to support customization for new inventory dimensions if that required extending every SQL statement that included inventory dimensions. Instead, we have added 10 inventory dimensions without any specific designated usage. Partner solutions will code through indirection models that hold their code, and other models are made for individual implementation projects that deploy one or more of the prefabricated inventory dimensions toward use in a partner solution. Documentation will be available on how to implement with

inventory dimensions under this model, and release of a sample app with a Flavor dimension will help you learn about the new model. The new inventory dimension can be freely deployed and used as either product dimensions or tracking dimensions.

The changes have led to changing multiple places across the application, including what is shown in the following list.

CHANGE
Extensible Product Dimensions
Form WHSInventOnHandReserve.updateInventDimFixedControls
InterCompanyInventDim: Condition with throw
InventDimFieldsMap - Added field
Inventory dimension InventUpdateOnhand::checkOnHand
Inventory Dimensions - Table InventDim.create
InventTransferUpdShip.populateIssueReceiptDimensions
Map InventInventoryDimensionEntityFieldsMapping::resolveInventDim()
Rename InventDimFieldsMap::getFieldIdForDimensionOnMappedTable to inventoryDimensionFieldIdOnMappedTable()
Table BOMConsistOfTmp mappings
Table BOMPartOfTmp mappings
Table EcoResTrackingDimensionGroup.isDimFieldTrackingDimension
Table InterCompanyInventDim mappings
Table InventAgeGroupDimTmp mappings
Table InventCheckRecieptCostPricePcsTmp mappings
Table InventCostTmpTransBreakdown mappings
Table InventCountStatisticsTmp mappings
Table InventDim mappings
Table InventOnhandTmp mappings
Table InventPhysicalPerWarehouseTransTmp_IT mappings
Table InventPriceOverviewTmp mappings
Table InventSumCriticalTmp mappings

CHANGE
Table InventSumDateTransReport mappings
Table InventSumDeltaDim mappings
Table InventTable mappings
Table InventTransferOrderOverviewTmp mappings
Table InventValueReportTmpLine mappings
Table ProdPickList mappings
Table SalesInvoiceTmp mappings
Table WHSPurchLine.registerPurchaseLine
Table WHSTmpCompleteWorkLine.lookupBatch
Table WHSTmpCompleteWorkLine.lookupTargetLicensePlateId
Table WMSCheckABCZonesTmp mappings
Table WMSPickingList_OrderPickTmp mappings
Table WMSPickingListReportTmp mappings

Metadata changes to enable extensibility

The following table lists changes made for enabling extensibility for specific metadata on these objects. These changes vary from instance to instance, you can consult the specific implementation to review the changes.

CHANGE
CountryRegionCodes property
CustCustomerEntity
EcoResProductCategoryAssignmentEntity made public
Form AssetSplit : FormControls
Form CustCollections.Cases
Form CustGroup
Form LedgerJournalTransCustPaym - menu item button auto declaration
Form LedgerJournalTransVendPaym - menu item button auto declaration
Table DimensionAttributeValueSetItem

CHANGE
Table EcoResReleasedProductCreationStaging missing ReplacementKey like other staging tables.
Tables SubledgerJournalAccountEntry(Tmp...)
View SubLedgerJournalAccountEntryView

Other changes

The following table lists additional changes that have been made for extensibility.

CHANGE
CustCollectionLetterCreate
CustCollectionLetterPost
Extensibility approach for number of decimal places for currency
Extensible edt decimal places: AssetDepreciationAmountUnit
Form Extension - DirPartyTable - registerOverrideMethod jumpRef
Form ProjCategoryLookup
Method signature changed: InventPostingSetupCache
Method signature changed: Table ProjCostPriceExpense.find
Method signature changed: Table ProjCostPriceExpense.findCostPrice
Method signature changed: Table ProjCostSalesPrice.find
Method signature changed: Table ProjCostSalesPrice.findCostSalesPrice
Method signature changed: Table ProjHourCostPrice.Find
Method signature changed: Table ProjHourCostPrice.FindCostPrice
Method signature changed: Table ProjHourSalesPrice.find
Method signature changed: Table ProjHourSalesPrice.findHourSalesPrice
New Quantity EDT added to ApplicationCommon
Other: New base enum for Price & Discount framework
Set Alternative Key = Yes to enable reference group lookups
Use of interface EcoResIProductCrossTableData

Bugs

The following table lists changes that were requested for extensibility but were acknowledged as bugs and fixed in the standard application.

CHANGE
class CaseUpdateStatus_Close, method changeStatus
Incorrect relation on CustCollectionLetterJour
Other: Bug fix on CompanyHelper.testCreateParameter
Table CustCollectionLetterJour - class cancelCollectionLetterCodeCustTrans

Extensibility changes in Finance and Operations, Enterprise edition (July 2017)

2/18/2021 • 9 minutes to read • Edit Online

This is a list of extensibility features that were implemented in the Dynamics 365 for Finance and Operations, Enterprise edition (July 2017). This version was released in July 2017 and has a build number of 7.2.11792.56024. For more information about the schedule of changes that support extensibility, see Application extensibility roadmap.

Soft-sealed application models

The following application middle-tier models were soft-sealed in this release. Overlayered code in these models will generate warnings on compilation.

CATEGORY	MODEL
Application Frameworks	CaseManagement
Application Frameworks	Dimensions
Application Frameworks	Directory
Application Frameworks	Organization
Application Frameworks	Currency
Application Frameworks	ApplicationCommon
HCM Core Models	3817938
Tax Models	Tax
Tax Models	Tax Books
Tax Models	Tax Books Application Suite Integration
Tax Models	Tax Engine Application Suite Integration
Tax Models	Tax Engine Configuration
Tax Models	Tax Engine Interface
Tax Models	Tax Engine Runtime Generation
Tax Models	TaxEngine

Middle Tier SCM Models	WMSAdvancedMigration
Middle Tier SCM Models	InventoryDimensionConversion
Workspaces	ApplicationWorkspaces
Finance	Fiscalbooks
Management tools	DataUpgrade

Hard-sealed application models

The following application middle-tier models were hard-sealed in this release. Overlayered code in these models will generate errors on compilation.

CATEGORY	MODEL
Accounts Payable	AccountsPayableMobile
Finance	FinancialReportingEntityStore
Tools	PerformanceTool
Expenses	ExpenseMobile
GER	ElectronicReporting
GER	ElectronicReportingCore
GER	Electronic Reporting Application Suite Integration

Enumerations that are now extensible

The following changes were made to support extending enumerations:

- Many enumerations in the standard application have been made extensible. An enumeration is made extensible by setting two properties on the enumeration. The **IsExtensible** property is set to **Yes**, and the **UseEnumValue** property is set to **No**.
- Some enumerations represent state. New façade methods have been added to help enable adding enumeration values by extension. For information about how to extend an enumeration, see Add values to enums through extension.
- Some application code that uses enumerations was changed to support extensibility. Common changes include:
  - Removing **throw** exception statements in the default case of a switch to allow post-event subscription.
  - Adding **SysExtension** support for extension.
  - Adding explicit delegates.

Foundation changes were made to improve support for extensible enumerations. The **SysPlugin** framework was enabled for enumerations where **IsExtensible** is set to **Yes**. Views were enabled with new name-based syntax for enumerations.

Data manipulation methods that do not raise DataEvents or missing insert, update, delete pre- and post-data events

As a general practice, you use data methods on tables to raise events that can be used for extending the application. The code base has not always followed this practice. For example, the **doInsert**, **doUpdate**, and **doDelete** data methods and certain table implementations did not make a call to **super()** in the data method.

The **insert**, **update**, and **delete** methods on the type classes have been refactored. Changes were made so that **super()** is called more consistently in data methods. These changes enable extensions to be added to these methods, so that pre- and post-events are now available for extension. The tables where the **insert**, **update**, and **delete** events were enabled for extension are listed in the following table.

Exposing class members

Additional private members are now available for customization as a result of the changes to the access modifier or new parm methods. The chain of command platform feature enables extension class access to protected methods and members. For more information about chain of command, see Extensible X++: Chain of Command.

Construct methods with throw statements

Some **construct** methods were implemented with **throw** statements if there was a missing implementation for a given type. This doesn't work well with extensibility, so to mitigate this, **construct** methods were changed so that they do not throw exceptions. These methods are now to open for extensibility through class augmentation or by post-event subscription.

OBJECT
BarcodeEAN128.string()
CustCreditLimit.Construct
FormLetterReport
JournalStatic
MarkupAllocation
PurchTable2LineField
SalesCalcTax
SalesEditLinesForm
SalesFormLetter
SalesFormLetterContract.newFromPackedVersion
SalesFormletterParmData.newData
SalesQuantity
SalesQuotationEditLinesForm.construct
SalesSummaryFields
SalesTable2LineField
VendInvoiceTableToLineUpdate

Find methods with throw statements

Some **find** methods were implemented with **throw** statements if there was a missing implementation for a given type. This does not work well with extensibility, so to mitigate this, **find** methods were changed so that they do not throw exceptions. These methods are now to open for extensibility through class augmentation or by post-event subscription.

METHODS
JournalStatic.findJournalTableFromTrans
JournalStatic.findJournalTableId

Methods made hookable

Extensibility support has been extended for some methods that were not public and were not hookable. The following methods have been explicitly decorated with hookable behavior.

METHOD
Class CustVendReversePosting.updateCustVendTrans
Class JournalTableData.construct
Class PriceDisc.makeKey
Class PurchInvoiceJournalCreate.initJournalHeader
Class SalesInvoiceJournalPost.checkSourceLine
Class SalesInvoiceJournalPost.postCustVend
Form LedgerTransVoucher.addDynaLink
ReqCalc.deleteItemRequirement
ReqCalc.initTransFromInventTrans
ReqCalcForecastItemTable.deleteRequirement
Table TmpCustVendTrans.createLineCreditLimit
Table TmpCustVendTrans.createLineCreditRemain
Table TmpCustVendTrans.createLineOrdered
Table TmpCustVendTrans.createLinePackingSlip
WHSLocationDirective.addRangeByTransType
WhsWorkCreate.createWorkLine

Inline delegates

Inline delegates are now available. The most common way to use inline delegates is to split the method into more granular methods and enable extensibility events in the smaller methods.

METHOD

WHSRFControlData.populateData
WHSRFControLData.processControl
WHSRFMenuItemTable.getWHSWorkExecuteMode

Other changes

The following table lists additional changes that have been made for extensibility.

CHANGE
Add indirection for existing product dimensions
Class FormLetterParmDataOutputContract is not extensible
Create an instantiation strategy for the SysExtensionFramework that supports one or more arguments

CHANGE
Customization: TableField: Extension Model: Change EDT type of on a table field
CustVendOpenTransBalances - initAccountNumCurrencies() switch statement
CustVendOpenTransBalances - new() switch statement
CustVendOutPaym (Class) needs extensibility improvement
CustVendPaymReconciliationSetStatus (Class) needs extensibility improvement
CustVendSumForPaym (Class) needs extensibility improvement
Decouple AddressCountyId and AddressStateId EDTs from SysGroup
Document Management event handling needs improved extensibility support
Exchange rate provider framework requires custom built providers to be placed in the Currency Model
Extending GS-128
Extension model: Allow customizations on the CountryRegionCodes property.
Form extension - Extension of "extended" form elements with new controls are not working
InventDim: Condition with throw
InventDimRenameDimValue
Method overlayering - Class VendInvoiceTableToLineUpdate.convertPurchTableFieldToVendInvoice
Method overlayering: class Markup - method delete
Method overlayering: class McrPriceHistoryForm.insertPotentialTradeAgreements
Method overlayering: Class OffsetVoucher - method markTransaction
Method overlayering: Form LedgerJournalTransDimension.init
Method overlayering: Form LedgerTransVoucher - method init
Method overlayering: Table CustInvoiceTable - method validateWrite
Method signature changed: RetailCreateLinesFromProductsToAdd.parmCallerCommon
Method signature changed: WHSInvent.getCommonFromWorkTransType
Method signature changed: WHSPoolProdBom.movementBuffer
Missing construct method: class SMAServiceOrderTableButtonStateProvider

CHANGE
Number sequence scope extensibility needed
Runbase needs a way for class extensions to pack/unpack their members
String EDT size extension issues
Support opening Inventory on-hand form based on custom InventDim
SysExtension framework: SysExtensionIInstantiationStrategy and SysExtensionIAttribute are not compatible
Variations of EventHandlerResult are requested to ensure that delegates used in Request/response scenarios are more robust
WHS Mobile Framework: passes
WhsLocationDirectiveLine To/FromQty not extensible
WHSMobileApp Extensibility
WHSMobileAppAttachedImageDetails.removeLabelFromDimValue() is not generic enough about Product dimensions
WHSMobileAppAttachedImageDetails.removeLabelFromDimValue() is not generic enough about Product dimensions
WhsRFControlData.processControl must reference WhsControl.data instead of _data in the switch block

Intrusive customizations

2/18/2021 • 3 minutes to read • Edit Online

This topic defines the characteristics of an intrusive customization. Intrusive customizations are the major obstacle to keeping continuous upgrade costs close to zero. Some types of intrusive customizations can be prevented by tooling, whereas other types remain the responsibility of the author of the extension. The X++ compiler and Microsoft Visual Studio designers will prevent some types of intrusive customizations. However, a subset of intrusive customizations can't be detected by tooling but might still prevent continuous upgrades. Ultimately, the developer is responsible for avoiding intrusive customizations.

A customization that violates any of the following principles is intrusive.

NOTE

When extending other solutions you are expected to be responsible. This includes:

- Accepting the responsibility of your extension. You are introducing new behavior and therefore own the full responsibility of the change.
- Allowing other extensions to co-exist. Recognize that you are not the only consumer of an extension point. For example, only respond when needed.
- Only adding extensions that are coherent with the extension point. The longevity of a solution is defined by its resilience to change. Recognize that extension points may be exercised in more or fewer scenarios in future versions. For example, only add relevant validation logic to a validate() method.
- Avoiding dependencies on implementation details. Implementation details are likely to change in future versions. Make your solution resilient by avoiding dependencies on local variables, call-stacks and, calling sequences and avoid using reflection.

Don't change type definitions

Types are referenced by their definition. A change to a type's definition is a breaking change and requires that all references be updated. It's impossible to ensure that future references will be implemented correctly (for example, in the model that hosts the type). There are several implications:

- Don't change a method signature. The method signature includes the return type, the name (which includes casing), and the parameters (which include optional parameters).
- Don't change requirements for implementers of interfaces and table maps. For example, don't add a new method to an interface or a new field to a table map.
- Don't change requirements for classes that are derived from abstract classes. For example, don't add a new abstract method to a class.
- Don't reduce access modifiers for types or members. For example, don't change classes, tables, or methods from public to private.
- Don't change constraints that are defined on a table or a data entity. Constraints include allowing editing, mandatory constraints, uniqueness constraints, and referential constraints.

Don't break encapsulation

The author of a model must be able improve the product by remaining in control of encapsulated code and types. Model owners must be able to change and delete encapsulated code and types at will, without prior notice, and without risk of downstream impact on extensions and customizations. Encapsulation is broken if, for example, a private method is deleted. Here are some of the implications:

- Don't increase access modifiers for types or members. For example, don't change classes, tables, or methods from private to public.
- If something should be closed for modification, don't open it for customizing behavior. Extension capabilities must be designed as open for extensibility but closed for modification.

Be additive in nature

New behaviors are enabled through added functionality as part of extensions. Extension capabilities must be designed in and open for extensions, and they must support multiple extensions that exist side by side in the same installation. There are several implications:

- Don't overlayer. Overlayering replaces the default implementation and prevents multiple solutions from changing the same element.
- Don't significantly change the characteristics of the standard functionality. These characteristics include the user experience and performance. For example, performance must not be adversely affected if an extension is installed but isn't used.
- Don't unconditionally set results in **EventHandlerResult** classes, and don't unconditionally set return values in **XppPrePostArgs** classes.
- Don't replace existing behavior by default, unless the replacing logic conforms to the Liskov Substitution Principle.

> **NOTE**
>
> The author of the extension is responsible for not violating these principles.

Class extension model in X++

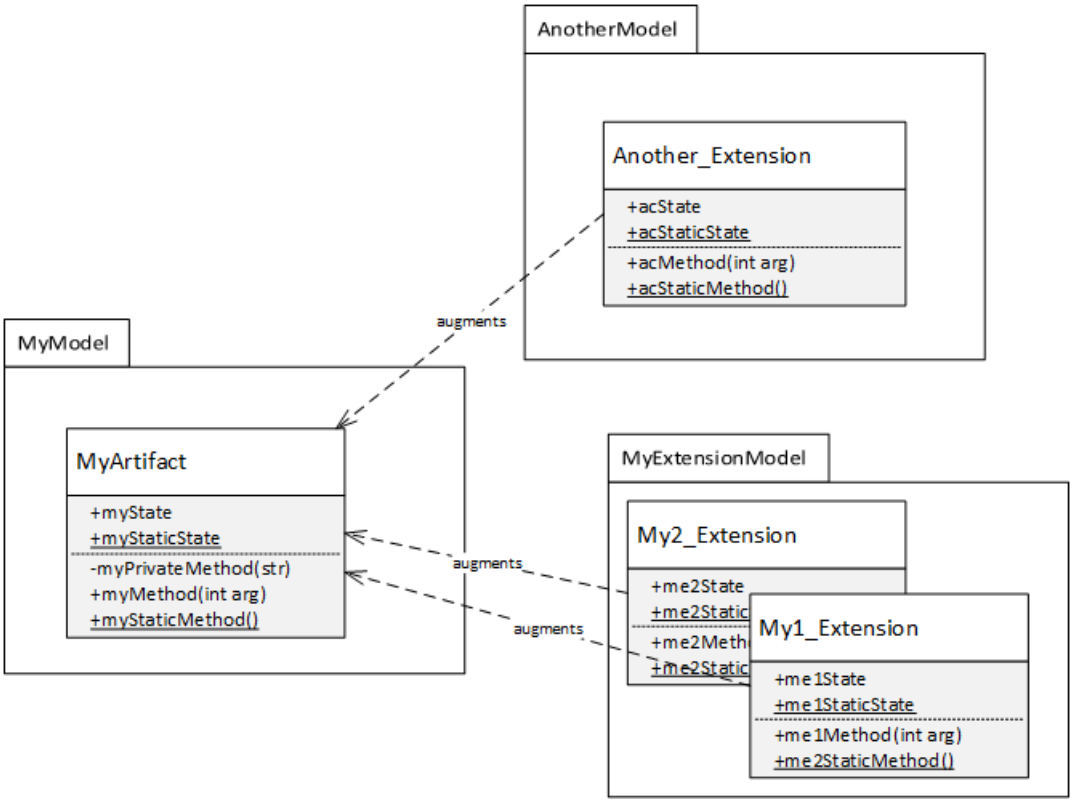
2/18/2021 • 7 minutes to read • Edit Online

This article describes the new class extension model in X++.

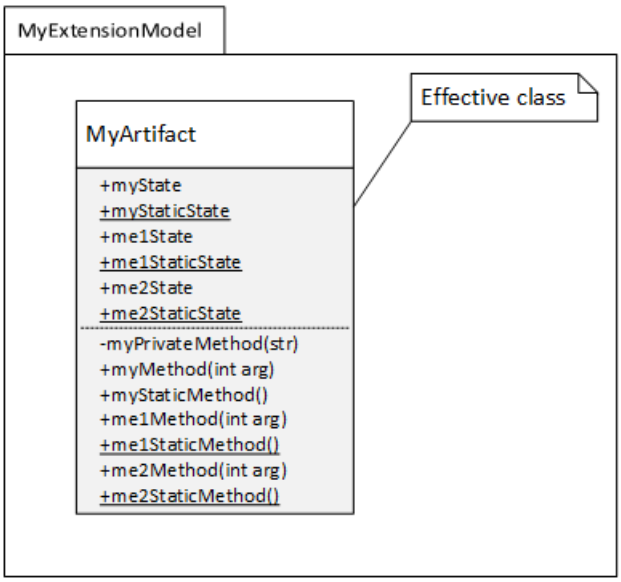
Because over-layering is a very intrusive feature, we recommend that you not use it. The alternative to over-layering is extension. Extension lets you extend existing artifacts in a new model. Extensions are easier to maintain, but the amount of extension that can be done during customization is limited. There are rich ways to extend the metadata. For example, you can add new fields to a table. This article describes how X++ code can be extended, so that you can add methods and state to artifacts that are defined in other models without recompiling those models. A similar code extension mechanism already exists for X++ and is modeled after the corresponding feature in C#. Under this mechanism, a class can be designated as an extension class through a naming convention and by hosting public static methods. In the existing feature, the type of the first argument that is passed to the extension method is the type to extend. What this article describes is the next step in that direction, which offers a more capable and natural extension story. In object-oriented programming, the term *extend* has a well-defined meaning. If we say, "class B extends class A," we mean that B inherits from A, that A is B's parent class, and the usual object-oriented rules are implied. In fact, this term is even used in the X++ syntax that is used in class declarations to express this relationship. At the same time, we use the term *extension* to talk about metadata that has contributions from several models. To avoid further overloading the term *extend*, we will instead use the term *class augmentation* to designate the relationship between a class A in a base model and a class B in a model that depends on it, where B provides additional functionality to class A in the context of that model. Nevertheless, we will also continue to use the term *extension class*, because it's prevalent.

The effective class concept

It's useful to have a term for a class that consists of the public members of the augmented artifact and all the public members of all the class extensions that augment that artifact. This class is called the effective class in a given model. The following illustration shows an artifact, **MyArtifact**, that is defined in a base model, **MyModel**, and two dependent models that have extension classes for **MyArtifact**.



In this example, the effective class is the class in the extension models that contains all the original methods and all the public artifacts from the extension classes. The effective class isn't the same in every model because it includes only the class extensions that are defined in a given model. The following illustration shows the effective class of **MyArtifact** in the **MyExtensionModel** model.



We will describe class extensions by using a class that is named **MyClass** in a model that is named **MyModel**.

```
class MyClass
{
    public int mycState;
    public str mycMethod(int _arg)
    {
        // ...
    }
}
```

We can add new methods and state to **MyClass** by introducing an extension class in the extension model (**MyExtensionModel**) that builds on top of (that is, has a dependency on) **MyModel**.

Extension class declarations

Extension classes are final classes that are adorned with the **ExtensionOf** attribute and that also have a name that has the **_Extension** suffix. (This restriction on the naming might be removed later.) The name of the extension class is otherwise unimportant. The class augments the artifact that is specified in the parameter of the **ExtensionOf** attribute, as shown in the following example.

```
[ExtensionOf(classStr(MyClass))]
final class MyClass_Extension
{
    private void new()
    {
    }
}
```

Because the classes are instantiated by the runtime system, it's not meaningful to derive from the extension class. Therefore, the extension class must be marked as **final**. The extension class **MyClass_Extension** does not extend the designated class (**MyClass**). Therefore, you cannot override methods from **MyClass** in **MyClass_Extension**. The **classStr** compile-time function must be used to designate the augmented class, and it serves two purposes:

- It produces a compilation error if the **MyClass** class doesn't exist.
- The compile-time function that is used tells the compiler what kind of artifact is augmented. Artifact names by themselves don't uniquely identify a given artifact to augment. For example, forms can have the same names as tables, classes, and enums.

Any number of extension classes can augment a given artifact in a particular model. Extension classes are never referenced directly by the programmer, only by the runtime system.

Extension class inheritance

Any class that inherits from an augmented class also inherits the effective class. In other words, the classes that inherit from a class that has extensions inherit the methods that are defined in the extension classes.

Constructors

X++ supports both instance constructors and static constructors.

Instance constructors

The instance constructor is the method that is named **new**. Constructors are useful for initializing the state of the extension objects. The instance constructor that is defined in an extension class can't have parameters. Instances of the extension classes are created, and the runtime system calls their constructors as required by the usage scenario. These constructors are never explicitly called by your code. It's guaranteed that the constructor that is provided in an extension class will be called once before any instance method or the instance state on the extension class is accessed. However, if no such references are made, the constructor isn't called.

Static constructors

Static constructors are the parameter-less static methods that are named **typenew**. Static constructors can be defined on extension classes. It's guaranteed that the runtime system will call the constructor exactly once before the first reference to the extension type. You can't assume any particular order of invocation for static construction among a set of extensions. This means that you should be careful about referencing static data from other classes in static constructors.

Methods

The public methods that are defined in extension classes provide additional functionality to the augmented class in the context of the model where the extension class is defined. Only public methods are exposed in this way. You can define private methods to help implement the public methods, but those private methods aren't part of the effective class. Because extension classes are final, methods should not be marked as **protected**.

Instance methods

The following example defines an extension method named **ExtensionMethod** in a class that augments **MyClass**.

```
[ExtensionOf(classStr(MyClass))]
final class MyClass_Extension
{
    private void new()
    {
    }
    public int ExtensionMethod(int arg)
    {
    }
}
```

The public instance method (**ExtensionMethod**) is defined in the extension class. Therefore, it's available just as if it were defined in **MyClass** in the context of the model where the extension class is defined. The following example shows how to call the method in the model.

```
MyClass c = new MyClass();
print c.ExtensionMethod(32);
```

Note that the instance method that is defined in the extension class is used as an instance method on the augmented artifact. An extension method can access public and protected members only from the artifact that it augments. This behavior is by design. No artifact should be able to interact directly with state and methods that are explicitly hidden through the **private**, or **internal** keywords. Otherwise, direct interaction with explicitly hidden state and methods could cause malfunction by invalidating key implementation assumptions in those artifacts. Methods and statements in the method body can use the **this** keyword. In this context, the type of **this** is the effective class of the augmented artifact.

Static methods

Methods that are defined as public and static in the extension class are available as static methods on the artifact that is augmented.

```
[ExtensionOf(classStr(MyClass))]
final class MyClass_Extension
{
    private void new()
    {
    }
    public int method1(int arg)
    {
    }
    public static real CelsiusToFahrenheit(real celsius)
    {
        return (celsius * 9.0 / 5.0) + 32.0;
    }
}
```

The following example shows how to call the method in the model.

```
var temp = MyClass::CelsiusToFahrenheit(20.0);
```

A static method can access the public static methods and state in the effective class of the augmented artifact. As an interesting side effect, static extension methods on the **Global** class become available in the language as functions, which are available without any prefix.

State

In addition to providing static and instance methods to an artifact, you can add instance state and static state.

Instance state

Instance state, which is state that pertains to a particular instance of an artifact, can be specified on extension classes. The following example defines a state that is named **state**.

```
[ExtensionOf(classStr(MyClass))]
final class MyClass_Extension
{
    public int state;
    private void new()
    {
    }
}
```

The following example shows how to use **state** in your code.

```
MyClass c = new MyClass();
c.state = 12;
```

Static state

Static state applies to the type, not instances of the type. The following example defines a static member called **staticState** in the Extension class augmenting the **MyClass** class.

```
[ExtensionOf(classStr(MyClass))]
final class MyClass_Extension
{
    public int state;
    public static int staticState;
    static void TypeNew()
    {
        staticState = 77;
    }
}
```

Class extension - Method wrapping and Chain of Command

2/18/2021 • 12 minutes to read • Edit Online

The functionality for class extension, or class augmentation, has been improved. You can now wrap logic around methods that are defined in the base class that you're augmenting. You can extend the logic of public and protected methods without having to use event handlers. When you wrap a method, you can also access public and protected methods, and variables of the base class. In this way, you can start transactions and easily manage state variables that are associated with your class.

For example, a model contains the following code.

```
class BusinessLogic1
{
    str doSomething(int arg)
    {
        // ...
    }
}
```

You can now augment the functionality of the **doSomething** method inside an extension class by reusing the same method name. An extension class must belong to a package that references the model where the augmented class is defined.

```
[ExtensionOf(classStr(BusinessLogic1))]
final class BusinessLogic1_Extension
{
    str doSomething(int arg)
    {
        // Part 1
        var s = next doSomething(arg + 4);
        // Part 2
        return s;
    }
}
```

In this example, the wrapper around **doSomething** and the required use of the **next** keyword create a Chain of Command (CoC) for the method. CoC is a design pattern where a request is handled by a series of receivers. The pattern supports loose coupling of the sender and the receivers.

We now run the following code.

```
BusinessLogic1 object = new BusinessLogic1();
info(object.doSomething(33));
```

When this code is run, the system finds any method that wraps the **doSomething** method. The system randomly runs one of these methods, such as the **doSomething** method of the **BusinessLogic1_Extension** class. When the call to the next **doSomething** method occurs, the system randomly picks another method in the CoC. If no more wrapped methods exist, the system calls the original implementation.

Supported versions

IMPORTANT

The functionality that is described in this topic (CoC and access to protected methods and variables) is available in Platform update 9. However, the class that is being augmented must also be compiled on Platform update 9 or later. As of August 2017, all current releases of the applications for Finance and Operations have been compiled on Platform update 8 or earlier. Therefore, to wrap a method that is defined in a base package (such as Application Suite), you must recompile that base package on Platform update 9 or later. As an example: If you create your own extension model that is augmenting a class that exists in the Application Suite model, and if you are using CoC or accessing protected methods/variables, you will need to build both Application Suite and your extension model. You will also need to create a deployable package that includes both models in order to deploy this functionality on a runtime environment.

Capabilities

The following sections give more details about the capabilities of method wrapping and CoC.

Wrapping public and protected methods

Protected or public methods of classes, tables, data entities, or forms can be wrapped by using an extension class. The wrapper method must have the same signature as the base method.

- When you augment form classes, only root-level methods can be wrapped. You can't wrap methods that are defined in nested classes.
- Currently, only methods that are defined in regular classes can be wrapped. Methods that are defined in extension classes can't be wrapped by augmenting the extension classes. This capability is planned for a future update.

What about default parameters?

Methods that have default parameters can be wrapped by extension classes. However, the method signature in the wrapper method must not include the default value of the parameter.

For example, the following simple class has a method that has a default parameter.

```
class Person
{
    public void salute(str message = "Hi") {...}
}
```

In this case, the wrapper method must resemble the following example.

```
[ExtensionOf(classStr(Person))]
final class APerson_Extension
{
    public void salute(str message)
    {
        // ...
    }
}
```

In the **APerson_Extension** extension class, notice that the **salute** method doesn't include the default value of the **message** parameter.

Wrapping instance and static methods

Instance and static methods can be wrapped by extension classes. If a static method is the target that will be wrapped, the method in the extension must be qualified by using the **static** keyword.

For example, we have the following **A** class.

```
class A
{
    public static void aStaticMethod(int parameter1)
    {
        // ...
    }
}
```

In this case, the wrapper method must resemble the following example.

```
[ExtensionOf(classStr(A))]
final class An_Extension
{
    public static void aStaticMethod(int parameter1)
    {
        // ...
        next aStaticMethod(parameter1);
    }
}
```

> **IMPORTANT**
> The ability to wrap static methods doesn't apply to forms. In X++, a form class isn't a new class, and can't be instantiated or referenced as a normal class. Static methods in forms don't have any semantics.

Wrapper methods must always call next

Wrapper methods in an extension class must always call **next**, so that the next method in the chain and, finally, the original implementation are always called. This restriction helps guarantee that every method in the chain contributes to the result.

In the current implementation of this restriction, the call to **next** must be in the first-level statements in the method body.

Here are some important rules:

- Calls to **next** can't be done conditionally inside an **if** statement.
- Calls to **next** can't be done in **while**, **do-while**, or **for** loop statements.
- A **next** statement can't be preceded by a **return** statement.
- Because logical expressions are optimized, calls to **next** can't occur in logical expressions. At runtime, the execution of the complete expression isn't guaranteed.

> **NOTE**
> If a method is replaceable, extenders don't have to unconditionally call **next** when wrapping the method by using chain of command. Although extenders can break the chain, the expectation is that they will only conditionally break it. The compiler doesn't enforce calls to **next** for methods with the attribute, **Replaceable**.

Wrapping a base method in an extension of a derived class

The following example shows how to wrap a base method in an extension of a derived class. For this example, the following class hierarchy is used.

```
class A
{
    public void salute(str message)
    {
        info(message);
    }
}

class B extends A {}
class C extends A {}
```

Therefore, there is one base class, **A**. Two classes, **B** and **C**, are derived from **A**. We will augment or create an extension class of one of the derived classes (in this case, **B**), as shown here.

```
[ExtensionOf(classStr(B))]
final class B_Extension
{
    public void salute(str message)
    {
        next salute(message);
        info("B extension");
    }
}
```

Although the **B_Extension** class is an extension of **B**, and **B** doesn't have a method definition for the **salute** method, you can wrap the **salute** method that is defined in the base class, **A**. Therefore, only instances of the **B** class will include the wrapping of the **salute** method. Instances of the **A** and **C** classes will never call the wrapper method that is defined in the extension of the **B** class.

This behavior becomes clearer if we implement a method that uses these three classes.

```
class ProgramTest
{
    public static void main(Args args)
    {
        var a = new A();
        var b = new B();
        var c = new C();

        a.salute("Hi");
        b.salute("Hi");
        c.salute("Hi");
    }
}
```

For calls to **a.salute("Hi")** and **c.salute("Hi")**, the Infolog shows only the message "Hi." However, when **b.salute("Hi")** is called, the Infolog shows "Hi" followed by "B extension."

By using this mechanism, you can wrap the original method only for specific derived classes.

Accessing protected members from extension classes

As of Platform update 9, you can access protected members from extension classes. These protected members include fields and methods. Note that this support isn't specific to wrapping methods but applies all the methods in the class extension. Therefore, class extensions are more powerful than they were before.

The Hookable attribute

If a method is explicitly marked as **[Hookable(false)]**, the method can't be wrapped in an extension class. In the following example, **anyMethod** can't be wrapped in a class that augments **AnyClass1**.

```
class AnyClass1
{
    [Hookable(false)]
    public void anyMethod() {...}
}
```

> **NOTE**
>
> For compatibility reasons, **[Hookable(false)]** overrides the behavior of chain of command in addition to pre- and post-handlers. However, **[Hookable(true)]** only applies to pre- and post-handlers and does not influence chain of command wrapping.

Final methods and the Wrappable attribute

Public and protected methods that are marked as **final** can't be wrapped in extension classes. You can override this restriction by using the **Wrappable** attribute and setting the attribute parameter to **true** (**[Wrappable(true)]**). Similarly, to override the default capability for (non-final) public or protected methods, you can mark those methods as non-wrappable (**[Wrappable(false)]**).

In the following example, the **doSomething** method is explicitly marked as non-wrappable, even though it's a public method. The **doSomethingElse** method is explicitly marked as wrappable, even though it's a final method.

```
class AnyClass2
{
    [Wrappable(false)]
    public void doSomething(str message) {...}

    [Wrappable(true)]
    final public void doSomethingElse(str message) {...}
}
```

Extensions of form-nested concepts such as data sources, data fields, and controls

In order to implement CoC methods for form-nested concepts, such as data sources, data fields, and controls, an extension class is required for each nested concept.

Form data sources

In this example, **FormToExtend** is the form, **DataSource1** is a valid existing data source in the form, and **init** and **validateWrite** are methods that can be wrapped in the data source.

```
[ExtensionOf(formdatasourcestr(FormToExtend, DataSource1))]
final class FormDataSource1_Extension
{
    public void init()
    {
        next init();
        //...
        //use element.FormToExtendVariable to access form's variables and datasources
        //element.FormToExtendMethod() to call form methods
    }

    public boolean validateWrite()
    {
        boolean ret;
        //...
        ret = next validateWrite();
        //...
        return ret;
    }
}
```

Form data fields

In this example, a data field is extended. **FormToExtend** is the form, **DataSource1** is a data source in the form, **Field1** is a field in the data source, and **validate** is one of many methods that can be wrapped in this nested concept.

```
[ExtensionOf(formdatafieldstr(FormToExtend, DataSource1, Field1))]
final class FormDataField1_Extension
{
    public boolean validate()
    {
        boolean ret
        //...
        ret = next validate();
        //...
        return ret;
    }
}
```

Controls

In this example, **FormToExtend** is the form, **Button1** is the button control in the form, and **clicked** is a method that can be wrapped on the button control.

```
[ExtensionOf(formControlStr(FormToExtend, Button1))]
final class FormButton1_Extension
{
    public void clicked()
    {
        next clicked();
        //...
    }
}
```

Requirements and considerations when you write CoC methods on extensions for form-nested concepts

- Like other CoC methods, these methods must always call **next** to invoke the next method in the chain, so that the chain can go all the way to the kernel or native implementation in the runtime behavior. The call to next is equivalent to a call to **super()** from the form itself to help guarantee that the base behavior in the runtime is always run as expected.
- Currently, the X++ editor in Microsoft Visual Studio doesn't support discovery of methods that can be

wrapped. Therefore, you must refer to the system documentation for each nested concept to identify the correct method to wrap and its exact signature.

- You **cannot** add CoC to wrap methods that aren't defined in the original base behavior of the nested control type. For example, you can't add **methodInButton1** CoC on an extension. However, from the control extension, you can make a call into this method if the method has been defined as public or protected. Here is an example where the **Button1** control is defined in the **FormToExtend** form in such a way that it has the **methodInButton1** method.

```
[Form]
public class FormToExtend extends FormRun
{
    [Control("Button")]
    class Button1
    {
        public void methodInButton1(str param1)
        {
            info("Hi from methodInButton1");
            //...
```

- You do **not** have to recompile the module where the original form is defined to support CoC methods on nested concepts on that form from an extension. For example, if the **FormToExtend** form from the previous examples is in the **ApplicationSuite** module, you don't have to recompile **ApplicationSuite** to extend it with CoC for nested concepts on that form from a different module.

Extensions of tables and data entities

An extension class is required for each concept.

Tables

In this example, **TableToExtend** is the table and **delete**, **canSubmitToWorkflow**, and **caption** are methods that can be wrapped in the table.

```
[ExtensionOf(tablestr(TableToExtend))]
final class TableToExtend_Extension
{
    public void delete()
    {
        next delete();
        //...
    }

     public boolean canSubmitToWorkflow(str _workflowType)
    {
        boolean ret;
        //...
        ret = next canSubmitToWorkflow(_workflowType);
        //...
        return ret;
    }

    public str caption()
    {
        str ret;
        //...
        ret = next caption();
        //...
        return ret;
    }
}
```

Data entities

In this example, **DataEntityToExtend** is the data entity and **validateDelete** and **validateWrite** are methods that can be wrapped in the data entity.

```
[ExtensionOf(tableStr(DataEntityToExtend))]
final class DataEntityToExtend_Extension
{
    public boolean validateDelete()
    {
        boolean ret;
        //...
        ret = next validateDelete();
        //...
        return ret;
    }

    public boolean validateWrite()
    {
        boolean ret;
        //...
        ret = next validateWrite();
        //...
        return ret;
    }
}
```

Restrictions on wrapper methods

The following sections describe restrictions on the use of CoC and method wrapping.

X++ classes that are compiled by using Platform update 8 or earlier

The method wrapping feature requires specific functionality that is emitted by an X++ compiler that is part of Platform update 9 or later. Methods that are compiled by using earlier versions don't have the infrastructure to support this feature.

Methods on types nested within forms can be wrapped in Platform update 16 and later

The ability to wrap methods on types nested within forms (data sources and controls) by using class extensions was added in Platform update 16. This means that Chain of Command can be used to provide overrides for data source methods and form control methods.

However, wrapping (extension) of purely X++ methods on those nested types (form controls and form data sources) is not yet supported like it is on other types (forms, tables, data entities). Currently, if a developer uses Chain of Command on purely X++ methods on types inside forms, then it compiles, but the extension methods are not invoked at runtime. This capability is planned for a future update.

Unimplemented system methods on tables and data entities can be wrapped in Platform update 22 and later

The ability to wrap methods in nested classes by using class extensions was added in Platform update 16. The concept of nested classes in X++ applies to forms for overriding data source methods and form control methods.

Next calls can be put inside try/catch/finally in Platform update 21 and later

In a CoC extension method, the next call must not be called conditionally. However, in Platform update 21 and later next calls can be placed inside a try/catch/finally to allow for standard handling of exceptions and resource cleanup.

```
public void someMethod()
{
    try
    {
        //...
        next updateBalances();
        //...
    }
    catch(Exception::Error)
    {
        //...
    }
}
```

Extensions of extensions are not yet supported

Currently, only methods that are defined in regular classes can be wrapped. Methods that are defined in extension classes can't be wrapped by augmenting the extension classes. This capability is planned for a future release.

Extensions of constructors

Constructors cannot be extended. A **new** method that is defined on an extension class will define a constructor for the extension class itself. Additionally, the **new** method has to be public, and it can't have any arguments. For more information, see Constructors.

Tooling

For the features that are described in this topic, the Microsoft Visual Studio X++ editor doesn't yet offer complete support for cross-references and Microsoft IntelliSense.

Naming guidelines for extensions

2/18/2021 • 5 minutes to read • Edit Online

High level guidance: use prefixes to reduce conflicts and improve identification

Naming model elements

Every element in a model must have a name that is unique across all models at installation time. However, at installation time, you don't know the names of all the models that your model might be installed together with. To accommodate this situation, every element name should include a prefix that is specific to your solution. By including this prefix when you name elements in your model, you significantly reduce the risk of naming conflicts.

- If a model contains multiple solutions, each solution in the model can be identified by a different prefix.
- You must carefully choose the prefix to minimize the risk that other models from other parties use the same prefix for their elements.

When you extend functionality in other models, elements that are being extended already contain a prefix. However, you should not add your prefix to the extension elements, so that the names include multiple successive prefixes. Instead, you should include your prefix or another term or abbreviation as an infix when you name extension elements.

Naming extensions

An extension element, such as a table extension, view extension, or form extension, must have a unique name that minimizes the risk of conflicts with extensions in other models. To minimize the risk of conflicts, the name should include a term, abbreviation, or infix that distinguishes the extension from other extensions to the same element in other models.

- Include either the name of the model where the extension element resides or the prefix that the extension is associated with. For example, a Warehousing module extends the HCMWorker table and uses the **WHS** prefix in the name of all other elements. In this case, the extension might be named **HCMWorker.WHSExtension**. Notice that the prefix that is used to name other elements in the module is inserted as an infix in the name. As another example, an extension of the ContactPerson table in the **ContosoCustomizations** model might be named **ContactPerson.ContosoCustomizations** if the extension is intended to contain all extensions to the ContactPerson table from the **ContosoCustomizations** model. The developer tools will default to using the model's name as the extension name, since the model name is already required to be unique.
- Don't name the extension just **<Element that is being extended>.Extension**. For example, an extension of the InventLocation table must not be named **InventLocation.Extension**, because the risk of conflicts is too high.

Naming extension classes

Extension classes that are used to augment the logic on tables, classes, or other elements must have a name that is unique across all types in all models. Preferably, the extension class should include the name of the type that is being extended. However, the name must also include a term, abbreviation, or prefix that distinguishes the class from other types.

- Start the name of the extension class with the name of the type that is being augmented, and end the name

with the term **_Extension**. Therefore, an extension class that augments the ContactPerson table should start with the name **ContactPerson** and end with **_Extension**. For example, one extension class might be named **ContactPersonWHS_Extension**.

- Include either the name of the model where the extension element resides or the prefix that the extension is associated with. For example, a Warehousing module uses an extension class to augment the ContactPerson table and uses the **WHS** prefix in the name of all other elements. In this case, the extension class might be named **ContactPersonWHS_Extension**. Notice that the prefix that is used to name other elements in the module is inserted as an infix in the name. As another example, an extension class that augments the ContactPerson table in the ApplicationSuite model might be named **ContactPersonApplicationSuite_Extension** if the extension class is intended to contain all extensions to the ContactPerson table in the ApplicationSuite model.
- Consider adding additional element type information in case you create a class extension for elements that can't be declared in the code (like Forms, DataSources, or FormControls). For example, **CustTableFormWHS_Extension** is the extension for the **CustTable** form.
- Don't name the extension just **<Element that is being extended>_Extension**. For example, an extension class that augments the InventLocation table must not be named **InventLocation_Extension**, because the risk of conflicts is too high.

Naming fields, field groups, indexes, relations, and metadata elements added in extensions

Fields, field groups, indexes, relations, and metadata elements added in extensions must have a name that is unique across both the element that is being extended and other extension elements. Therefore, **these artifacts should include a prefix** that minimizes the risk of conflicts across models. In addition, these artifacts should have clear terms and abbreviations so that they can be easily understood.

- Include a prefix, term, or abbreviation at the beginning of the name of the metadata node. For example, an approving worker foreign key field is added as part of a table extension, and **WHS** is one of prefixes that are dedicated to other elements in the hosting model. In this case, the field might be named **WHSApprovingWorker**.

Naming variables and methods added in extension classes

Variables and methods added in extension classes must have a name that is unique across both the type that is being extended and all other extension classes that extend the same type. You should take care to create unique and readable names for variables and methods. When you can't create a unique name, then you should apply a prefixto minimize the risk of conflicts across models.

- Create unique and readable names for variables and methods. For example, an approving worker class-level member variable might be named **approvingWorkerForLocalWarehouse** if the area of functionality is related to supporting some local warehouse extension functionality. An **approveWork** method for the same area of functionality might be named **approveWorkForLocalWarehouse**.

- When you cannot create a unique and readable name, then add a prefix, term, or an abbreviation at the beginning of the member variable or method name. For example, an approving worker class-level member variable might be named **whsApprovingWorker** if **WHS** is one of the prefixes that is used by other elements in the model. An **approveWork** method might be named **whsApproveWork** if **WHS** is a prefix that is used by other elements in the hosting model.

- Avoid generic names, because the risk is high that multiple extensions could be using the same term or that the base functionality would be enhanced with an identical name in a future release. Some example of names likely to collide are **Approver**, **Delay**, **Group**, **Lookup**, and **Process**.

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Relax model restrictions to refactor overlayering into extensions

2/18/2021 • 2 minutes to read • Edit Online

Development tools for Finance and Operations apps, starting with version 8.0, do not allow Microsoft code to be customized by using over-layering. Instead, extension capabilities should be used to modify and add behavior. The "no over-layering" restriction is a key part of the evolution of the product toward providing customers with a cloud service that is simple to update and always running the most recent version possible to allow all customers to receive the benefits of the latest features and fixes.

After you upgrade code from Dynamics AX 2012 or from Dynamics 365 for Finance and Operations version 7, any customizations that still use over-layering will cause errors when you compile your code. To refactor the code, the over-layering restriction can be temporarily relaxed in the model descriptor file of the model that is being over-layered. This temporary relaxation only works on development and demo environments and cannot be deployed on runtime environments like Standard Acceptance Test (or higher) sandbox or production environments. Relaxing the descriptor restriction will enable the code to be gradually refactored to extensions, compiled, run, and then tested.

Detailed process

Complete the following steps to relax model restrictions. This procedure can be completed on a cloud environment or a local virtual machine (VM).

1. Deploy the development environment for the Finance and Operations app.
2. Run the Lifecycle Services (LCS) code upgrade service to upgrade the solution.
3. Temporarily allow over-layering in Microsoft models as needed to enable compilation.

   a. Locate the desired model within the C:\AOSService\PackagesLocalDirectory folder.

   b. Navigate to the descriptor folder. For example, \Currency\Descriptor.

   c. Open the XML file. For example, Currency.xml.

   d. Add a **Customization** metadata element inside the **AxModelInfo** metadata element to indicate **AllowAndWarn** so that the start of the file now looks like this.

   ```
   <AxModelInfo xmlns:i="http://www.w3.org/2001/XMLSchema-instance">
   <AppliedUpdates xmlns:d2p1="http://schemas.microsoft.com/2003/10/Serialization/Arrays" />
   <Customization>AllowAndWarn</Customization>
   ```

4. Refactor over-layering to extensions and test. Make use of extension capabilities to eliminate over-layering. If needed, make extensibility requests.
5. Revert the temporary changes to Microsoft models. The deployment of a model that uses over-layering will not be possible, so it's important to ensure that the descriptor file is updated.

Prototyping extensibility requests

As a solution gradually migrates toward extensions, there will be places where an extensibility request is required to unblock the solution. To fully understand what is needed to unblock a solution and smooth the

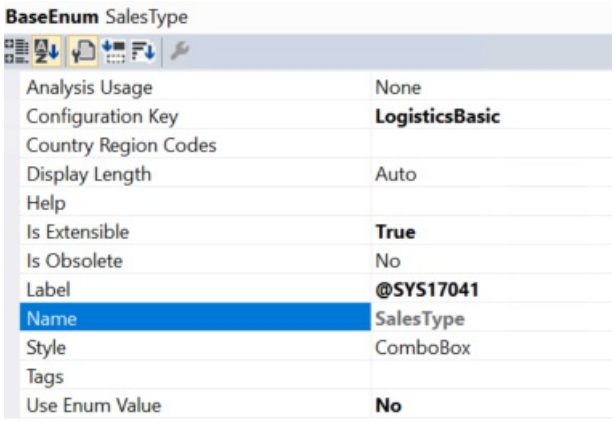
migration process toward extensions, extension capabilities can be prototyped in a separate model.

1. Identify the need for an extension capability to refactor some over-layering.
2. Add a prototype of extension capabilities into an extension prototype model.
    - For enumeration extensibility, put a copy of the enumeration into the extension prototype model and mark it as extensible.
    - For extract method extensibility, prototype the extracted method and the overlayered original in the extension prototype model.
3. Use the prototype extension capability.
4. If the prototype extension capability is sufficient, create a matching request.
5. When the extension capability has been implemented in the platform or application, the prototype extension capability and any associated over-layering should be removed from the extension prototype model.
6. After the solution has all over-layering refactored to extensions and the extension prototype model is empty, the solution refactoring is complete.

Add values to enums through extension

2/18/2021 • 2 minutes to read • Edit Online

To add new values to an enum, you should extend the enum. Any enum that is marked as **Extensible** (**IsExtensible = true**) can be extended. You can find the extensibility information in the **Properties** window in Microsoft Visual Studio, as shown in the following illustration.



When enum values of extensible enums are synchronized, the integer values of the baseline enum are deterministic, whereas the integer values of the extension enum values are non-deterministic. The values are generated during synchronization. Therefore, you can't have logic that depends on the integer value of the enum values. Here are some examples:

- Range comparisons, such as `<`, `>`, and `..`
- Modeled ranges in views and queries
- Query ranges that are created from code

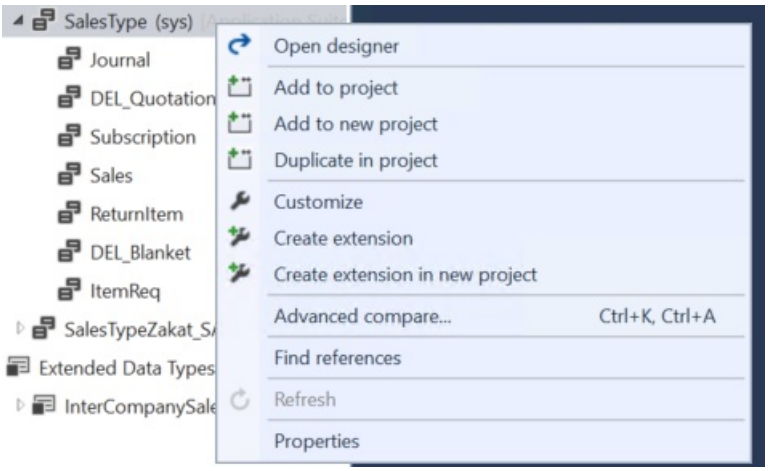
Usually, an extended enum must have its own implementation wherever it's used. Look for all uses of the enum, and uptake the implementation where it's required. Here are some significant places to look for:

- Switch blocks:
  - If the switch block doesn't have a default case block or a default case block that doesn't throw an exception, handle the extended enum value by subscribing to a delegate, if a delegate is provided. Otherwise, add a post-event handler to the method.
  - If the enum is used in a switch that has a default case block that throws an exception, contact Microsoft to request a delegate.
- If the enum has an associated class hierarchy that handles the enum, create a subclass for the extended enum–specific implementation, and uptake the construct on the base class as required. For more information, see Register subclasses for factory methods.

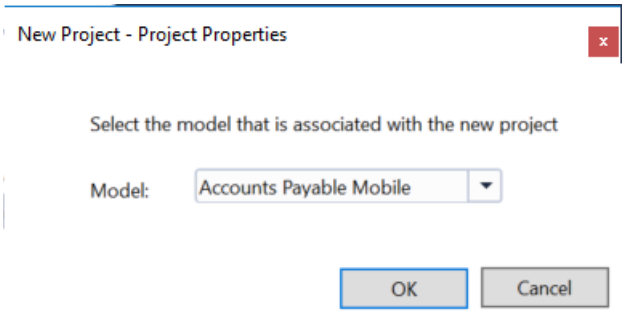
Extend an enum

There are two ways to extend an enum:

- Create a project that has a model reference where you want the new enum extension. Right-click the enum to extend, and then select **Create extension**.



- Right-click the enum to extend, and then select **Create extension in new project**. You're prompted to select the model that the extension enum should be created in.



The enum extension is created in the selected model. You can add new enum values to this extension.

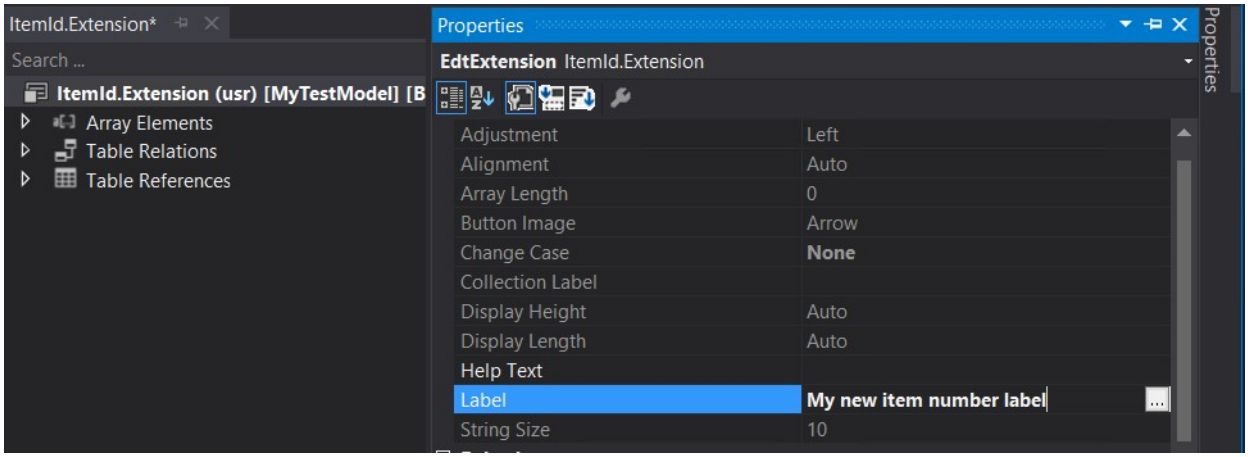
Modify extended data types (EDTs) through extension

2/18/2021 • 2 minutes to read • Edit Online

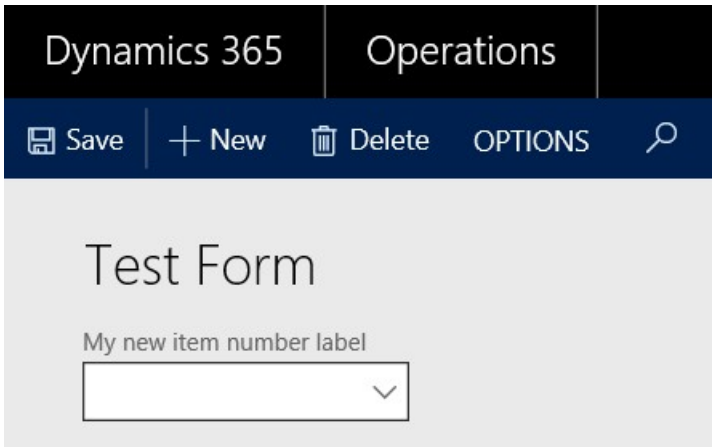
There are several properties that can be customized on existing extended data types (EDTs) through extension:

- Label
- Help text
- Form help
- Country region codes
- String size
  - You can only modify the value if the EDT does not extend from another EDT.
  - You can only set the new String size to a value equal to or larger than the base EDT value.
- Decimals (NoOfDecimals property)
  - For more information, see Extending decimal point precision for selected data types.

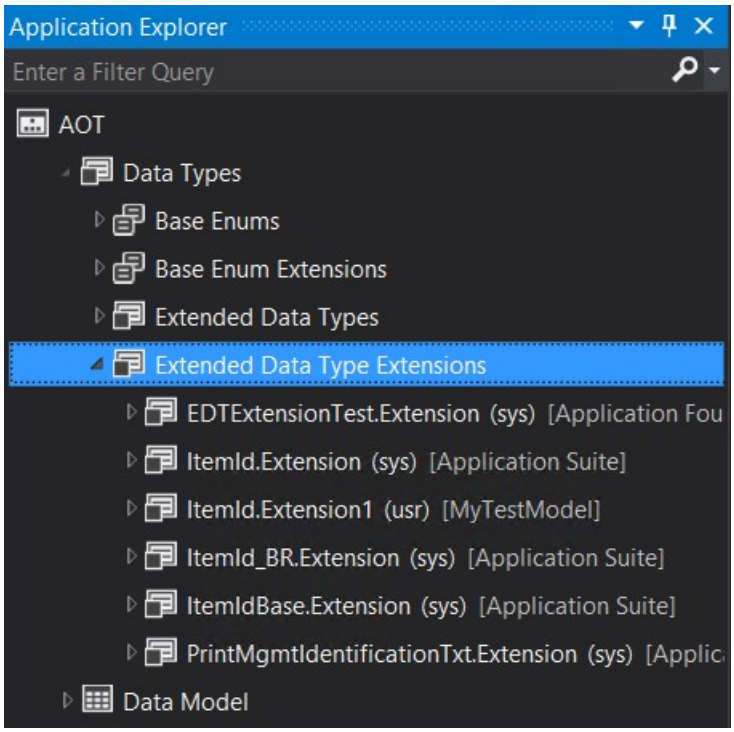
You modify the properties as you would for newly added elements, using the property sheet.



After compiling the code, you can see the changes in the application.



You can view the created extensions in the Application Explorer in Visual Studio.



If the EDT is modified in more than one model

If multiple ISVs have extended the same extended data type, the properties of the EDT from the model with the highest Model ID (closest to USR) will be used. If there are multiple models with changes in the same layer, changes from the model with the highest Model ID will be used. For example, if ISV 1 modified the label of ItemId to "Awesome item number" in model AwesomeModel (USR layer) with ID 15, while ISV 2 modified the label of ItemId to "Super item number" in model SuperModel (USR layer) with ID 12, the end user would see "Awesome item number" in the user interface instead of "Item number".

> **NOTE**
>
> Instead of extending an existing EDT, you can create a new one, deriving it from the existing EDT. This allows you to edit more properties than you could edit using the extension approach. This means that you would need to modify the fields using this EDT to use your new EDT.

Register subclasses for factory methods

2/18/2021 • 2 minutes to read • Edit Online

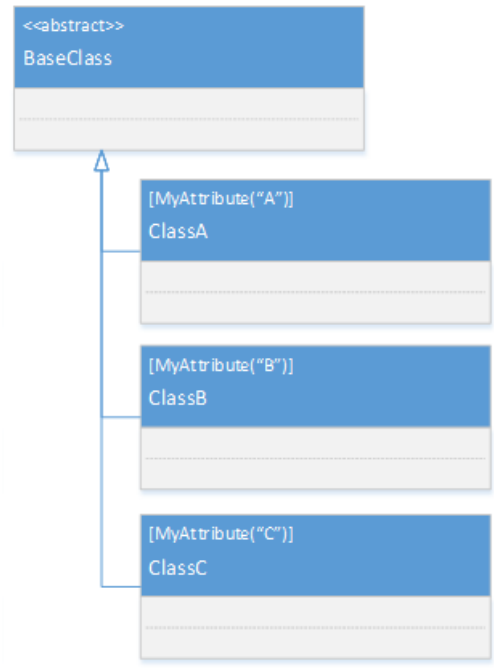
Class inheritance is a central concept in X++, as in other object-oriented languages. The object-oriented strategy pattern is used throughout the X++ business logic. In this pattern, variations in behavior can be encapsulated by subclasses, and the business process uses an abstract base class or interface. A factory method determines the variation that is used, by creating an instance of a specific subclass.

This topic describes how to register your own variations for the factories.

In X++, the factories use reflection to perform the following tasks:

- Find the correct subclass. The factory uses an extension framework to search all subclasses in a hierarchy for a specific set of attributes. If the attributes that decorate a subclass match the parameters that were passed to the factory, that specific class is used.
- Create an instance. After the right type is identified, reflection is used to create an instance of the class.

The following illustrations shows a typical decorated hierarchy.



In X++, two extension frameworks serve the same purpose. The implementer of the factory method determines which extension framework should be used:

- SysExtension
  - This extension framework uses custom attributes that make it easier to consume.
  - It supports singletons that save a little performance when the same instance is created repeatedly. This extension framework is especially useful for stateless subclasses.
  - It seamlessly supports extensible enums that are often used to determine the variant.
- SysPlugin
  - This extension framework is based on the Managed Extension Framework. The Managed Extension Framework makes the SysPlugin extension framework available to non-X++ code.
  - It uses the **ExportMetadataAttribute** attribute to decorate the variants and is string-based.
  - It uses the **ExportAttribute** attribute to make the variant discoverable.

Introduce a new variant

1. Identify the base class (or interface) of the variant that you must implement.
2. Create a new subclass of the base class, and implement your variation.
3. Identify which attribute is required in order to register your class. There are two approaches:
   - Look for attributes that are defined on other subclasses in the hierarchy.
   - Look at the implementation of the factory method. That implementation will contain the attributes that the factory method is searching for.
4. Decorate your subclass with the attribute that was used to match your variation.

SysExtension example

```
[WHSWorkExecuteMode(WHSWorkExecuteMode::About)]
class WHSWorkExecuteDisplayAbout extends WHSWorkExecuteDisplay
{
    // Your code here.
}
```

SysPlugin example

```
[ExportMetadataAttribute('CaseIAssociation', 'Lead'),
ExportAttribute('Dynamics.AX.Application.CaseIAssociation')]
class smmLeadCaseAssociationProvider implements CaseIAssociation
{
    // Your code here.
}
```

Respond by using EventHandlerResult

2/18/2021 • 4 minutes to read • Edit Online

Some delegate methods are implemented so that they can request a response from subscribing delegate handler methods. The delegate calling logic then uses the response from a potential subscriber when it continues execution after the response has been received. These delegate methods usually have a signature that has an **EventHandlerResult** parameter as the last parameter. However, because of the support for the **EventHandlerAcceptResult** and **EventHandlerRejectResult** types, the parameter can be of any type that implements the **IEventHandlerResult** interface.

- In general, the logic that is implemented in the delegate handler method should contain a condition that verifies that the subscribing logic is responsible for providing a response. It should also include logic to provide the response in the form of a result.
- When the delegate handler method must provide the response to an **EventHandlerResult** object parameter, the subscribing logic might also contain logic to calculate or retrieve the result.
- When the condition and the response logic are implemented, the calculation of the result must occur only when the condition is evaluated to **true**.
- All the subscribing delegate handler methods are run when a delegate is called. Therefore, you should make sure that the overhead of running your method is as low as possible when the method isn't responsible for providing a response. Therefore, make sure that the condition is evaluated to **false** as quickly as possible when your delegate handler method isn't responsible for providing a result.

Examples

The following example shows a delegate handler that has a condition in the form of a **switch** statement. The delegate handler also has logic to provide a response in the form of the result. The responding logic is run only when the condition is evaluated to **true**.

```
[SubscribesTo(tableStr(InventWarehouseEntity), delegateStr(InventWarehouseEntity,
validateWarehouseTypeDelegate))]
public static void validateWarehouseTypeIsSupportedStandardDelegateHandler(InventLocationType
_inventLocationType, EventHandlerResult _result)
{
    switch (_inventLocationType)
    {
        case InventLocationType::Standard:
        case InventLocationType::Quarantine:
        case InventLocationType::Transit:
            _result.result(true);
            break;
    }
}
```

When the delegate method requests a response by using an **EventHandlerAcceptResult** or an **EventHandlerRejectResult** object parameter, the subscriber is expected to respond only with an accept or a reject. The subscribing logic might also add messages to the Infolog.

The following example resembles the previous example. However, the delegate method now requests a response by using an **EventHandlerAcceptResult** object and by calling the **accept** method.

```
[SubscribesTo(tableStr(InventWarehouseEntity), delegateStr(InventWarehouseEntity,
validateWarehouseTypeDelegate))]
public static void validateWarehouseTypeIsSupportedStandardDelegateHandler(InventLocationType
_inventLocationType, EventHandlerAcceptResult _result)
{
    switch (_inventLocationType)
    {
        case InventLocationType::Standard:
        case InventLocationType::Quarantine:
        case InventLocationType::Transit:
            _result.accept();
            break;
    }
}
```

The following example shows a delegate handler method that responds by using an **EventHandlerRejectResult** object. To respond by using an **EventHandlerRejectResult** object, you can call the **reject** method or the **checkFailed** extension method. If you use the **checkFailed** method, you can add a warning message to the Infolog. Internally, the **checkFailed** method calls the **reject** method.

```
[SubscribesTo(classStr(ProdTableType), delegateStr(ProdTableType,
validateWriteProdTableInventRefTypeDelegate))]
public static void validateWriteProdTableInventRefTypeDelegateHandler(ProdTable _prodTable,
EventHandlerRejectResult _result)
{
    if (_prodTable.InventRefType == InventRefType::ProdLine)
    {
        if (! _prodTable.InventRefId || !_prodTable.InventRefTransId)
        {
            _result.checkFailed("@SYS19558");
        }
        ProdBOM prodBOM;
        select prodBOM
            where prodBOM.InventTransId  == _prodTable.InventRefTransId;
        if (! _prodTable.checkRefProdBOM(prodBOM))
        {
            _result.reject();
        }
    }
}
```

Guidelines

In addition to the previously described practices, the following general guidelines apply:

- Respond only when the subscribing logic is responsible for responding. The delegate handler methods were implemented to provide a response when a specific condition is met. Therefore, the subscribing logic must provide a result when a specific condition is met. Before the subscribing logic responds, it should not evaluate whether the result object parameter already contains a result. For example, a delegate handler method should not contain logic that resembles the logic in the following example. This logic evaluates whether the **EventHandlerResult** object parameter already contains a result when the method is run.

  > **WARNING**
  > This example is an example of code that you should **not** write.

```
[SubscribesTo(tableStr(InventWarehouseEntity), delegateStr(InventWarehouseEntity,
validateWarehouseTypeDelegate))]
  public static void validateWarehouseTypeIsSupportedStandardDelegateHandler(InventLocationType
_inventLocationType, EventHandlerResult _result)
  {
      // this if statement is an example of the bad practice.
      if (_result.hasResult())
      {
           return;
      }
      switch (_inventLocationType)
      {
          case InventLocationType::Standard:
          case InventLocationType::Quarantine:
          case InventLocationType::Transit:
               _result.result(true);
              break;
      }
  }
```

- Don't provide a response on behalf of other subscribers. If the delegate handler method isn't responsible for providing a response, the method must not provide a response. If the method provides a response when the condition isn't met, it provides a response on behalf of other subscribers. The requesting logic must be responsible for handling situations where no subscribers have responded. The delegate handler method must not contain logic that resembles the logic in the following example. This logic which provides a result when the condition is evaluated to **false**.

  WARNING

  This example is an example of code that you should **not** write.

```
  [SubscribesTo(tableStr(InventWarehouseEntity), delegateStr(InventWarehouseEntity,
validateWarehouseTypeDelegate))]
  public static void validateWarehouseTypeIsSupportedStandardDelegateHandler(InventLocationType
_inventLocationType, EventHandlerResult _result)
  {
      switch (_inventLocationType)
      {
          case InventLocationType::Standard:
          case InventLocationType::Quarantine:
          case InventLocationType::Transit:
              _result.result(true);
              break;
       // this default block is an example of the bad practice
          default:
              _result.result(false);
              break;
      }
  }
```

Extend the RunBase class

2/18/2021 • 2 minutes to read • Edit Online

When you extend functionality of the application suite, you will encounter classes that extend the **RunBase** class. This topic shows how a **RunBase** class can be augmented end to end.

For example, you want to extend the SysUserLogCleanup class. Out of the box, this class can delete records from the SysUserLog table. However, you want to archive these records to a different table before they are deleted.

The SysUserLogCleanup class is a **RunBase** class. The **RunBase** class has a dialog box, where the user is prompted for parameters before the class is run. For this example, we will add a toggle button control to the dialog box, get the value of the control, act on the value in the run method, and make sure that the value is serialized via the pack and unpack methods. Serialization helps guarantee that the user's last selection is presented again if the dialog box is reopened. It also helps guarantee that the settings are applied if the class is run in the background.

To avoid collisions with other eventual extensions, we followed these best practices:

- **Prefix members and methods**. In the example, the prefix "my" is used. This practice is important, because it helps prevent name clashes with other extensions and future versions of the augmented class.
- **Use RunBase.packExtension() and RunBase.unpackExtension()**. These methods provide serialization in a nonintrusive manner. They enable serialization of multiple extensions of the same class. The methods are available starting in Platform Update 5.

The following example shows how to implement this scenario.

```
[ExtensionOf(classStr(SysUserLogCleanup))]
final class MySysUserLogCleanup_Extension
{
    // static members
    static private SysUserLogCleanup myRunningInstance;

    // Extending class state...
    private boolean myArchive;
    private DialogField myDialogArchive;
    #define.CurrentVersion(1)
    #localmacro.CurrentList
        myArchive
    #endmacro

    public Object dialog()
    {
        Dialog dialog = next dialog();

        myDialogArchive = dialog.addField(extendedtypestr(NoYesId), "Archive");
        myDialogArchive.value(myArchive);

        return dialog;
    }

    public boolean getFromDialog()
    {
        boolean result = next getFromDialog();
        myArchive = myDialogArchive.value();
        return result;
    }

    public void initParmDefault()
```

```
    public void initParmDefault()
    {
        next initParmDefault();
        myArchive = true;
    }

    public void run()
    {
        try
        {
            myRunningInstance = this;
            next run();
        }
        finally
        {
            myRunningInstance = null;
        }
    }

    public container pack()
    {
        container packedClass = next pack();
        return SysPackExtensions::appendExtension(packedClass, classStr(MySysUserLogCleanup_Extension),
this.myPack());
    }

    private boolean myUnpack(container packedClass)
    {
        Integer version = RunBase::getVersion(packedClass);
        switch (version)
        {
            case #CurrentVersion:
                [version, #currentList] = packedClass;
                break;
            default:
                return false;
        }
        return true;
    }

    private container myPack()
    {
        return [#CurrentVersion, #CurrentList];
    }

    public boolean unpack(container _packedClass)
    {
        boolean result = next unpack(_packedClass);

        if (result)
        {
            container myState = SysPackExtensions::findExtension(_packedClass,
classStr(MySysUserLogCleanup_Extension));
            //Also unpack the extension
            if (!this.myUnpack(myState))
            {
                result = false;
            }
        }

        return result;
    }

    private void myArchiveUserLog(SysUserLog _userLog)
    {
        if (myArchive)
        {
            //...
        }
    }
```

```
    }

    // Wire up event handler for deletion of the record
    [DataEventHandler(tableStr(SysUserLog), DataEventType::Deleting)]
    static public void SysUserLog_onDeleting(Common _sender, DataEventArgs _e)
    {
        if (myRunningInstance)
        {
            myRunningInstance.myArchiveUserLog(_sender as SysUserLog);
        }
    }
}
```

Customize application startup by using delegates

2/18/2021 • 2 minutes to read • Edit Online

In Dynamics AX 2012, there were customization points that allowed you to subscribe to events (Application.Startup delegates) that were raised when the client was initializing. These events were deprecated because there is no concept of a rich client. On the server, only server sessions are considered, however because you can migrate logic from previous releases, new events have been added to the **ApplicationStartupEventManager** class.

The following sections highlight the new data sources that you can add to existing forms by using extensions.

static delegate void onSystemStartup()

- This event occurs when the system starts up.
- It is raised once per AOS upon startup.

static delegate void onFirstTimeUserInteractiveSessionCreated()

- This event occurs when the system is creating an interactive session for the first time for a user.
- It is raised once per user per AOS.

static delegate void onFirstTimeUserNonInteractiveSessionCreated()

- This event occurs when the system is creating a non-interactive session for the first time for a user.
- It is raised once per user per AOS.

static delegate void onInteractiveSessionCreated()

- This event occurs when an interactive session is created and ready for use.
- It is raised once per interactive session creation for any user.

static delegate void onSessionCreated(boolean _isBatch, boolean _isInteractive)

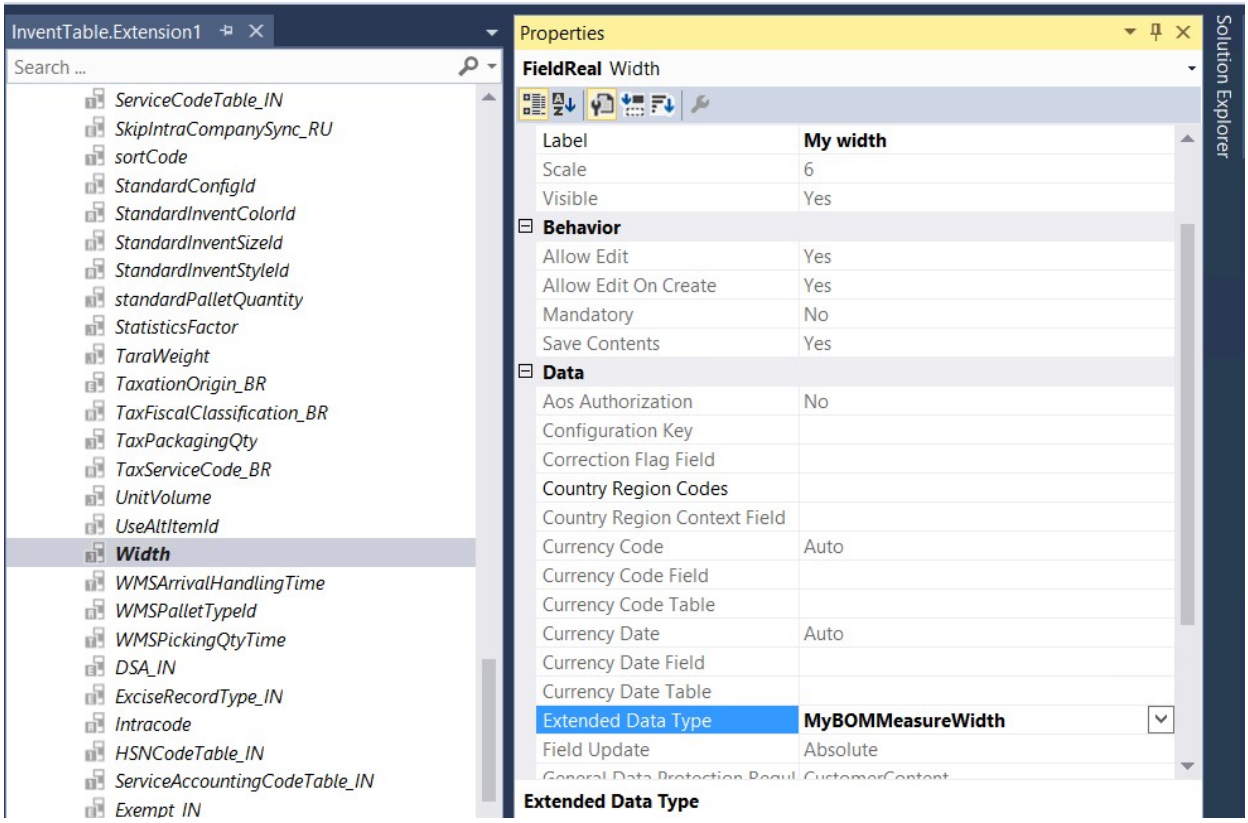
- This event occurs when the session is created and ready for use.
- It is raised once per interactive session creation for any user.
- *_isBatch* specifies whether the system is running a batch job.
- *_isInteractive* specifies whether the session is interactive.

Modify existing fields in a table through extension

2/18/2021 • 2 minutes to read • Edit Online

To modify properties on an existing field in a table, you must first create an extension for the table. You can modify the following properties:

- **Label**
- **Help text**
- **Country Region Codes**
- **Extended Data Type** – You can select only extended data types (EDTs) that are derived from the currently selected EDT. The lookup in the property sheet is filtered so that only those EDTs are shown. For example, to edit the EDT on the **Width** field in the InventTable table, you can create a derived EDT that is based on **BOMMeasureWidth**, and then modify the **Extended Data Type** property on the **Width** field in the **InventTable** extension. In this way, you can modify the look and feel of the **Width** field in the user interface when the new package is deployed.



NOTE

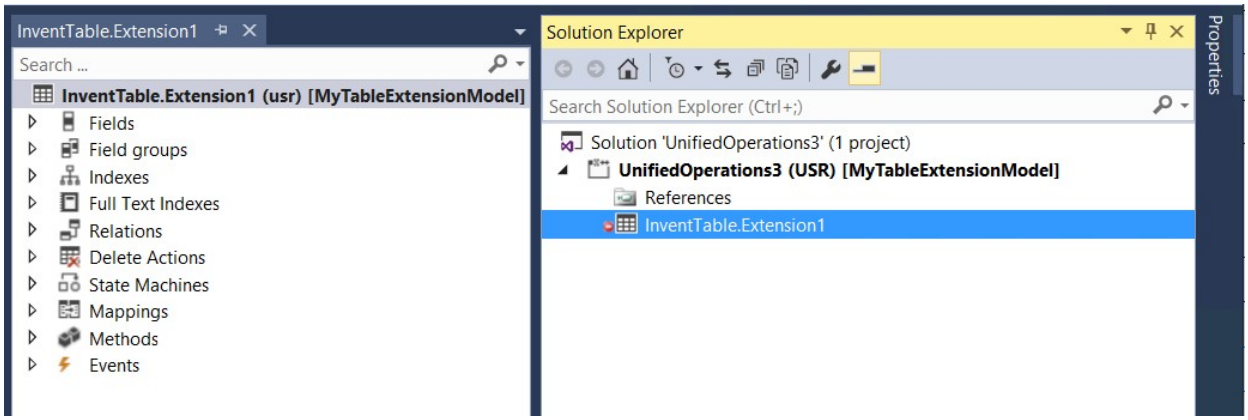
Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Add fields to tables through extension

2/18/2021 • 2 minutes to read • Edit Online

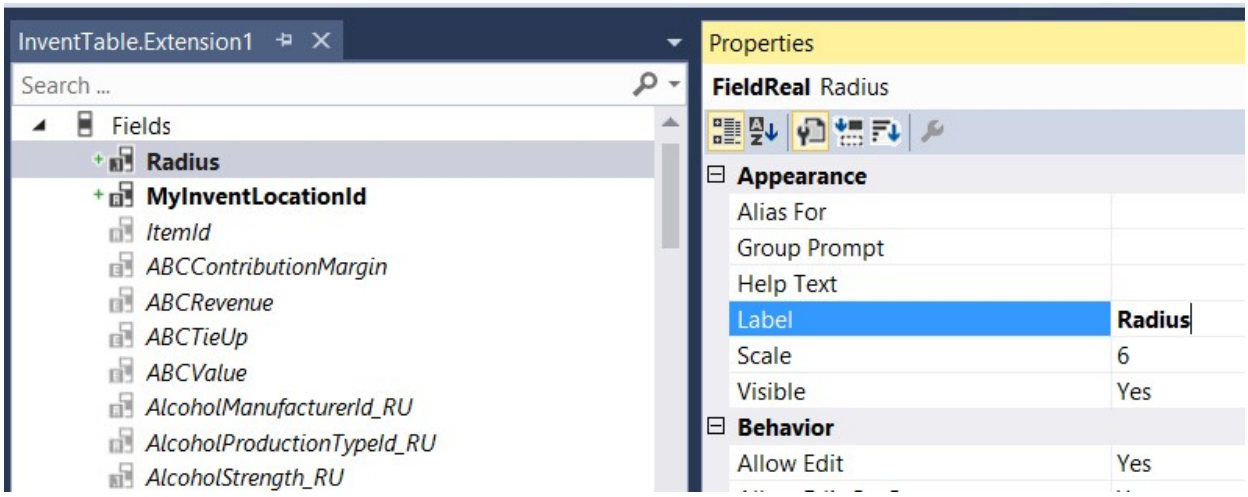
To add a new field to an existing table, you must first create a table extension. For example, to add a field that holds the radius of the released product, you must create an extension for the InventTable table in your model, as shown in the following illustration.



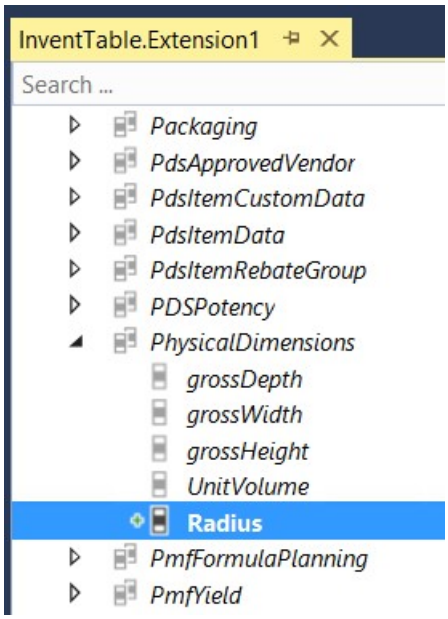
You can now add the field to the extension, just as you would add a field to a table in your model. You can use two methods:

- In the designer, right-click the **Fields** node, select **New**, and then select the type of field to add.
- Drag an existing Extended Data Type or Base Enumeration from your project onto the **Fields** node.

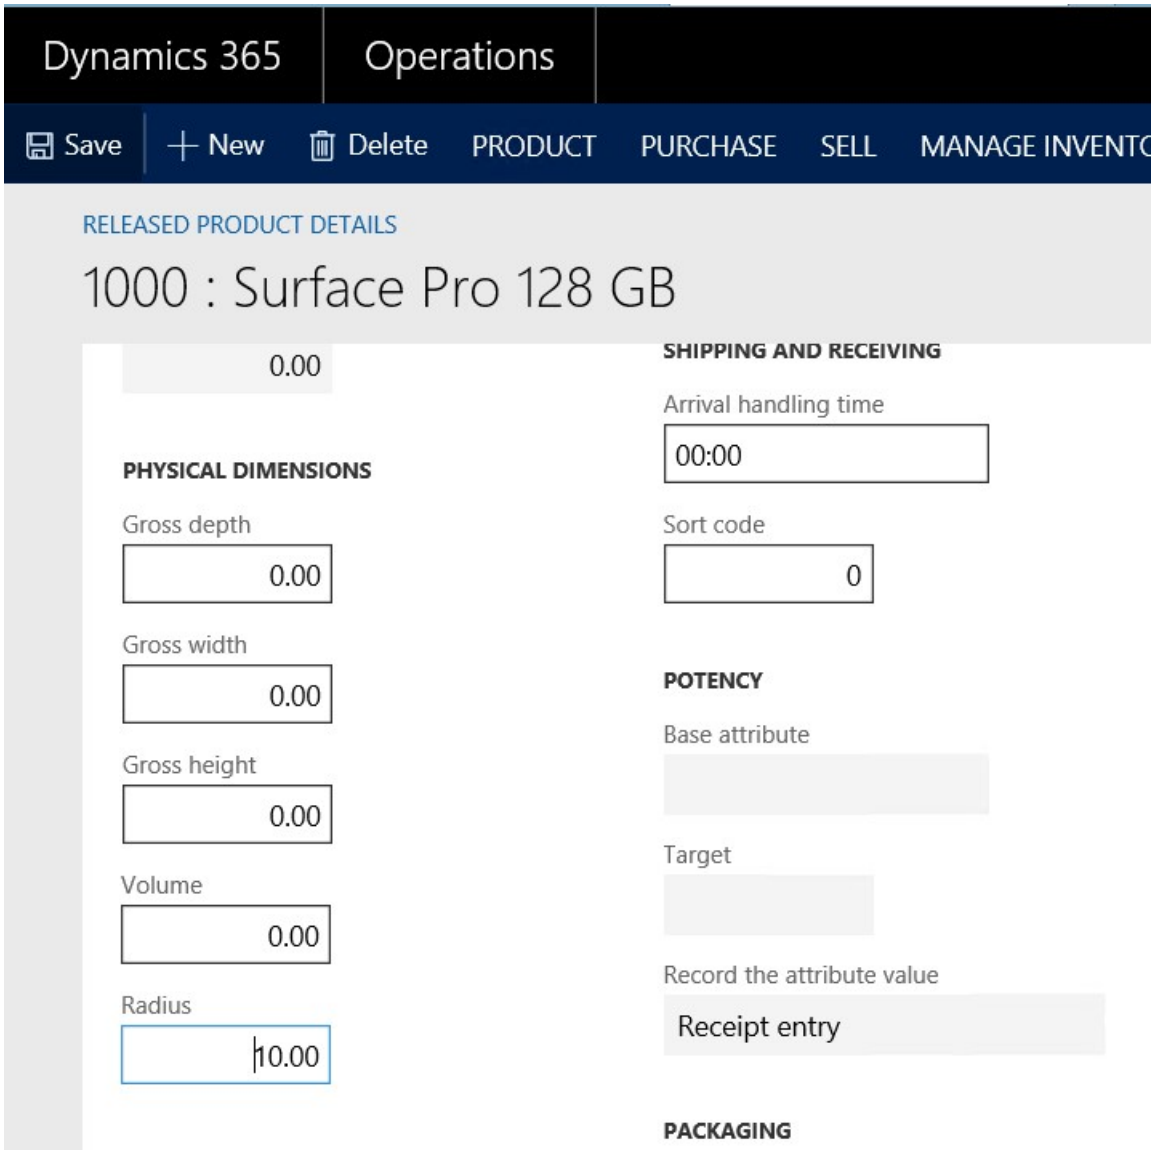
When you've finished, you can modify the properties of the new field. In the following illustration, only the **Label** property was modified.



You can now optionally add the new field either to one of the existing field groups or to a new field group that you create. In the following illustration, the **Radius** field was added to the **PhysicalDimensions** field group.



After compilation and synchronization of the database, you can see and edit the new field in the user interface.



NOTE

Can you tell us about your documentation language preferences? Take a short survey.

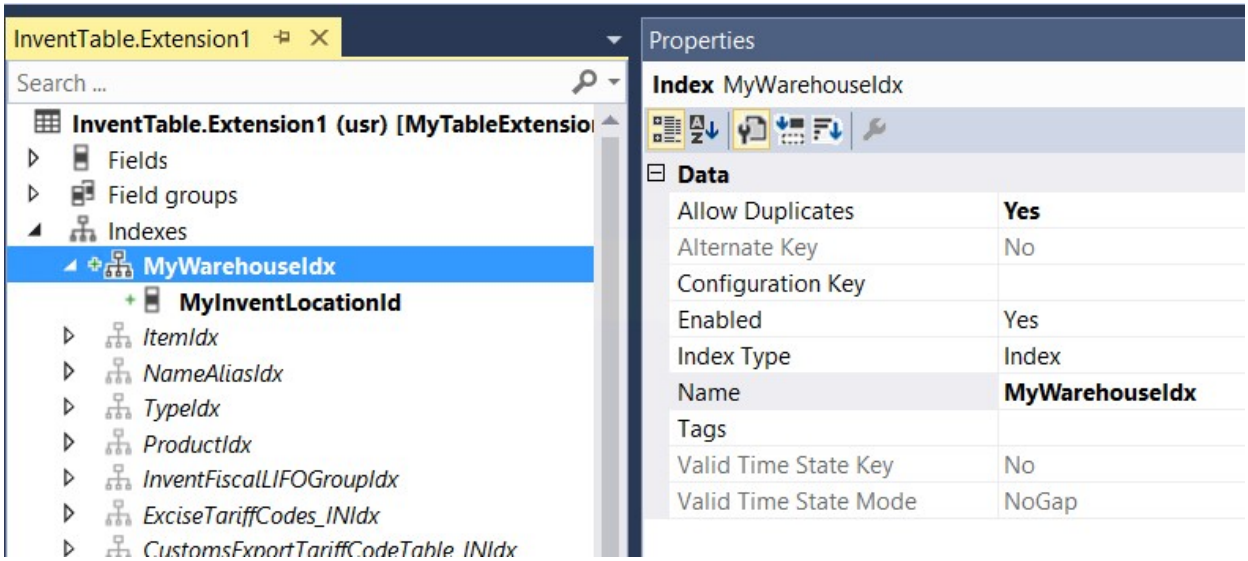
The survey will take about seven minutes. No personal data is collected (privacy statement).

Add indexes to tables through extension

2/18/2021 • 2 minutes to read • Edit Online

Often, you extend tables so that you can store additional data for later but also quickly access the data that is based on the new fields. Therefore, it's often beneficial to have a dedicated index that speeds up the database search. You can add a new index to an existing table through extension. To add an index to an existing table, you extend the selected table and then create an index just as you would create an index on a new table. You can add both new and existing fields so that they are part of the new index.

In the following illustration, an InventTable extension is used to define an index for a new field on the InventTable table.



WARNING

You should not use this approach to create unique indexes. This change is an intrusive change that might break the solutions of other independent software vendors (ISVs) if those solutions are deployed in the same environment. This capability will be removed in future platform releases.

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Add relations to tables through extension

2/18/2021 • 2 minutes to read • Edit Online

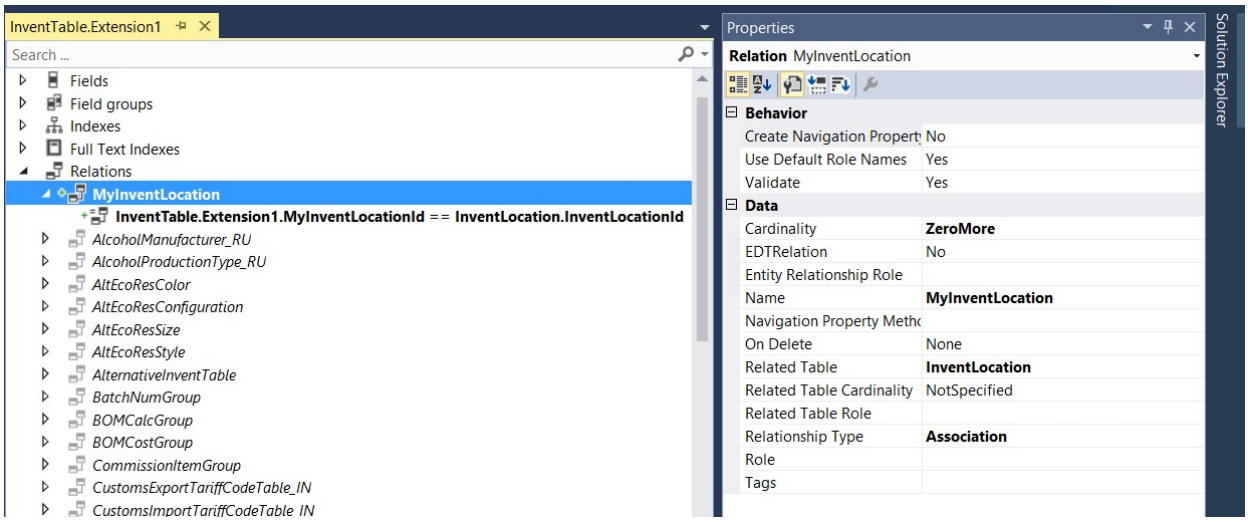
To enable rich and secure interactions with data in multiple tables, you must help guarantee referential integrity by defining relations that describe the link between two tables. By defining relations, you enable validation of the data that is entered and lookup capabilities for the related information.

You can add a new relation by extending a table.

In the following example, a new field, **MyInventLocationId**, is added to the InventTable table. This field is a reference to the InventLocation table that contains warehouses.

1. In the new extension model, create an extension of the InventTable table.
2. Create a new relation, just as you would create a relation on a regular table.
3. Specify the **Related Table**, **Relationship Type**, and **Cardinality** properties, and any other properties that apply to the relation.
4. Add the link by specifying the fields from the InventTable table and the InventLocation table that have the same value. In this case, the fields are **MyInventLocationId** in the InventTable table and **InventLocationId** in the InventLocation table.

The following illustration shows the new relation.



Troubleshooting

Navigation property methods not working

Issue - Navigation property methods do not work when a foreign key relation is created using a table extension. The compiler will not allow a call to a navigation method on the extended table.

Solution - Navigation methods are not supported at this time.

> **NOTE**
>
> Can you tell us about your documentation language preferences? Take a short survey.
>

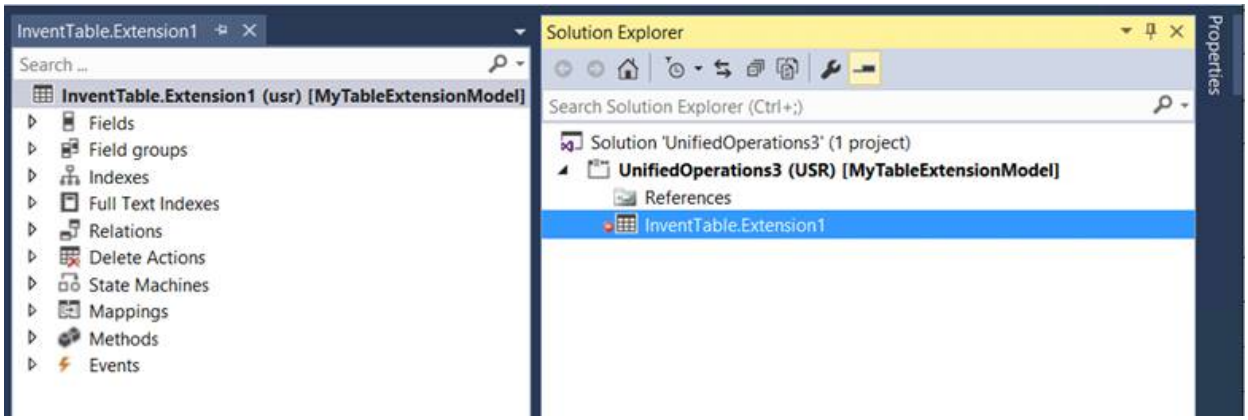
Modify table properties through extension

2/18/2021 • 2 minutes to read • Edit Online

To modify properties on a table, you must create an extension of that table. In Application Explorer, right-click the table, and then select **Create extension**. A new table extension is created in the selected project, as shown in the following illustration.



You can now modify the following properties through the property sheet:

- Created By
- Created Date Time
- Modified By
- Modified Date Time
- Country Region Codes

By setting the **Created By**, **Created Date Time**, **Modified By**, or **Modified Date Time** property to **Yes**, you help guarantee that a corresponding field is added to the table. Corresponding tracking information about the user is then stored in the table when records are created or updated. You can't set these properties to **No** if they are set to **Yes** on the base table.

By adding country or region codes to the list, you help guarantee that the corresponding table is also applicable when the system runs in the context of the specified country or region.

> **NOTE**
>
> Can you tell us about your documentation language preferences? Take a short survey.
>
> The survey will take about seven minutes. No personal data is collected (privacy statement).

Add methods to tables through extension

2/18/2021 • 2 minutes to read • Edit Online

When you extend the business logic that is related to a table, the general coding principles that help keep your code clean still apply. Therefore, you must eventually encapsulate actions in separate methods on the table. In Microsoft Dynamics AX 2012, you completed that task by adding the method directly on the table through overlayering. To complete the same task through extension, you use a different approach. Specifically, you create an augmentation class.

For example, a new field that is named **MyInventLocationId** was added to the InventTable table through extension. A data event handler was also created for the **Inserting** event, and you must implement the logic of filling the new field there. To encapsulate that action, you will create a new method on InventTable and name that method **myDefaultInventLocationId**.

You first create a new class in the extension model. This class will augment the InventTable table, and enable access to the table's fields and methods in a manner that is easy to read and understand. It's important that you choose the correct name for your augmentation class. This name must be unique across all types in all models that are deployed. For more information, see Naming guidelines for extensions.

```
[ExtensionOf(tableStr(InventTable))]
final class InventTableMy_Extension
{
    public void myDefaultInventLocationId()
    {
        // This would have partner specific logic to initialize the new field.
        this.MyInventLocationId = this.inventLocationId();
    }
}
```

You can now add new methods to the augmentation class. These methods will then appear in IntelliSense for variables of the **InventTable** type, just as if they were defined directly on the table. This behavior applies to both static methods and instance methods.

There are a few rules for augmentation classes:

- They must be final.
- They must be suffixed by **_Extension**.
- They must be decorated with the **[ExtensionOf()]** attribute.

Now you can use your new method, for example, from an event handler:

```
class InventTableMy_EventHandler
{
    [DataEventHandler(tableStr(InventTable), DataEventType::Inserting)]
    public static void InventTable_onInserting(Common sender, DataEventArgs e)
    {
        InventTable inventTable = sender as InventTable;
        // Call the method as if it was defined directly on InventTable.
        inventTable.myDefaultInventLocationId();
    }
}
```

NOTE

It is common for event handler classes to contain handlers for any number of events. However, it is **not** good practice to put event handlers in augmentation classes. Doing so makes the event handler methods available as methods on the augmented type. This is incorrect because the event handler is intended to be called through the event, not explicitly as a method on the type.

Perform business actions throughout the lifecycle of table records

2/18/2021 • 2 minutes to read • Edit Online

As part of your business workflows, records are regularly inserted, updated, and deleted. To customize the system behavior, you can hook into some of the record operations that are most often used. For example, you can fill additional fields on the record, perform additional data validation, or insert additional data into related tables. Several events that are available on the table let you achieve those customizations through extensions. Your code can subscribe to these events, and can insert your logic before or after the event is run.

For a list of the events that you can subscribe to, see the "Table extensions" section in Customize through extension and overlayering.

The survey will take about seven minutes. No personal data is collected (privacy statement).

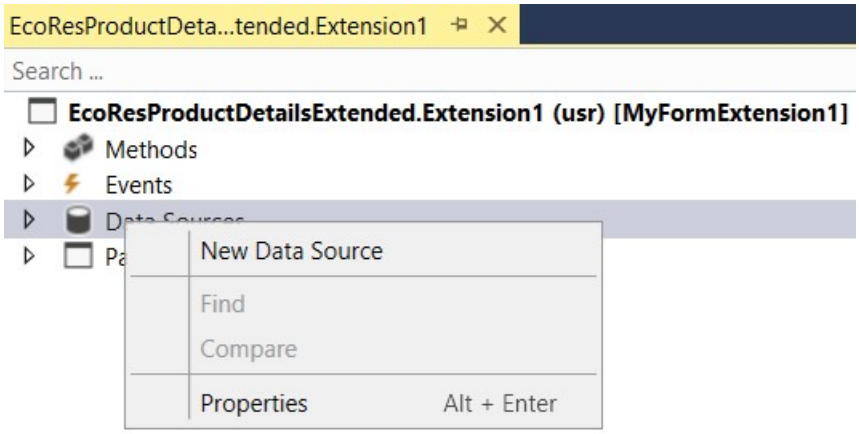
Add data sources to forms through extension

2/18/2021 • 2 minutes to read • Edit Online

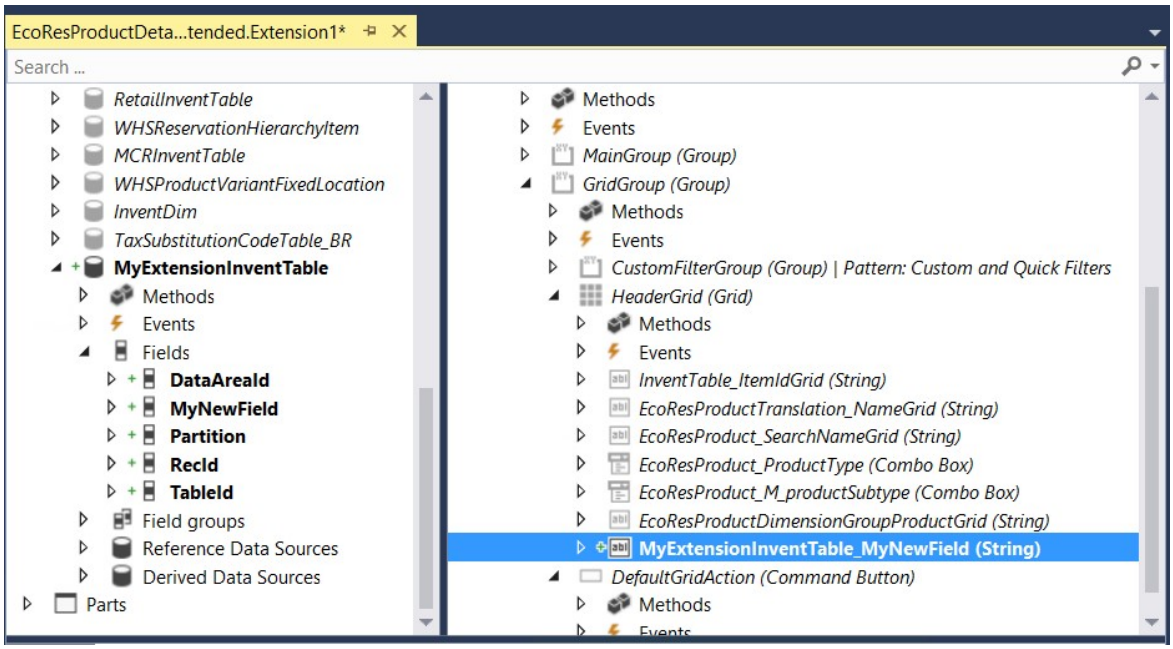
Often, the information that is stored in existing tables doesn't satisfy customer requirements. Therefore, additional tables must be created, and data from those tables must be shown on pages.

You can add new data sources to existing forms through extension. Follow these steps.

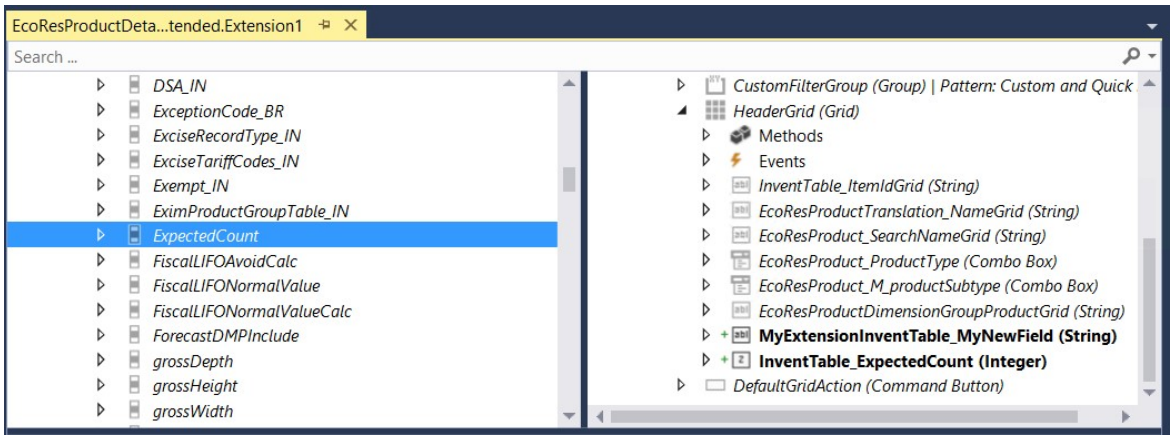
1. In the extension model, create a form extension for the selected form.
2. Right-click the form extension, and then select **New Data Source**.



3. Specify the **Table** property and other required properties on the data source. For example, define how the data source should be linked with the other data sources for the form.
4. Drag fields from the new data source into the form design, as shown in the following illustration.



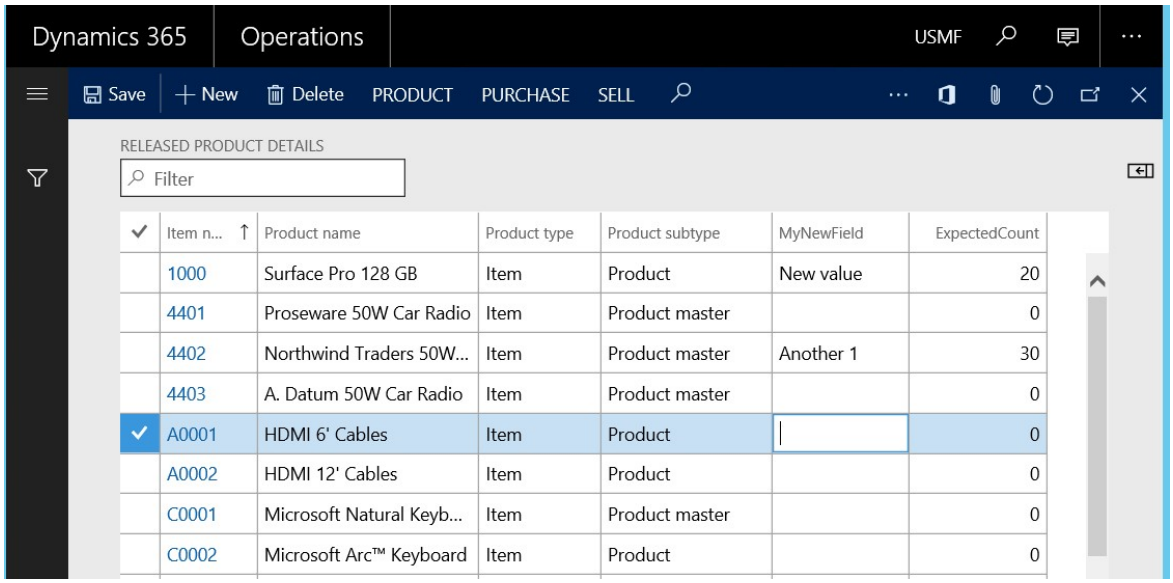
5. In a similar manner, you can add fields from existing data sources. For example, the table behind the form might have been extended with additional fields, as shown in the following illustration.



TIP

You might have to right-click the form extension data source and then select **Restore** to make the new fields appear in the list.

6. You can now view and edit the data in these new fields and tables, as shown in the following illustration.



Item n...	Product name	Product type	Product subtype	MyNewField	ExpectedCount
1000	Surface Pro 128 GB	Item	Product	New value	20
4401	Proseware 50W Car Radio	Item	Product master		0
4402	Northwind Traders 50W...	Item	Product master	Another 1	30
4403	A. Datum 50W Car Radio	Item	Product master		0
A0001	HDMI 6' Cables	Item	Product		0
A0002	HDMI 12' Cables	Item	Product		0
C0001	Microsoft Natural Keyb...	Item	Product master		0
C0002	Microsoft Arc™ Keyboard	Item	Product		0

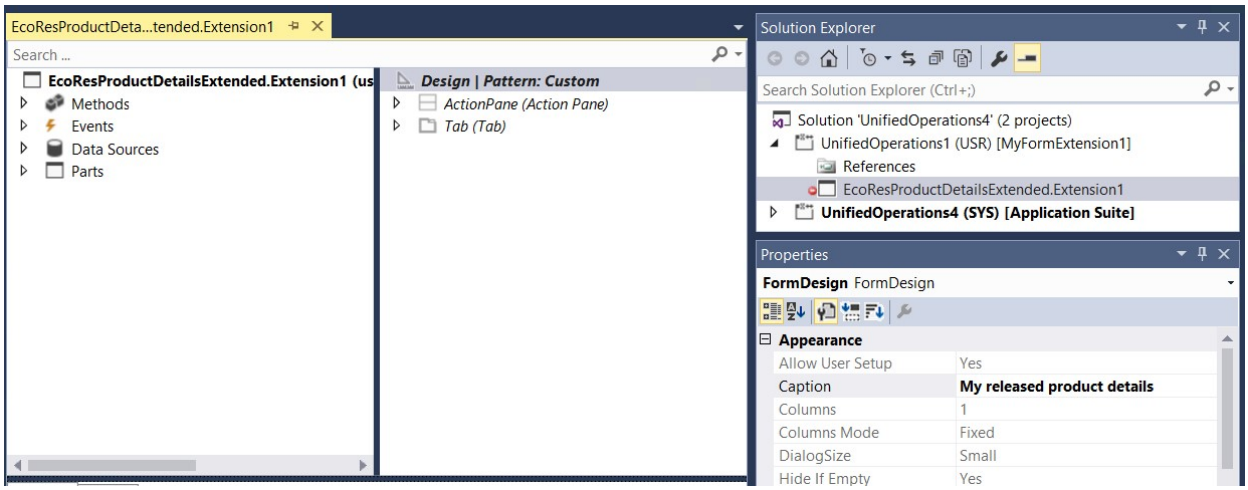
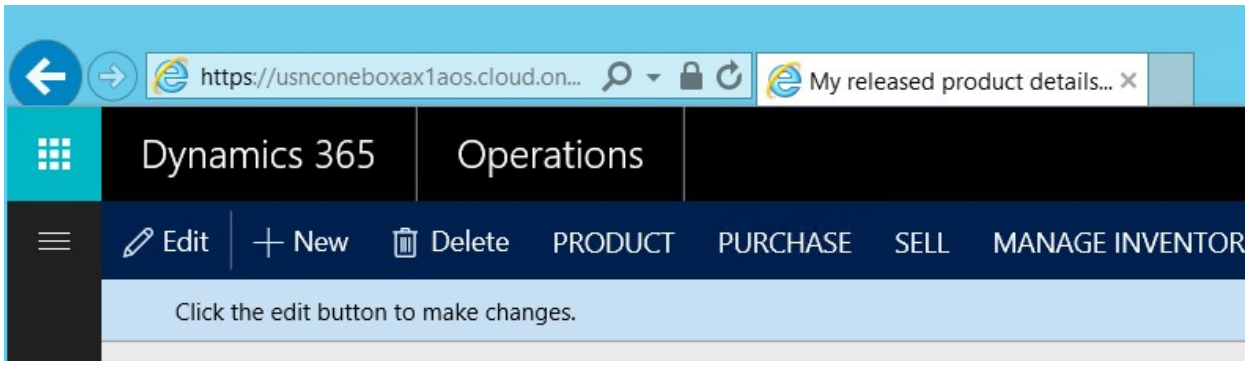
Change the captions of forms through extension

2/18/2021 • 2 minutes to read • Edit Online

The form caption appears in the page tab next to the web browser's Address bar and helps the user identify the page that is currently open. In metadata, the form caption is represented by a property on the form design. Therefore, to change the caption, you must modify the **Caption** property on the form design. You can make this change through extension. Create an extension of the selected form in the extension model, and then change the **Caption** property as usual.



The following illustration shows what the form caption looks like in a browser.



NOTE

None of the other properties on the form design can be changed.

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Modify the properties of form controls through extension

2/18/2021 • 2 minutes to read • Edit Online

Often, the way that users interact with the application requires modification. Typically, you hide or disable controls on the page, replace standard labels with labels that are more appropriate, or even add new controls that the user requires. You can also create a form extension.

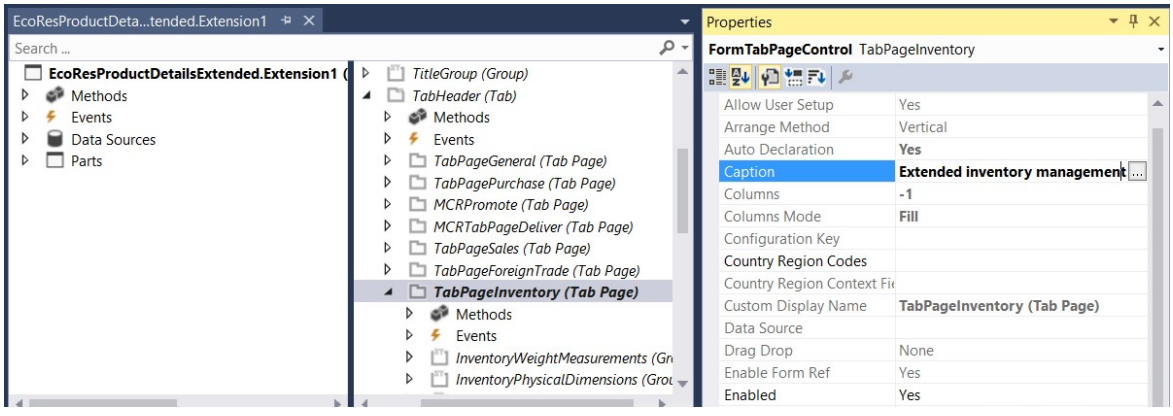
> **TIP**
>
> You can achieve even more flexibility through event subscription on form control events. This approach is discussed in other topics. In this topic, the focus is on metadata changes.

Example

The customer requires changes to the **Manage inventory** FastTab on the **Released product details** page. You must change the label of the FastTab, disable the field group that shows the catch weight configuration, and add new controls. (For this example, the new controls aren't bound to existing fields in the data source).

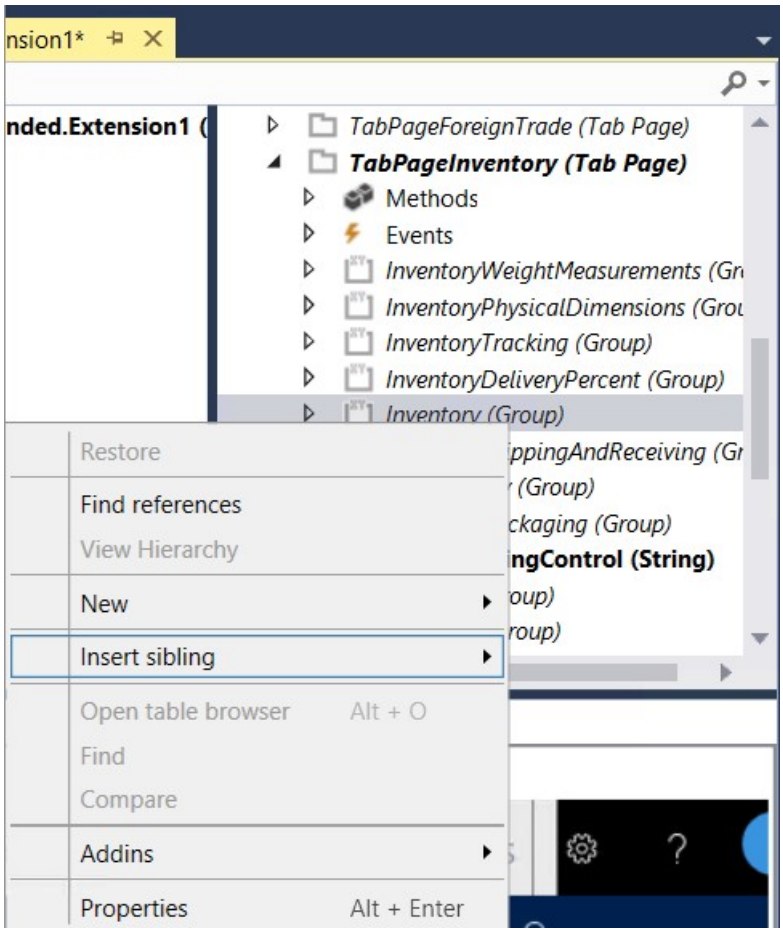
Follow these steps to make the required changes.

1. In the extension model, create an extension of the **EcoResProductDetailsExtended** form.
2. Navigate through the form design tree to the **TabPageInventory** tab page (**Design** > **Tab** > **Details** > **GroupDetails** > **TabHeader** > **TabPageInventory**), select it in the designer, and open the **Property** sheet.
3. Update the **Caption** property to the desired value.



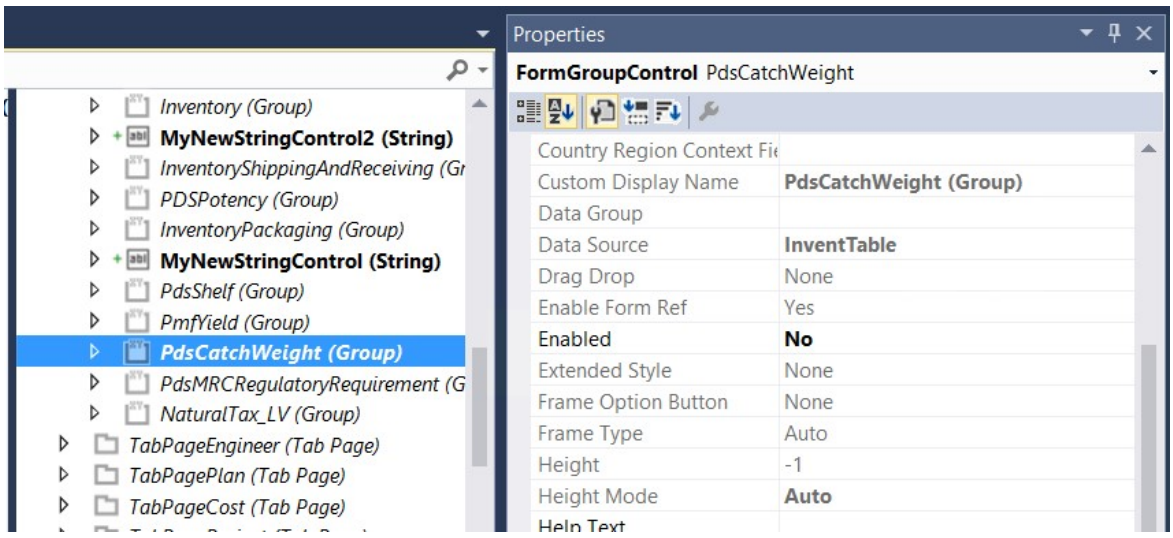
4. Right-click the tab page, and then select **New**. Set the required properties on the new control. You can also move the control up and down in the immediate container to position it correctly.

> **NOTE**
>
> Alternatively, right-click the subnode that the new control should appear after, select **Insert sibling**, and then select the type of control to add.



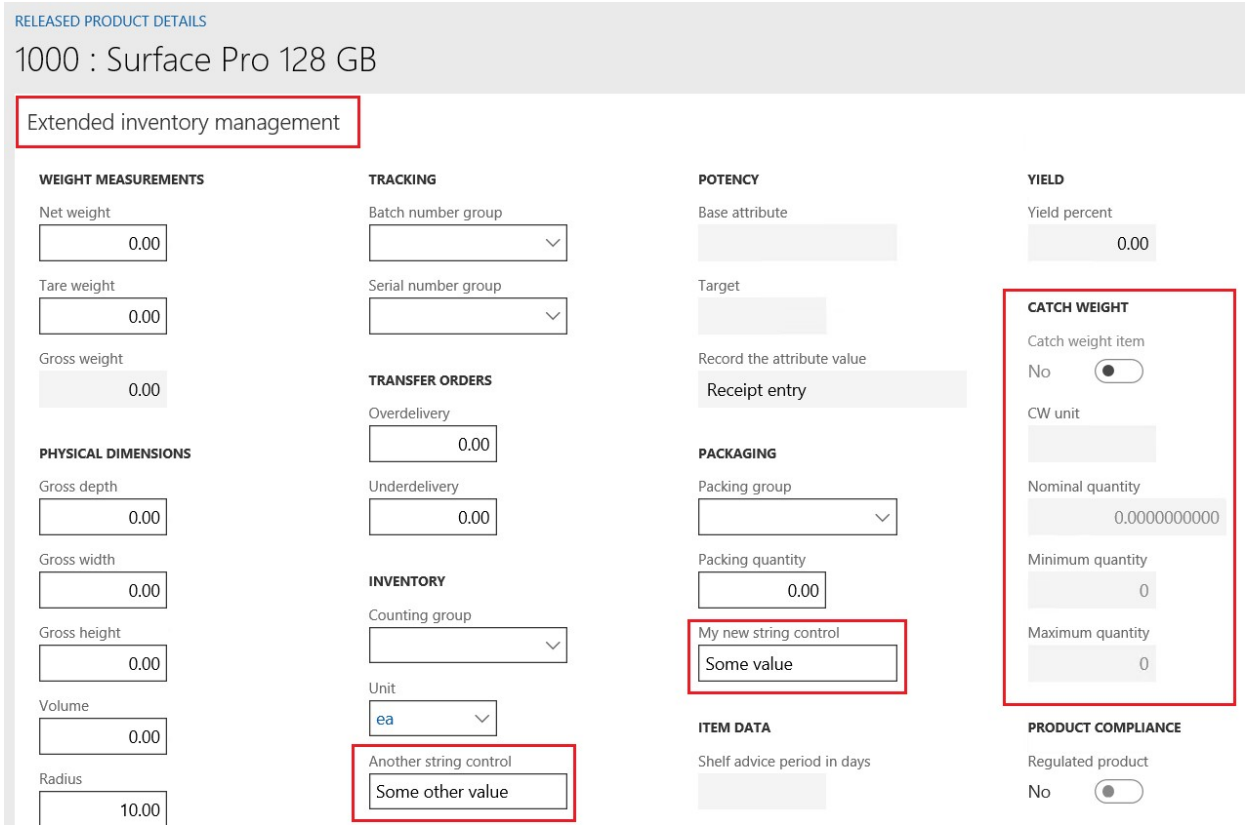
Of course, you can just drag bound controls over from the corresponding data source.

5. Select the **PdsCatchWeight** group control, and change the **Enabled** property to **No**.



> **NOTE**
>
> If you change metadata properties such as **Enabled** and **Visible**, there is no guarantee that the control will stay in that state at runtime. After a form is loaded, business logic on that form can change the state of controls through code.

When you've finished, the page includes additional fields, catch weight information can't be edited, and the whole FastTab has a different caption.



NOTE

You can't modify the **AutoDeclaration** property on controls. However, you can still access the controls by name from code.

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Extend the scope of number sequences

2/18/2021 • 2 minutes to read • Edit Online

This topic shows you how to extend the number sequence scope.

The scope of a number sequence defines which organization uses the number sequence. The scope can be **Shared**, **Company**, **Legal entity**, or **Operating unit**. **Company** and **Legal entity** scopes can be combined with fiscal calendar periods to create even more specific number sequences. New number sequence scopes can be added through extensions.

To create a new scope and have it show up in the client, complete the following steps:

1. Create an enum extension for **NumberSeqParameterType**. In the extension, add a new enum value for the new scope type.
2. Create an enum extension for **NumberSequenceType**. Add a new enum value for the new scope type. The **NumberSequenceType** enum is used in **NumberSequenceTableEntity** and **NumberSequencesReferenceEntity**.
3. Create a table extension for the **NumberSequenceScope** table. Add a new field for the new scope type.
4. Create an extension class for **NumberSeqScope** class.
    a. Create a post handler for the **NumberSeqScope::getValidScopeTypes** method. In the event handler method, add the new scope type to the valid scope types list.
    b. Create an event handler for the **onGetFormatSegmentShortName** delegate. In the event handler, return the short name for the new scope type.
    c. Create a post handler for the **NumberSeqScope::find** method and add logic for the new scope type so the corresponding **NumberSeqScope** instance can be found.
    d. Create a post handler for the **NumberSeqScope::getId** method and add logic for the new scope type, so the corresponding record can be found (or created if it does not exist) in the **NumberSequenceScope** table.
5. Create an extension class for the **NumberSequenceScopeFactory** class. Add a method that initializes the new **NumberSeqScope** that represents the new scope type.
6. Create a form extension for the **NumberSequenceDetails** form. Add controls that show the new scope type to the **Scope** tab.
7. Create an extension class for the **NumberSequenceDetails** form.
    a. Create a post handler for the **updateScopeControlVisibility** method to show the new scope type when the new scope type is selected in the **Scope** box.
    b. Create a post handler for the **updateScopeControlValues** method to update the values of the controls in the **Scope** tab.
    c. Create a post handler for the **createScope** method to initialize a **NumberSeqScope** instance when the new scope type is selected.
    d. Create an event handler for the **getShortNameForParameterType** delegate to return the short name for the new scope type.
8. Add an extension class for the **NumberSequenceTableEntity** and **NumberSequencesReferenceEntity** data entities. Create post handlers for the **GenerateNumberSequenceScopeTypes** and **GenerateNumberSequenceScopeValues** methods to generate the **NumberSequenceScope** for the new scope type.

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Add new inventory dimensions through extension

2/18/2021 • 4 minutes to read • Edit Online

This topic provides a high-level overview of how to add new inventory dimensions through extensions. It also includes information about how to access a sample application that contains an actual implementation.

Solution overview

The cornerstone in this solution is that multiple roles participate in the life cycle of adding new inventory dimensions through extensions. The following description simplifies and generalizes this solution, however, in real life there is overlap between the roles, and sometimes it might even be the same person filling several roles.

Microsoft's role

Microsoft provides a finite set of unused dimension fields.

In addition to the 15 existing dimensions, Microsoft supports 10 generic dimensions:

- 8 string-based
- 1 real-based
- 1 utcdatetime-based

This brings the total number of inventory dimensions in the standard application to 25:

- 5 product dimensions: Color, Size, Style, Config, and Version
- 5 tracking dimensions: Serial, Batch, Owner, Profile (Russia only), and GTD (Russia only)
- 6 storage dimensions: Site, Warehouse, Location, Status, License Plate, and Pallet (for upgrade and migration only)
- 12 unassigned generic dimensions: InventDimension1 to InventDimension12

Microsoft provides the physical schema.

ISV role

The ISV adds new inventory dimensions. The ISV solution provides all the specific functionality for the dimension - it must be strong-typed, maintainable, testable, and performant. In addition, the solution must be agnostic to other ISV's solutions. The ISV builds a solution that doesn't reference the physical schema directly, but goes through an indirection, which can be done seamlessly.

The ISV provides the logical implementation.

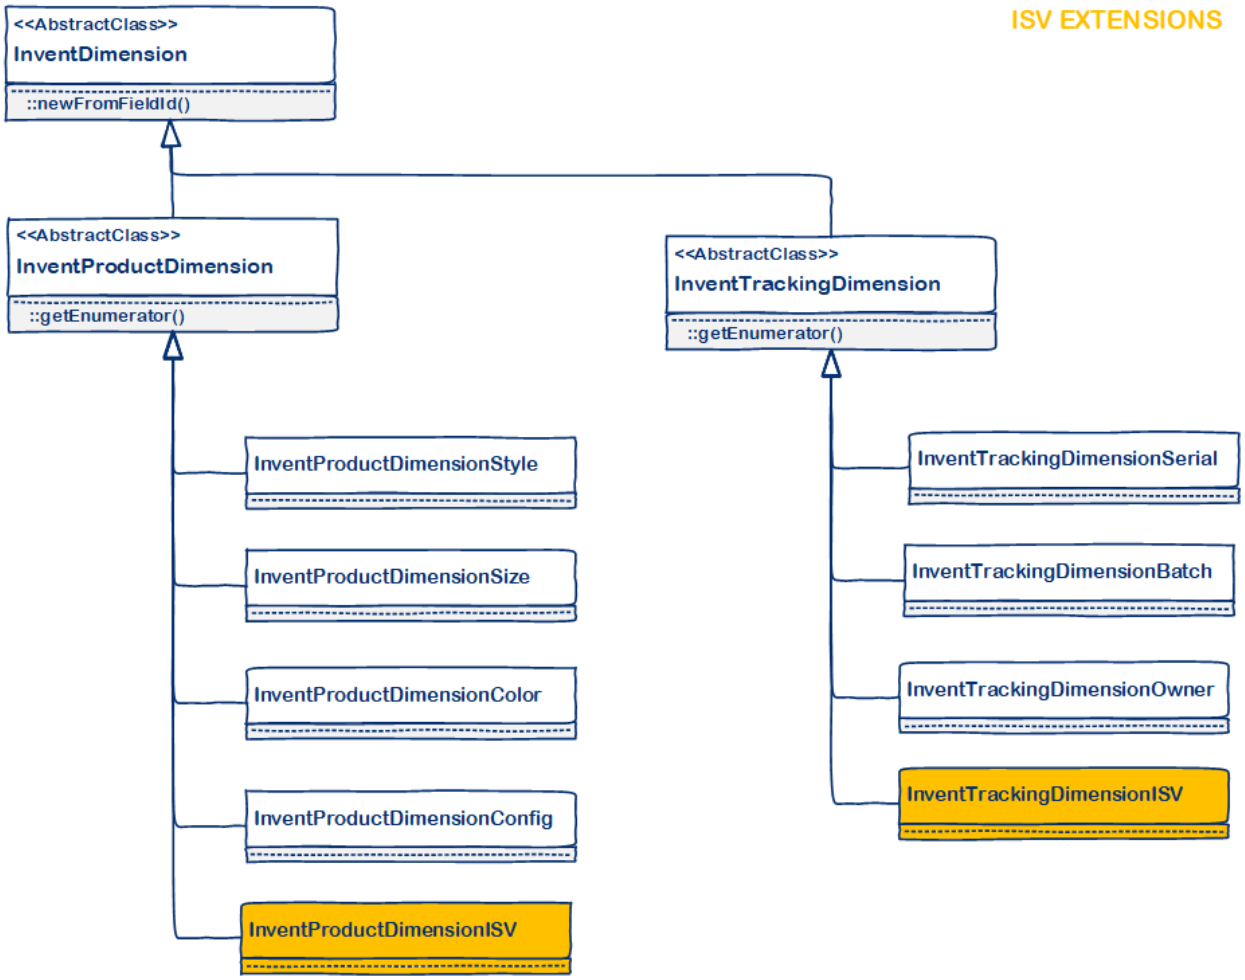
VAR role

The VAR must be able to deliver a fully functional system to a customer. The system can contain solutions from multiple ISV's - each potentially containing new inventory dimensions. In total, up to 10 ISV dimension fields are supported.

The VAR provides the binding between the physical data model and logical implementation.

Details

The first half of the solution is straight forward. A new class hierarchy is introduced. Each new dimension must be implemented in a new class deriving from either InventProductDimension or InventTrackingDimension. Currently, there is no support for storage dimensions. With this, ISVs can introduce new dimensions without having to change any of the logic on the InventDim table.



To reference the new dimension in a strongly-typed fashion, the ISV introduces a table extension class to the InventDim table. The extension classes for Style, Color, and Size can be used as templates.

Example: InventDimStyle_Extension

```
/// <summary>
/// The <c>InventDimStyle_Extension</c> class extends the <c>InventDim</c> table with behavior for the style
dimension.
/// </summary>
[ExtensionOf(tableStr(InventDim))]
final class InventDimStyle_Extension
{
    public EcoResItemStyleName parmInventStyleId(EcoResItemStyleName _style =
this.getValueForDimension(classStr(InventProductDimensionStyle)))
    {
        if (!prmIsDefault(_style))
        {
            this.setValueForDimension(classStr(InventProductDimensionStyle), _style);
        }
        return _style;
    }

    /// <summary>
    /// Returns the field id for the style dimension.
    /// </summary>
    /// <returns>The field id.</returns>
    public static FieldId fieldIdStyle()
    {
        return InventDim::fieldIdForDimension(classStr(InventProductDimensionStyle));
    }
}
```

The dimensions can be referenced like this.

```
//Setting a value
inventDim.parmISVDim("Some value");

//Select statements
select inventDim
    where inventDim.(InventDim::fieldIdISVDim()) == "Some value";
```

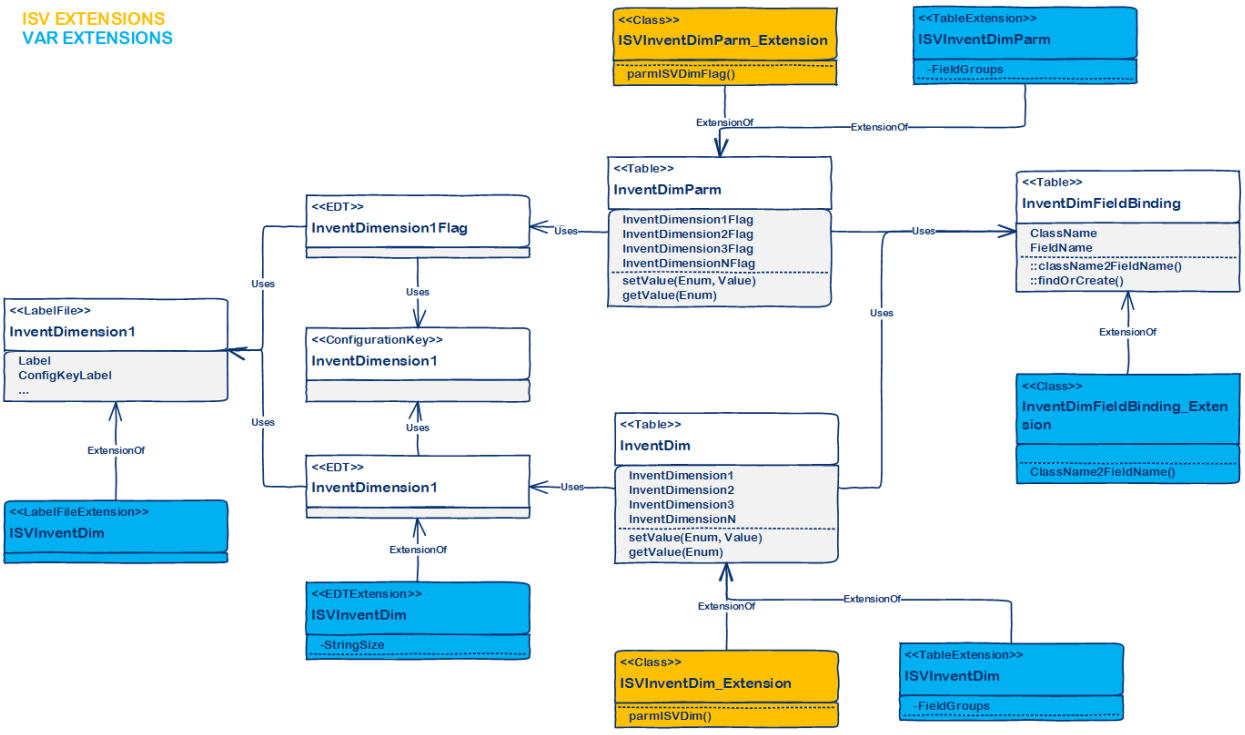
The ISV can now build logic, including the data model and user interface for maintaining the list of dimension values, for the new inventory dimension.

The second half of the solution is the data model. The standard application will contain the following for each new dimension:

- A label file.
- A configuration key.
- Two extended data types (EDTs) (for the field on InventDim and for the flag on InventDimParm).
- One field on InventDim table.
- One field on InventDimParm table.
- One field on InventDimFieldMap map and one field on each of the tables (approximately 30) mapped.

The VAR's job is to wire the ISV solutions to the available dimension fields on InventDim for a given customer. To minimize this work, it currently includes the following:

- Implement the binding mapping. This is accomplished by extending the method InventDimFieldBinding.className2FieldName().
- Enable the configuration key.
- Extend the EDT to specify the right string size.
- Extend the Label file, such as copy the ISV-provided labels into the correct label file.
- Extend the ProductDimensions or TrackingDimensions field groups on InventDim, and a few other tables, depending on the type of dimension.
- Extend relations and index as needed on InventDim.



Known issues

There are some technical limitations influencing the design of the solution. The most significant is the SQL statements throughout the application that contain where-clauses on InventDim. Most of these are implemented using macros, which doesn't change the fact that SQL statements are not extensible. Many of the SQL statements could be rewritten to use query objects to make them extensible, however many delete_from and update_recordset would remain. A viable solution cannot require changes to these SQL statements when adding new dimensions.

Another technical limitation is the amount of inventory dimensions that can be supported. Each adds a small overhead, and the InventDimFixed EDT sets an upper limit at 32. This EDT contains a bit mask for each dimension, and because the EDT is an integer, the limit is 32. The provided solution stays within the limit of 32. If required in the future, InventDimFixed could be changed to be an Int64, a container, or it could be removed.

Sample application

A sample application called "Product flavor dimension sample app" can be found on GitHub.

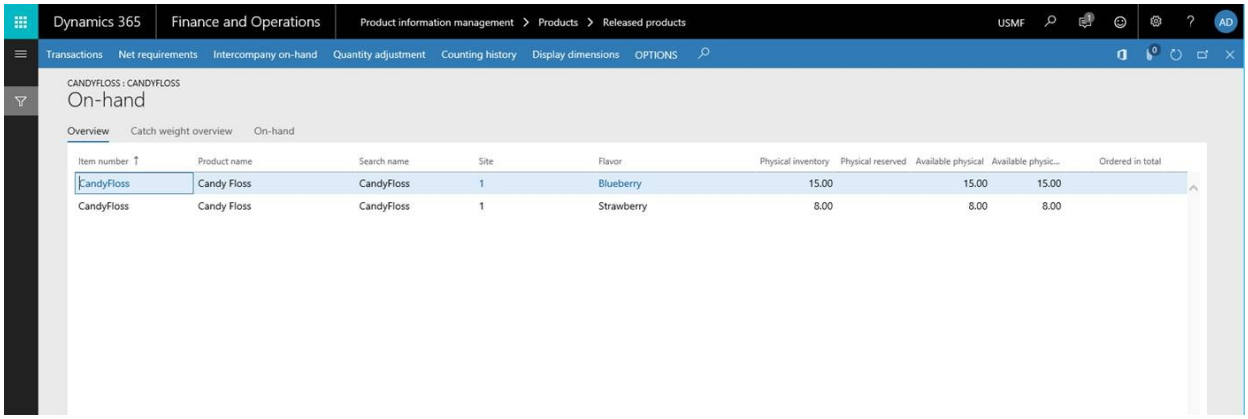
This sample consists of three models:

- ISV production code
- ISV test code
- VAR integration code

Together these models provide a great starting point for implementing new inventory dimensions. The sample application introduces a new product dimension: Flavor.

The application supports many end-to-end business scenarios, for example creating, buying, and selling items with various flavors.

If needed, please log issues directly in GitHub, and feel free to contribute to the sample application to provide additional coverage.



Price and discount extensibility

2/18/2021 • 2 minutes to read • Edit Online

In Microsoft Dynamics 365 for Finance and Operations, Enterprise edition 7.3 and later, the pricing area is extensible. Some common customizations for price and discounts include:

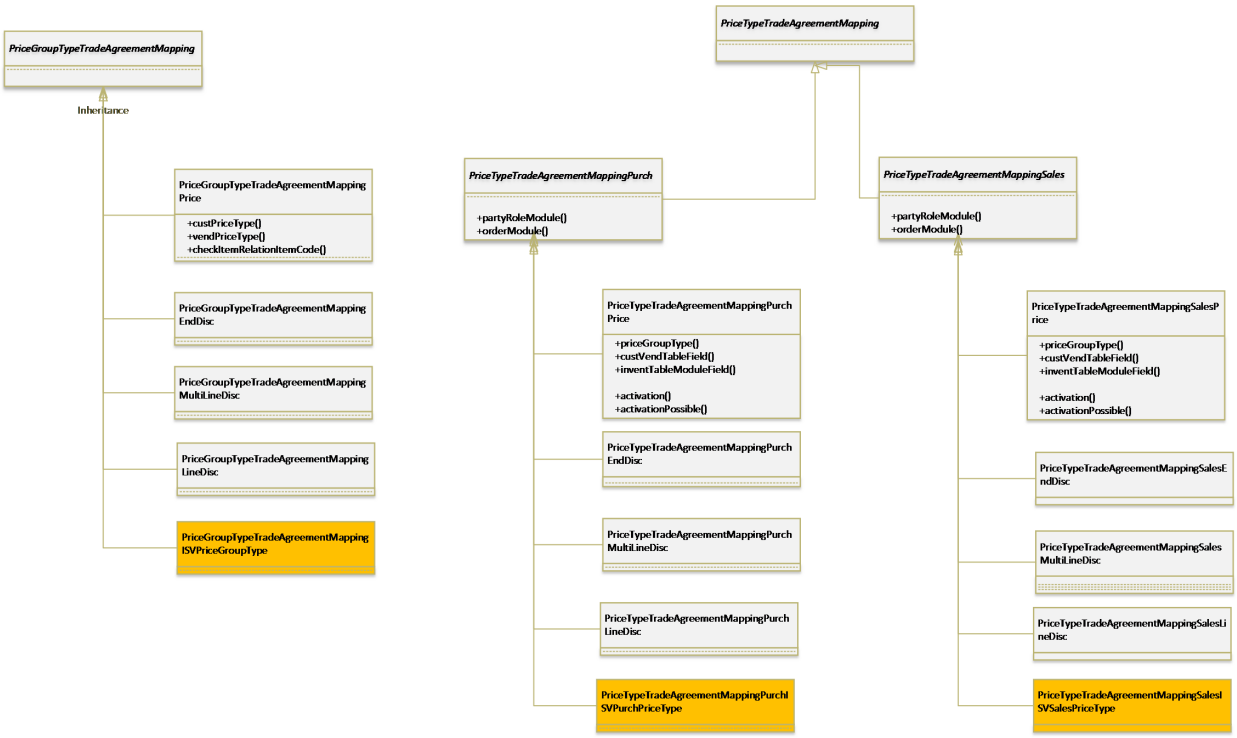
- Adding new price group types and the corresponding price types (enum values for **PriceType** and **PriceGroupType**), in addition to adding search mechanisms for the new price types.
- Modifying the price and discount search, including passing in any additional parameters to the **PriceDisc** class.

PriceType and PriceGroupType enums

Typically, adding a new type of price discount search starts with adding a new enum value in the two enums: **PriceType** and **PriceGroupType**. To support extensibility, **PriceType** and **PriceGroupType** enum values are now encapsulated in the class hierarchies **PriceGroupTypeTradeAgreementMapping** and **PriceTypeTradeAgreementMapping**, respectively. These can be extended for any new **PriceType** and **PriceGroupType** extended enum values.

The mapping of fields on the **Customer**, **Vendor**, and **InventTable** tables that correspond to the price types is defined in **PriceTypeTradeAgreementMapping**.

The following diagram highlights the implementation. Note that the methods show only one of the sub-classes. The implementation needs to be on each sub-class.

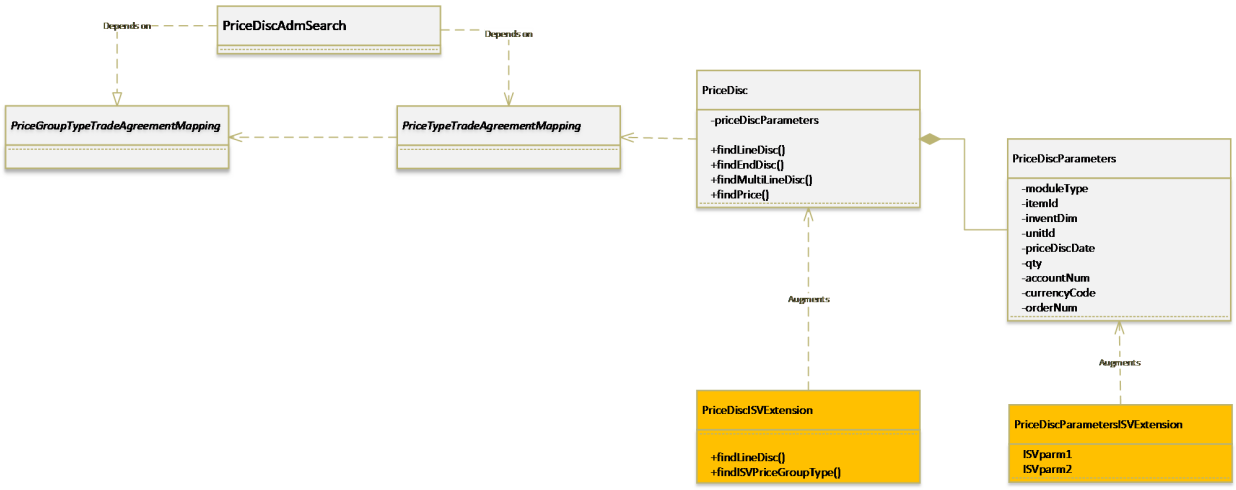


PriceDisc class

The **PriceDisc** class is the search engine for price and discounts. This class uses a **PriceDiscParameters** object as a member for passing in the parameters that are used in the price and discount search. This enables you to pass in the additional search parameters for the specific solutions. Only the parameters for a given **PriceGroupType** search are passed through the corresponding find methods on the **PriceDisc** class.

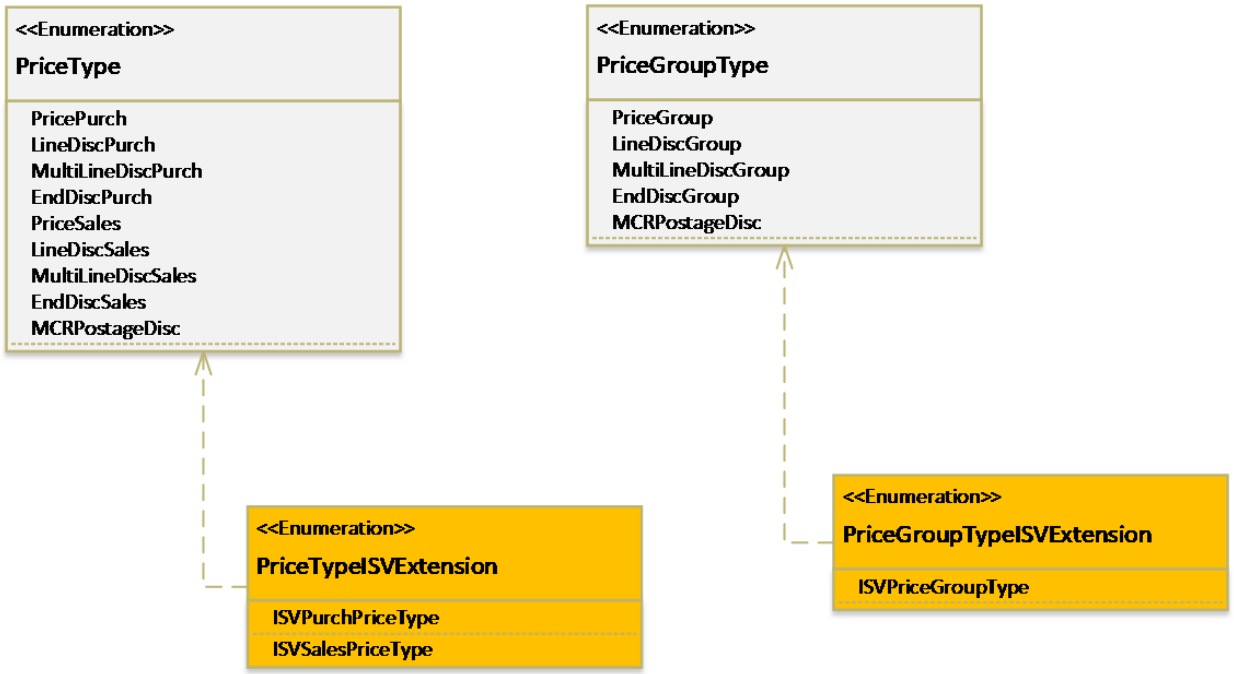
The ability to wrap and modify the instantiation of the **PriceDiscParameters** class is enabled for all price and discount search calls made throughout AppSuite.

In the following diagram, you can see how the **PriceDisc** class can be extended to modify existing searches or to add new search methods that correspond to the extended **PriceType** enum values.

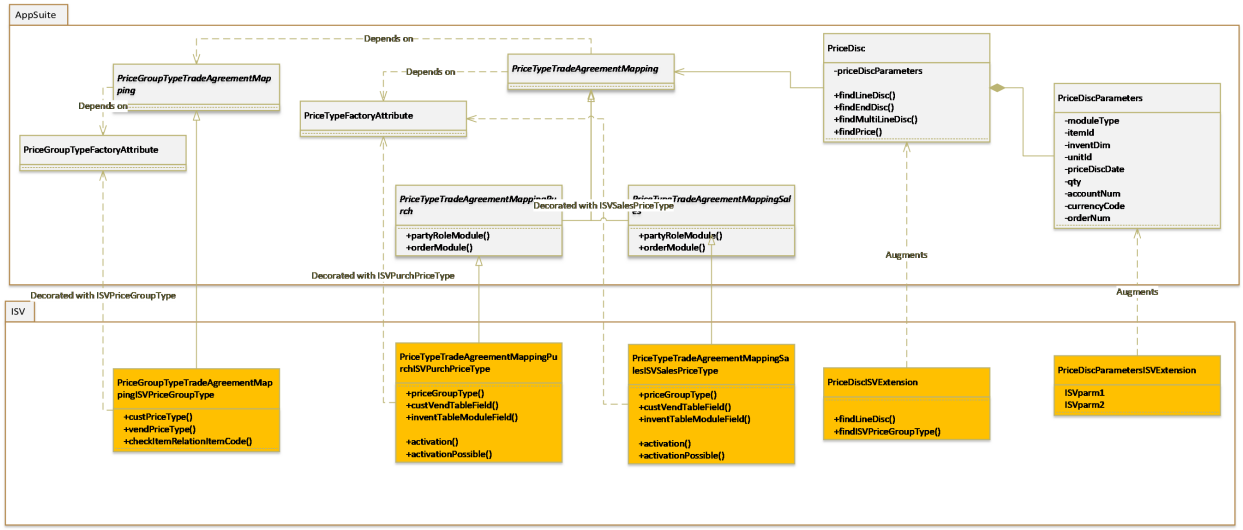


Add a new price search

In this scenario, you have extended the **PriceGroupType** enum with a new value **PriceGroupTypeISVExtension**, and two corresponding **PriceType** enum values - **ISVPurchPriceType** and **ISVSalesPriceType**.



The following diagram illustrates how a new price search can be added for the **PriceType** and **PriceGroupType** values.



This example shows the following:

- For the newly created **PriceGroupType** value, a **PriceGroupTypeTradeAgreementMappingISVPriceGroupType** class decorated with the attribute **ISVPriceGroupType** defines the behavior of the price group type.
- For the newly created **PriceType** value, the **PriceTypeTradeAgreementMappingISVPurchPriceType** and **PriceTypeTradeAgreementMappingISVSalesPriceType** classes correspond to Purchase and Sales.
- Augmenting the **PriceDiscParameters** class to add any generic parameters for the price discount search.
- Augmenting the **PriceDisc** class to create the new price discount search methods for the new price types.
- The **PriceDiscParameters** is accessible from all classes related to price and discount search and these could be augmented, based on the requirements.

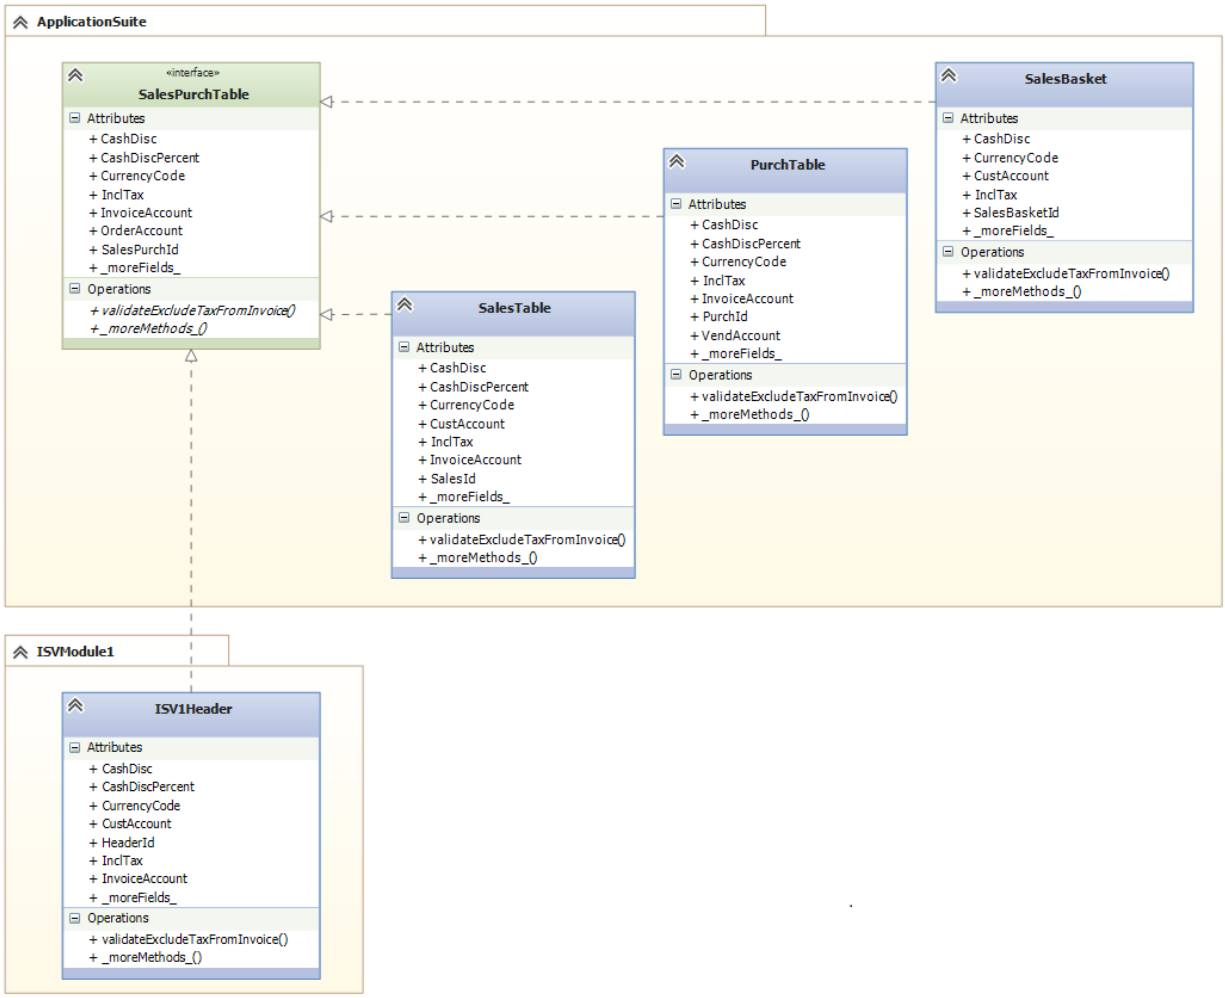
Table map extension

2/18/2021 • 2 minutes to read • Edit Online

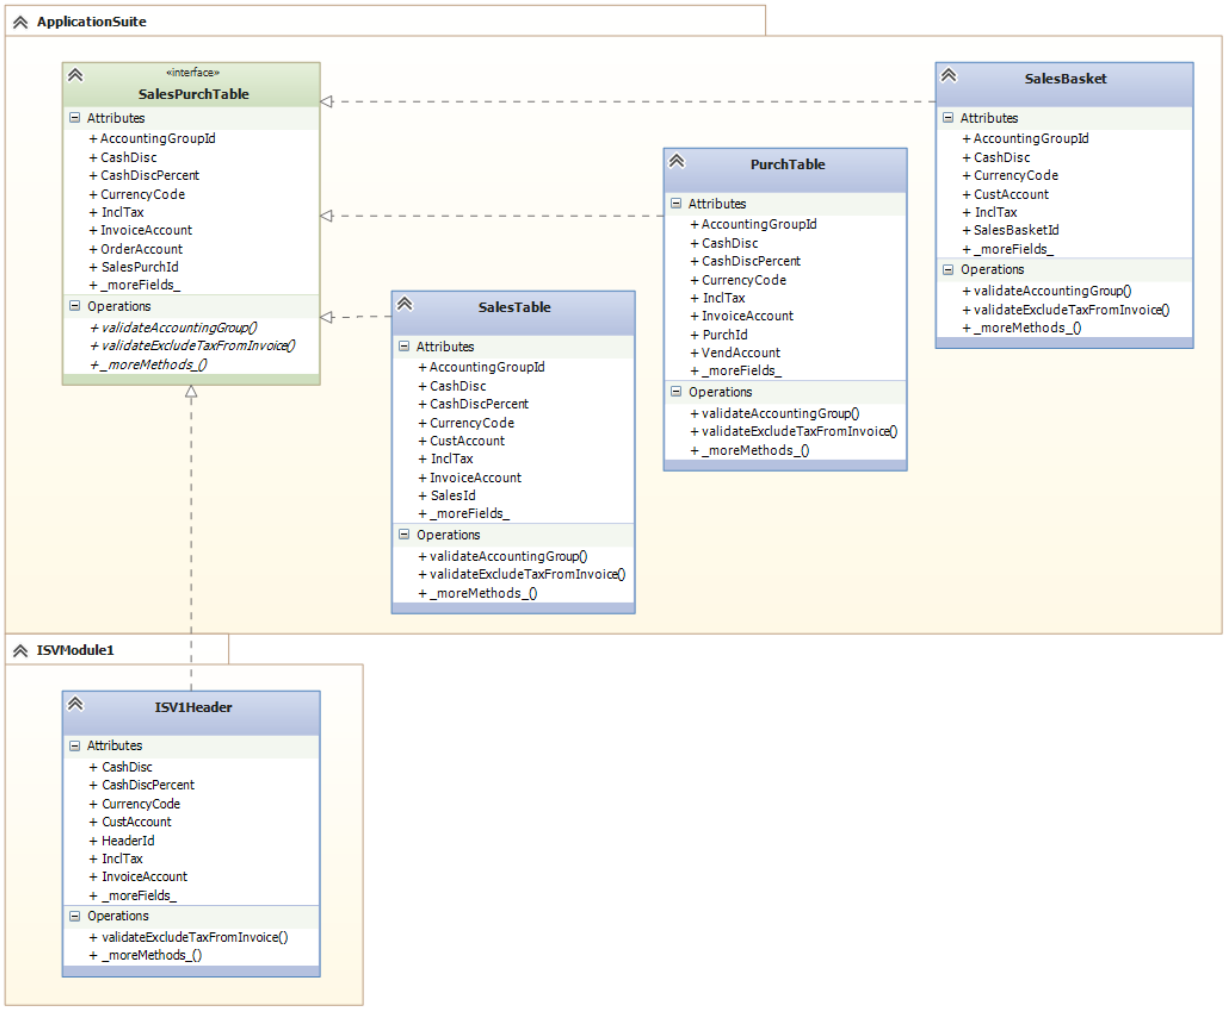
To extend table maps, we have refactored table maps into a model, which allows you to extend a solution with additional fields and methods. This topic discusses why you need a model to extend a table map.

Adding a field to an existing table map through extension can present some challenges. If these issues are not addressed during the implementation, there can be runtime errors. The errors occur because the developer cannot modify all the tables that are involved in implementing the table map. The same is true for adding a method to a table map if the method is called directly as an instance method on the table map. There is no way to enforce how fields on table maps must be mapped to fields on all tables that implement the table map. Similarly, there is no way to enforce how methods on table maps must be also be methods on all tables that implement the table map.

The following diagram shows the **SalesPurchTable** table map, which is implemented by the **SalesTable**, **PurchTable**, and **SalesBasket** tables in the **ApplicationSuite** model. In addition, the **ISV1Header** table implements the **SalesPurchTable** table map, but **ISV1Header** is part of an **ISVModule1** model.



For example, if a new field named **AccountingGroupId** and a new method named **validateAccountingGroup** are added to the table map in the **ApplicationSuite** model, then the tables that you implement the table map can be updated to include the field and method added as well. The **ISV1Header** table in the **ISVModule1** model is, however, outside of the control of the developer making the changes to the **ApplicationSuite** model.



If you add business logic to the **ApplicationSuite** model, and that logic queries the new **AccountingGroupId** field and the table map record is of type **ISV1Header**, a runtime error occurs.

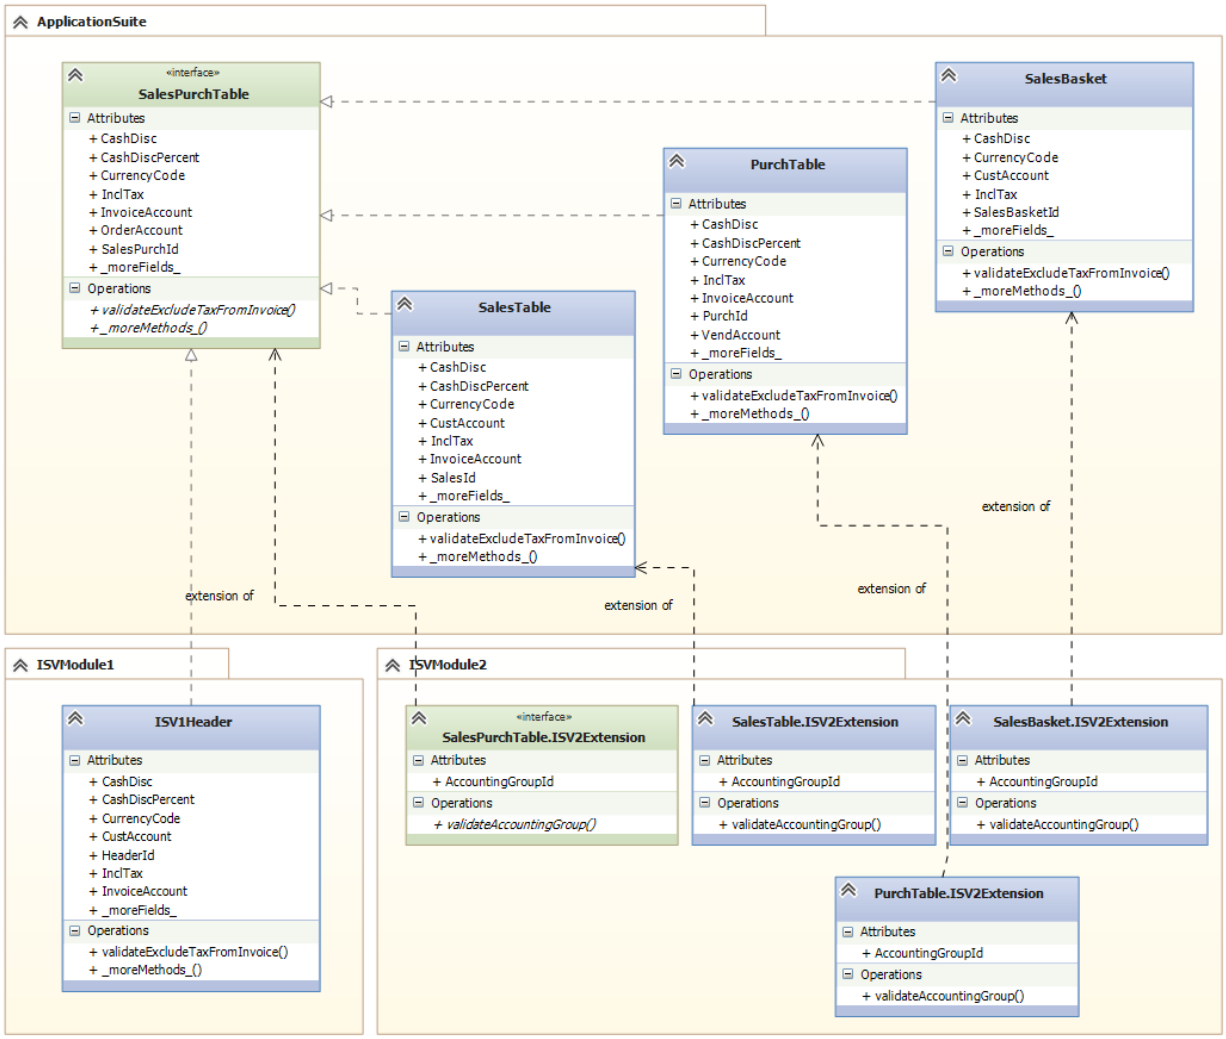
```
SalesPurchTable      headerTable;
...
...
if (headerTable.AccountingGroupId)
```

Similarly, if you add business logic to the **ApplicationSuite** model, and that logic queries **validateAccountingGroup**, then a runtime error occurs.

```
SalesPurchTable      headerTable;
...
...
if (headerTable.validateAccountingGroup())
```

As a result, the solution is broken, unless you add mapping to the new field and add the new method to the **ISV1Header** table.

The conflict is not resolved if the ability to add fields or methods is added to table maps through extension. This is illustrated in the following diagram, where **ISVModule2** includes extensions of the table map and the implementing tables in the **ApplicationSuite** model. The developer implementing **ISVModule2** has no control over the **ISV1Header** table in the **ISVModule1** model, so the **ISV1Header** table lacks a mapping of the **AccountingGroupId** field and implementation of the **validateAccountingGroup** method.



Even if the the compiler enforced that all fields and methods on a table map must be mapped to all tables implementing the table map, the conflict would not be resolved. Instead of receiving runtime errors, adding a field or a method would clear a breaking change, as tables not having a new field mapped or a new method implemented would compile when the model containing the added field/method is applied. To extend table maps, we have refactored table maps into a model, which allows you to extend a solution with additional fields and methods.

Extend table maps that are used as interfaces

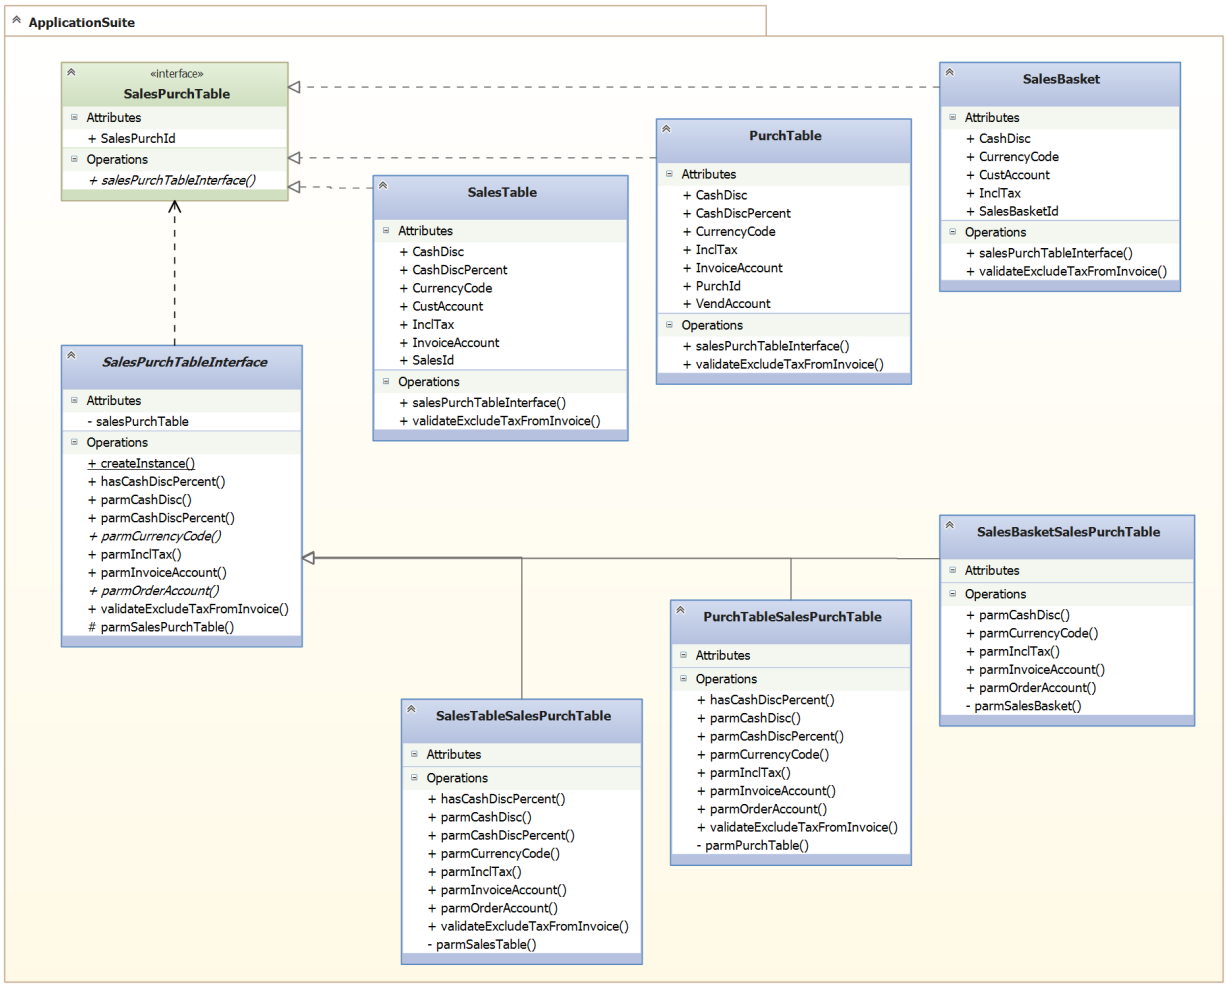
2/18/2021 • 3 minutes to read • Edit Online

The **SalesPurchLine** and **SalesPurchTable** table maps expose a set of common fields and methods that are used by a variety of product features. The mapping of fields and the implementation of methods have been refactored into a class hierarchy. Some of these changes include:

- Methods on the table maps have been moved to the class hierarchy.
- Fields are exposed through parm-methods on the class hierarchy.
- The table map still exists and tables still implement the mapping to the table map, but the fields on the table map have been made obsolete, and field mapping has been removed.
- The methods on the table map have been made obsolete.

SalesPurchTableInterface hierarchy

The new **SalesPurchTableInterface** class is the abstract base class for the ApplicationSuite functionality that has been introduced by the refactoring of the **SalesPurchTable** table map. The class contains abstract methods for fields and methods, which must exist for each table implementing the interface. It also contains the default logic in methods, which is common across all implementations. Each table that implements the **SalesPurchTable** table map must be represented as a derived class in the **SalesPurchTableInterface** class hierarchy. Each derived class must be decorated with a **SalesPurchTableInterfaceFactory** attribute class. The attribute is used to associate the derived class with the table, so that it is possible to instantiate a class of the correct type depending on a **SalesPurchTable** record.



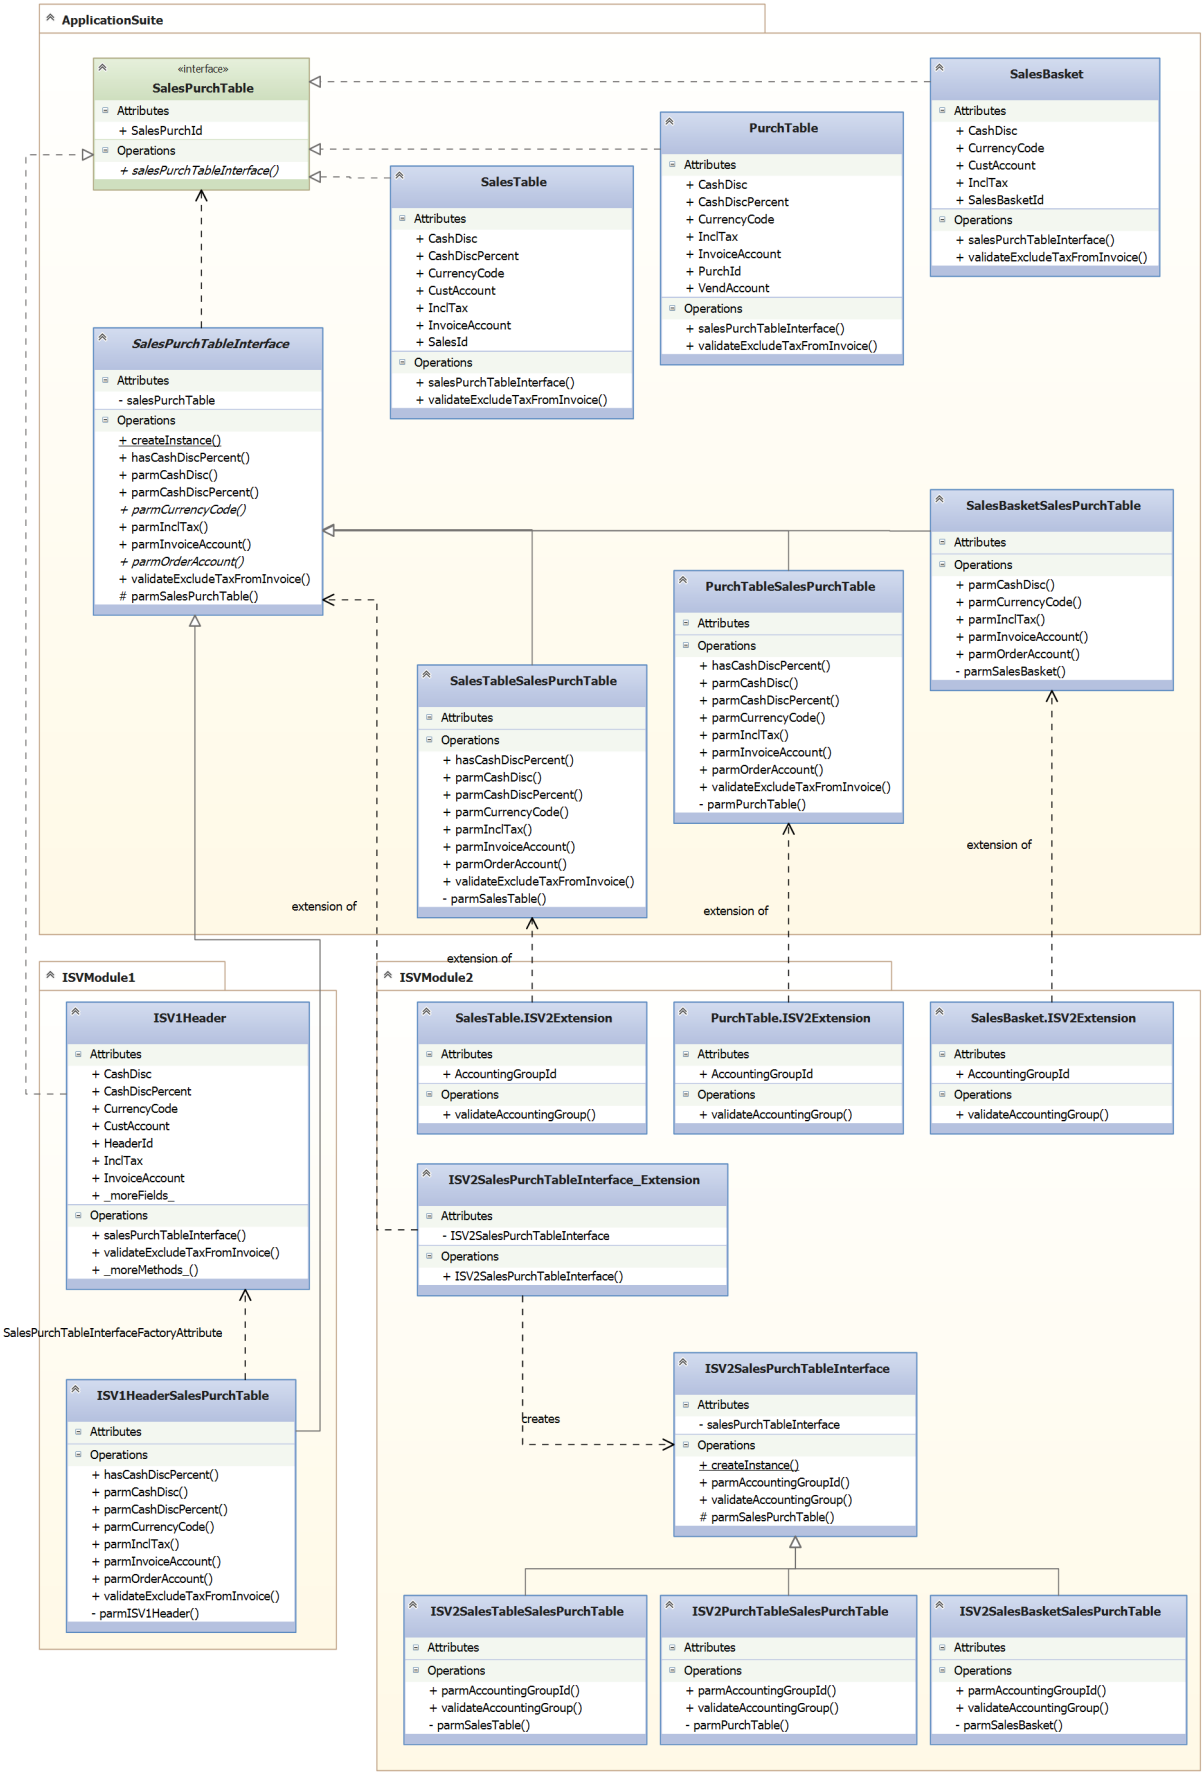
Even though the table map methods have been made obsolete, the corresponding methods still exist on the implementing tables. The logic in these methods have been refactored from delegating calls to the method on the table map, to the corresponding method on the base class of the hierarchy.

Extension scenario

In this example, if you want your ISVModule2 model to extend the interface class hierarchy and the tables implementing the **SalesPurchTable** table map, you must perform the following steps:

1. Add the fields and methods through table extension to the necessary tables implementing the **SalesPurchTable** table map.
2. Create a new interface class hierarchy, which exposes the new fields as parm-methods and other additional methods. The base class of the class hierarchy must be concrete and not abstract.
3. Create derived classes for each table that has been extended.
    a. Decorate each derived class with the **SalesPurchTableInterfaceFactory** attribute class to associate the class with the correct table.
    b. Create a static factory method on the base class of the new class hierarchy. The factory method should instantiate the proper derived class that leverages the **SalesPurchTableInterfaceFactory** attribute. If no derived class can be found, then an instance of the base class must be returned.
4. Create an extension class of the **SalesPurchTableInterface** class. The class augments the **SalesPurchTableInterface** class with a method that creates an instance from the new class hierarchy by calling the factory method on the new class hierarchy.

The class and extensions described above are shown in the following diagram.



The diagram contains an ISVModule1 model, which includes the **ISV1Header** table that implements the **SalesPurchTable** table map and contains its own **SalesPurchTableInterface** derived class. The model is independent of the ISVModule2, so when logic in the ISVModule2 creates an instance from the **ISV2SalesPurchTableInterface** class hierarchy, then an instance of the base class will be returned when the **SalesPurchTable** record is of type **ISV1Header**. If the methods on the base class return a reasonable result for unknown tables, then the two ISV models will co-exist within the same installation.

Code example

The following code example demonstrates a way to extend table maps.

```
[ExtensionOf(classStr(SalesPurchTableInterface))]
final public class ISV2SalesPurchTableInterface_Extension
{
    private ISV2SalesPurchTableInterface ISV2SalesPurchTableInterface;

    public ISV2SalesPurchTableInterface ISV2SalesPurchTableInterface()
    {
        if (!ISV2SalesPurchTableInterface)
        {
            ISV2SalesPurchTableInterface = ISV2SalesPurchTableInterface::createInstance(this);
        }

        return ISV2SalesPurchTableInterface;
    }

}

public class ISV2SalesPurchTableInterface
{

    SalesPurchTableInterface salesPurchTableInterface;

    private void initializeSalesPurchTableInterface(SalesPurchTableInterface _salesPurchTableInterface)
    {
        salesPurchTableInterface = _salesPurchTableInterface;
    }

    public SalesPurchTable parmSalesPurchTable()
    {
        return salesPurchTableInterface.parmSalesPurchTable();
    }

    protected void new()
    {
    }

    public static ISV2SalesPurchTableInterface createInstance(SalesPurchTableInterface
_salesPurchTableInterface)
    {
        SalesPurchTableInterfaceFactoryAttribute attr =
  new SalesPurchTableInterfaceFactoryAttribute(
   tableId2Name(_salesPurchTableInterface.parmSalesPurchTable().tableId));

        ISV2SalesPurchTableInterface instance =
  SysExtensionAppClassFactory::getClassFromSysAttribute(classStr(ISV2SalesPurchTableInterface), attr)
  as ISV2SalesPurchTableInterface;

        instance.initializeSalesPurchTableInterface(_salesPurchTableInterface);

        return instance;
    }

    public AccountingGroupId parmAccountingGroupId()
    {
        return '';
    }

}
[SalesPurchTableInterfaceFactoryAttribute(tableStr(SalesTable))]
public class ISV2SalesTableSalesPurchTable extends ISV2SalesPurchTableInterface
{
    private SalesTable parmSalesTable()
    {
```

```
        return this.parmSalesPurchTable();
    }

    public AccountingGroupId parmAccountingGroupId()
    {
        return this.parmSalesTable().AccountingGroupId;
    }

}

[SalesPurchTableInterfaceFactoryAttribute(tableStr(PurchTable))]
public class ISV2PurchTableSalesPurchTable extends ISV2SalesPurchTableInterface
{

    private PurchTable parmPurchTable()
    {
        return this.parmSalesPurchTable();
    }

    public AccountingGroupId parmAccountingGroupId()
    {
        return this.parmPurchTable().AccountingGroupId;
    }

}
```

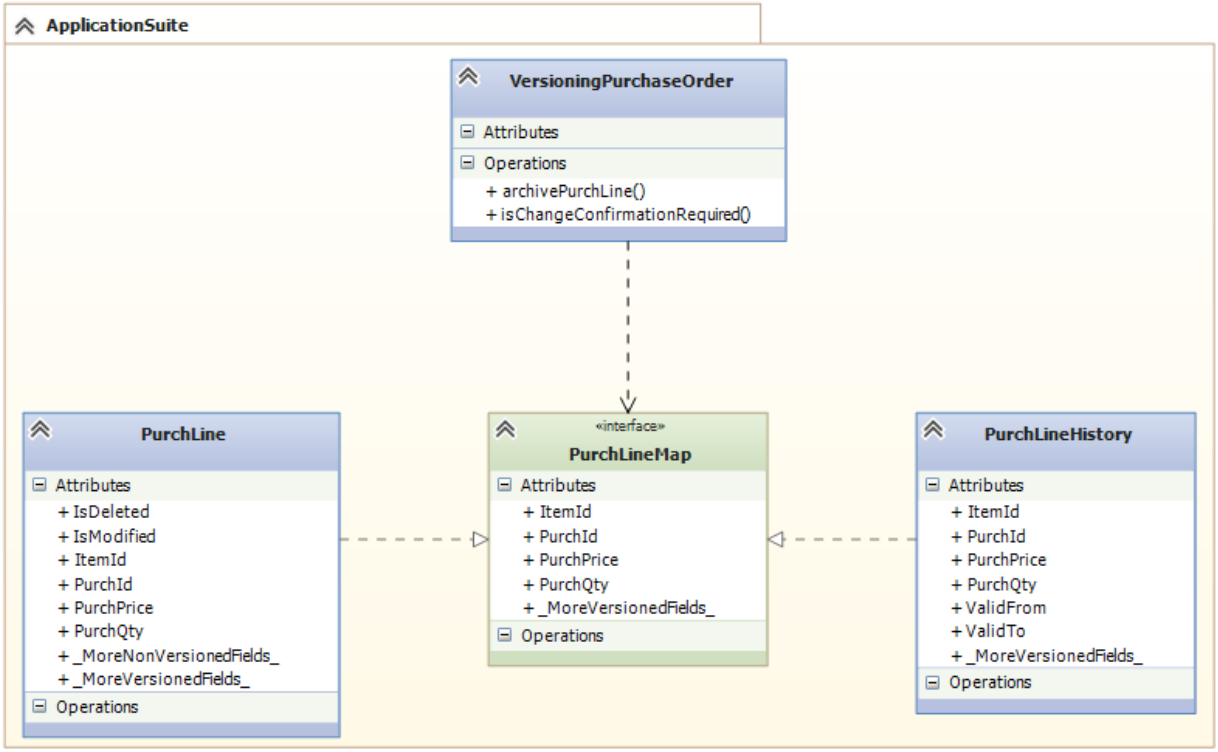
Extend table maps that are used for versioning

2/18/2021 • 2 minutes to read • Edit Online

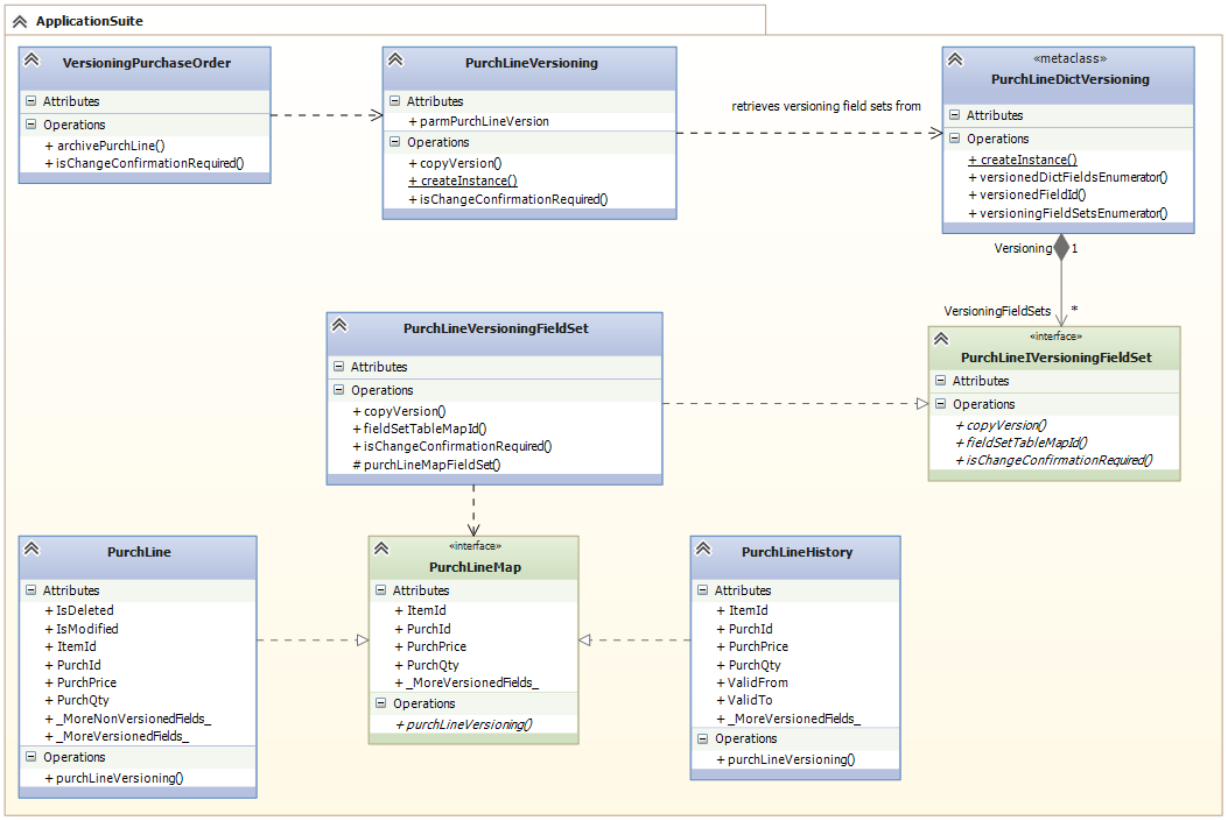
PurchLineMap table map logic

When new fields are added to the **PurchLine** and **PurchLineHistory** tables using table extensions, the new fields must be copied between the tables when a purchase order is versioned. The **PurchLineMap** table map specifies the fields that must be copied between the **PurchLine** table and the **PurchLineHistory** table when a new purchase order version is created or edited. To accomplish this, extend the **PurchLineMap** map table to include the additional fields. Additionally, the **PurchLineMap** is used by the **VersioningPurchaseOrder** class when archiving purchase order lines. The model is shown in the following diagram.



To be able to specify new fields to be copied, the **PurchLineMap** table map logic and its usage have been refactored. The copy logic has been moved to the **PurchLineVersioning** class, so the **VersioningPurchaseOrder** class references the **PurchLineVersioning** class instead of the **PurchLineMap** table map. The **PurchLineVersioning** class delegates the logic to copy the fields and the logic to determine whether a confirmation is required from the classes that implement the **PurchLineIVersioningFieldSet** interface. Each class that implements the interface is associated with a table map that specifies the fields to copy.

The **PurchLineDictVersioning** class instantiates the **PurchLineIVersioningFieldSet** object using reflection. The **PurchLineDictVersioning** class collects the entire set of fields which need to be copied. The field data is collected based on all the table maps associated with a class that implements **PurchLineIVersioningFieldSet**. The following diagram displays the new classes and their dependencies.



How to extend PurchLine and PurchLineHistory tables with new fields

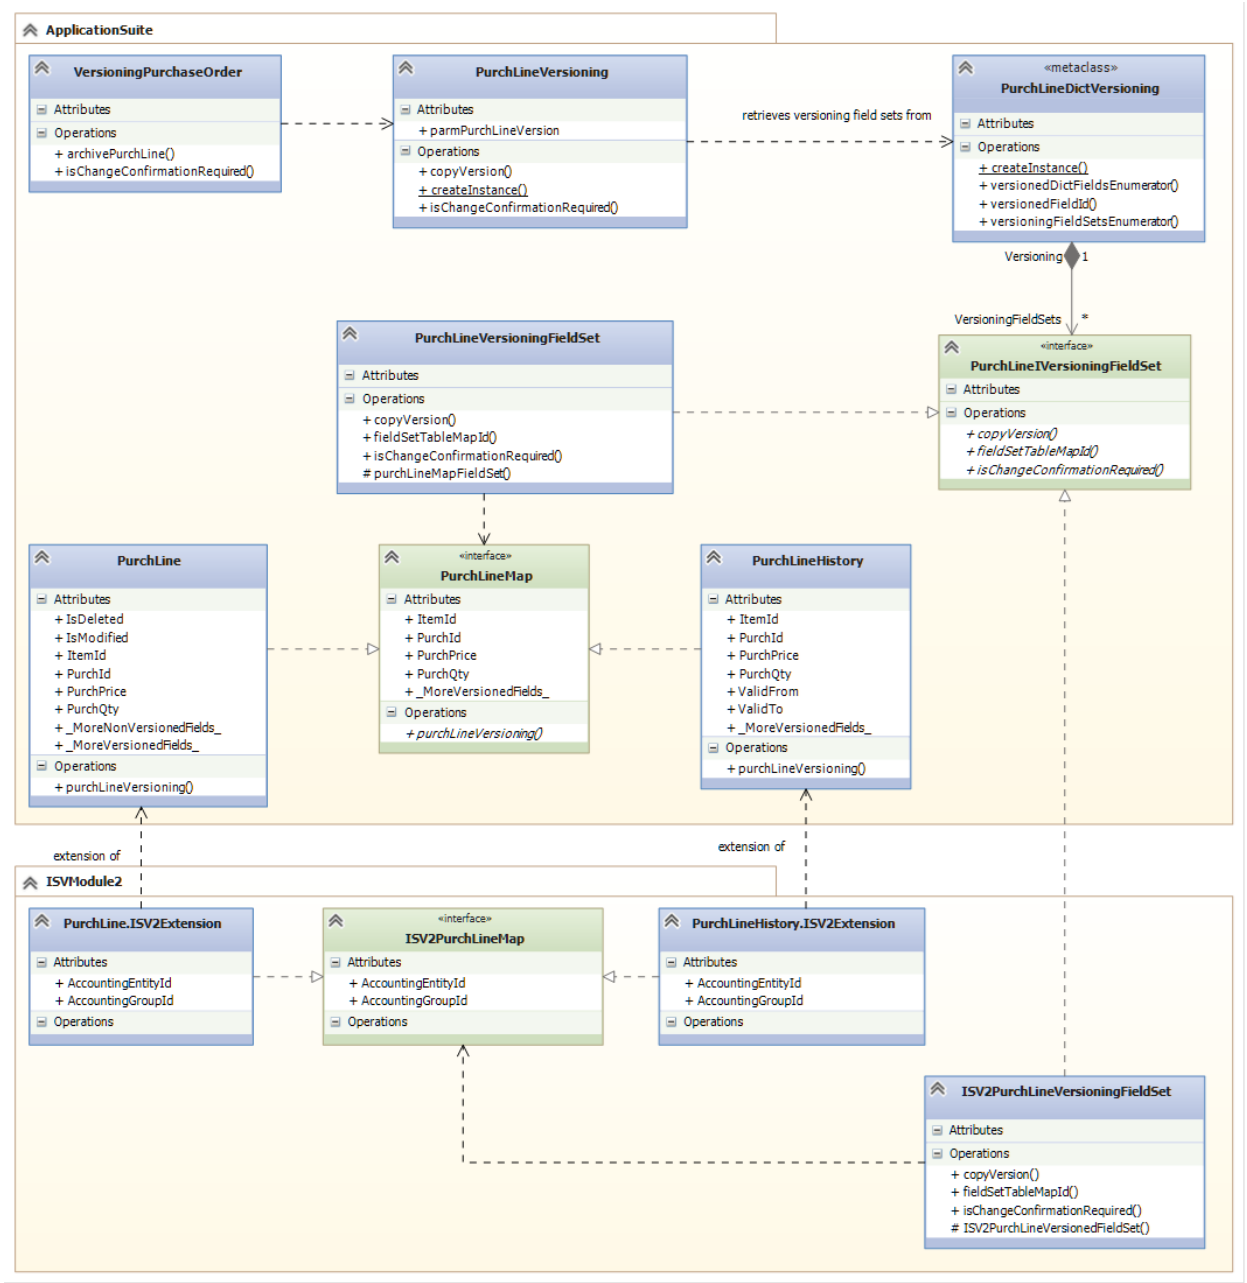
Suppose that you want the ISVModule2 model to extend the **PurchLine** and **PurchLineHistory** tables with new fields that must be copied when creating a new version of a purchase order.

> **NOTE**
>
> You must have developer access to the ISVModule2 model.

To complete this task, you must perform the following steps:

1. Add fields by using table extensions to the **PurchLine** and **PurchLineHistory** tables.
2. Create a new table map containing the fields that must be copied, and implement the new table map on the two new table extensions.
3. Create a new class to implement the **PurchLineIVersioningFieldSet** interface and implement the following required methods.
   - **copyVersion** method - Copies data between two records of the new table map type.
   - **fieldSetTableMapId** method - Returns the ID of the new table map.
   - **isChangeConfirmationRequired** method - Returns true or false based on whether the change to the newly added field values requires a confirmation to be created.

The classes, interfaces, and extensions described in these steps are shown in the following diagram.



Extending decimal point precision for selected data types

2/18/2021 • 5 minutes to read • Edit Online

This topic describes how to extend decimal point precision for selected data types. You can create extensions of specific extended data types of the type Real, to change the decimal point precision for certain scenarios. To change the decimal point precision, change the **NoOfDecimals** property as needed.

Extended data types are hierarchical and inherit behavior from the data type they extend. When changing the number of decimals for one extended data type, the number of decimals on all derived extended data types will follow. In other words, if you find an extended data type where **NoOfDecimalsIsExtensible** is false, then check the parent extended data type, as the number of decimals might be extensible in this wider scope.

Weight

Weight data can be maintained with a maximum of two decimals by default. If you require the ability to enter, maintain, and view weight data with a maximum precision of six decimals, you must extend the decimal point precision for the **WeightBase** extended data type.

Product width, height and depth

These physical dimensions can be maintained with a maximum of two decimals by default. If you require the ability to enter, maintain, and view this data with a maximum precision of six decimals, you must extend the decimal point precision for the **InventWidth**, **InventHeight**, and **InventDepth** extended data types respectively.

Product quantity

Quantity data that is related to the procuring, consuming, producing, storing, and selling of products can be maintained with a maximum of two decimals by default. If you require the ability to enter, maintain, and view product quantities with a maximum precision of six decimals points, you must extend the decimal point precision of the **ProductQuantity**, **CostQuantity**, and **CAMMagnitude** extended data types.

Bill of materials, formulas, and production orders allow maintaining quantities with four decimals by default. If you require more than four decimals, extend the decimal point precision for the **BOMProductQuantity** extended data type.

Related data types

Price unit, **Price quantity**, and **Charge quantity data** can be extended independently from product quantities. You can extend the **PriceUnit** extended data type to change the decimal point precision to a value other than the default two for price units.

You can extend the **PriceQty** extended data type to change the decimal point precision to a value other than the default two for price and charge quantities.

Overloaded data types

There are two extended data types that are used for storing both quantity data and other types of data. These data types must be extended separately.

The **AmountQty** extended data type is used for storing and presenting both amounts and quantities. The

AmountQty extended data type should be extended to the maximum amount of required decimals for both amounts and quantities. For example, if amounts need to be maintained with three decimal points, but quantities still need to be maintained with two decimal points, then the data type should be extended to three decimal points.

The **ProductQuantityHourValue** extended data type is used for storing and presenting both hours and quantities. The **ProductQuantityHourValue** extended data type should be extended to the maximum amount of required decimal points for both hours and quantities. For example, if quantities need to be maintained with four decimal points, but hours still need to be maintained with two decimal points, then the data type should be extended to four decimal points.

Unit amounts

By default, unit amounts including prices, line discount amounts, and line charge amounts can be maintained with a maximum of two decimals.

If you require the ability enter, maintain, and view unit amounts with a maximum precision of six decimal points, you must extend the decimal point precision of the **UnitAmountCur**, **UnitAmountMST**, and **CostPriceNonMonetary** extended data types.

If you require a decimal point precision of more than four, you should also extend the PriceRoundOff extended data type.

Overloaded data types

There are five extended data types that are used for storing both unit amount data and other types of data.

The **PriceDiscAmount** extended data type is used for storing and presenting amounts and unit amounts. The **PriceDiscAmount** extended data type should be extended to the maximum amount of required decimals points for both amounts and unit amounts. For example, if amounts need to be maintained with three decimal points, but unit amounts need to be maintained with four decimal points, the data type should be extended to four decimal points.

The **MCRRoyaltyValue**, **PdsRebateValue**, **TAMRebateValue**, and **MarkupValue** extended data types are used for storing and presenting amounts, unit amounts, and percentages. The extended data types should be extended to the maximum amount of required decimal points for amounts, unit amounts, and percentages. For example, if amounts need to be maintained with three decimal points, but unit amounts need to be maintained with four decimal points and percentages should remain maintained with two decimal points, then the data type should be extended to four decimal points.

Amounts

Amounts, including unit amounts, can be maintained with a maximum of two decimals by default.

If you require the ability to enter, maintain, and view amounts including unit amounts with a precision of maximum six decimal points, you must extend the decimal point precision of the **Amount**, **AmountMST**, and **CostAmountNonMonetary** extended data types. If you require a different precision for unit amounts other than for amount, follow the description for how to extend the decimal point precision for unit amounts.

Overloaded data types

There are three extended data types that are used for storing amount data and other types of data. This means that they must be extended separately.

The **AmountQty** extended data type is used for storing and presenting amounts and quantities. The **AmountQty** extended data type should be extended to the maximum amount of required decimals for both amounts and quantities. For example, if amounts need to be maintained with three decimal points, but quantities still need to be maintained with two, then the data type should be extended to three decimal points.

The **PriceDiscAmount** extended data type is used for storing and presenting amounts and unit amounts. The **PriceDiscAmount** extended data type should be extended to the maximum amount of required decimals points for amounts and unit amounts. For example, if amounts need to be maintained with three decimal points, but unit amounts need to be maintained with four decimal points, then the data type should be extended to four decimal points.

The **MarkupValue** extended data type is used for storing and presenting amounts, unit amounts, and percentages. The extended data types should be extended to the maximum amount of required decimals points for amounts, unit amounts, and percentages. For example, if amounts need to be maintained with three decimal points, unit amounts need to be maintained with four decimal points, and percentages should remain with two decimal points, then the data type should be extended to four decimal points.

Write extensible code

2/18/2021 • 4 minutes to read • Edit Online

X++ and the metadata model provide a powerful foundation for building business solutions. One of the design pillars is to automate as many technical concerns as possible, so that the engineer can focus on the business domain. For example, if you put all the text resources in label files, one technical concern that you don't have to worry about is the localization of text resources.

Extensibility is another technical concern. You want other people to be able to extend your solution in a safe, robust, and maintainable way. By default, your solution is highly extensible. However, there are a few guidelines that you should follow to help guarantee completeness.

Responsibilities

Any Finance and Operations environment runs a business solution that includes components from many sources. Typically, each solution has code from Microsoft, independent software vendors (ISVs) and partners, and also internally developed code. Each contributor is responsible for its own contribution to the solution and for the way that its contribution interacts with other contributions.

When you write extensible code, you invite other people to interact with your solution. Your responsibility is to enable other people to be good guests. Here is how you meet this responsibility:

- **Make robust extension points** – Extension points are the foundation of extenders' solutions. They must be well-defined and robust from release to release.
- **Invite side-by-side customizations** – Recognize that multiple extenders might use the same extension point. Enable 1:n (one-to-many) interactions instead of 1:1 (one-to-one) interactions.
- **Trust that extenders will be well-behaved** – All responsible parties share the same goal: to create great, lasting solutions for the customer. When you create extension points, you give up control and share the responsibility with other people. Assume that extenders will be cautious and use your extension points as they were intended.

Proven principles

All the good engineering practices that you're already using still apply. Everything that you've learned still applies. You don't have to learn new principles or unlearn old practices. This topic is just highlighting three principles of software craftmanship that have been sought and taught for decades. These principles not only make your code easier to read, maintain, test, review, and refactor, but also make your code easier to extend. Apply and advocate these principles.

Extend code by using the SOLID principles

SOLID is an acronym for five principles that you can use to make your code easier to extend:

- **Single responsibility** – Classes and method should have a single responsibility and should not have side-effects. By following this principle, you help guarantee that extension points that are automatically created on public and protected methods will be great extension points.
- **Open/closed**
  - **Open for extension** – Open your solution for extensions by designing and considering the extension surface. After an extension point is made available, you're responsible for maintaining it. This responsibility adds significant restrictions to future development. It's often preferable to open a

solution up for extension by demand. For example, use internal methods over public methods or private methods over protected methods.

- **Closed for modification** – Make your properties private, and make your methods either private or final-protected. In this way, no one can take advantage of a dependency on your logic, either through inheritance or extension.

- **Liskov substitution** – Derived classes must be able to be substituted for their base classes. For example, this substitution can be done by providing factories, by using SysExtension, and by using simple construct methods.

- **Interface segregation** – Create concise interfaces. This principle lets extenders provide replacement implementations and is particularly valuable when it's used together with the next SOLID principle, dependency inversion.

- **Dependency inversion** – Depend on abstractions, not concretions. This principle enables decoupling and lets extenders provide concrete instances that conform to the abstraction that your logic depends on.

Write clean code

Clean code can be read like an article. The name of a method provides the heading of the article. The body of the method comes next and really consists of just a few lines of summary. This summary calls a few other methods that have good descriptive names. In this way, the reader can keep exploring details and can also stop at any time without missing any conceptual information.

When code is written like in this manner, methods are short, often less than 5 to 10 code lines. Additionally, the number of parameters is low, often less than two, and the conditions and blocks of code are always a single code line.

Here is an example.

```
public void processOrder(SalesOrder _salesOrder)
    {
        if (this.approveOrder(_salesOrder))
        {
            this.confirmOrder(_salesOrder);
        }
        else
        {
            this.rejectOrder(_salesOrder);
        }
    }
```

In X++, every protected and public method is an extension point. By writing clean code, you automatically produce extensible code. In the previous example, an extender can change how approval, confirmation, and rejection are implemented. If the implementations had been inline, the code would not be extensible.

Don't repeat yourself (DRY)

To help prevent misalignment of implementations, avoid redundancy in your logic. This principle is especially important in the case of extensible code, because the extender might not extend all required pieces and might therefore unintentionally leave the solution broken.

Best practices to create an extensible solution in X++

The following best practices can help you create extensible solutions in X++, so that consumers of your code can extend your solution:

- Classes
- Methods

- Forms
- Extended data types
- Extensible enums
- Delegates
- Tables
- Attributes that make methods extensible

Breaking changes

When you make your solution extensible, you also help guarantee that you won't break extension points later. For more information, see Breaking changes.

External resources

The following external resources can help you make sure that you're writing clean code:

- SOLID Principles
- Pluralsight - Clean Code: Writing Code for Humans
- Clean Code: A Handbook of Agile Software Craftsmanship
- Clean Coders
- Don't repeat yourself

Write extensible classes

2/18/2021 • 2 minutes to read • Edit Online

A class and its methods should have a single responsibility. Keep the following in mind in order to design classes that are resilient to changes in the long run. Class should have:

- A clear purpose
- Good names (class name and method names)
- Only methods that should be extended are exposed for extensibility, i.e. the key rule is allow extending as little as necessary.
  - Every public and protected method is an extensibility point in X++. Every time that a new method is introduced, downstream consumers get a new way to inject additional logic into the method.

Example

Non-extensible code

```
    void calculatePrice(SalesLine _saleLine, AmountMST _amount)
    {
        // cannot add extra condition if needed
        if(_saleLine.QtyOrdered > 0 && _saleLine.SalesType == SalesType::Sales)
        {
            ttsbegin;
            // calculation of SalesPrice is locked and cannot be extended
            _saleLine.SalesPrice = _saleLine.QtyOrdered * _amount;
            _saleLine.update();
            ttscommit;
        }
    }
```

Extensible code

```
protected boolean canUpdateSalesPrice(SalesLine _saleLine)
   {
       return (_saleLine.QtyOrdered > 0 &&
   _saleLine.SalesType == SalesType::Sales);
   }

   protected SalesPrice calculateSalesPrice(
   SalesLine _saleLine, AmountMST _amount)
   {
       return _saleLine.QtyOrdered * _amount;
   }

   public void updateSalesPrice(SalesLine _saleLine, AmountMST _amount)
   {
       // extra condition can be added in CoC on the method
       if(this.canUpdateSalesPrice(_saleLine))
       {
           ttsbegin;
           // extra calculation/value can be added in CoC on the method
           _saleLine.SalesPrice = this.calculateSalesPrice(_saleLine, _amount);
           _saleLine.update();
           ttscommit;
       }
   }
```

Class hierarchies

For new or existing class hierarchies where a factory pattern can be used, the SysExtension framework enables easy extensions. Because these extensions are truly decoupled, new subclasses can be added without requiring any changes to the base class. Therefore, less code is required. Additionally, because the contract of the construct remains the same, there is no change to the public application programming interface (API). Therefore, refactoring involves low risk.

Some existing factory methods might not instantiate subclasses by using the instance constructor. Instead, they might call a static constructor, such as **construct**. If the SysExtension framework is used for these factory methods, a breaking change occurs, because the static constructors on the subclasses are no longer invoked. In these situations, use the SysExtension framework only for the default case.

For more information about class hierarchies, see the following blog posts:

- SysExtension Framework – to the rescue
- Embrace the extensions mindset with Dynamics 365 for Finance and Operations #2 – SysExtension framework

Deprecation

If a class or a public or protected method is no longer required, always use a warning first to notify consumers that the method is obsolete. Then, when all consumers have had the chance to uptake the changes or the new API, the method can be deprecated. Deprecation of classes and methods (or removal of class members in other cases) is a breaking change. For more information, see Breaking changes.

Write extensible methods

2/18/2021 • 5 minutes to read • Edit Online

Before you make a method extensible, you should assess the exposed functionality of the method and the impact that the extensions might have on the scenario where the method is used. For example, depending on the business scenario, there is low risk if you enable extensions to initialize a table record but high risk if you enable extensions to skip a specific validation. You might also want to consider the impact if the method is extended in parallel with other extensions.

After you've made a method extensible, future modifications to the method are restricted because of the potential user impact if the method signature or logic is changed.

Here are some guidelines to follow when you write extensible code:

- **Write short and concise methods** – A method should have only one responsibility. This approach enables easy extensions of the method, where the extensions can act only on the specific responsibility of the method. As a simple example, keep the construction and initialization of a class object in two separate methods.
- **Expose only what is necessary** – For any new class members or methods that are added, 'Keep any new class members or methods that you add private, to allow minimal access to them.
- **Use private, protected, public, and final explicitly** – For methods and class fields, this approach will guide any extenders of your code to your extension points but still let you keep full control of the parts that the extenders should not care about or depend on.
- **Method parameters**
  - The method is most likely long and should be refactored. Consider whether you should refactor the whole method into a class or split the method into smaller methods that require fewer parameters.
  - In other cases, when several parameters are required, the parameters often have a coherence that can be expressed by a class. By encapsulating these parameters in a class, you make it easy for extenders to add additional parameters to the base method, without breaking application programming interfaces (APIs) later.
- **Switch blocks**
  - Avoid switch blocks in the middle of methods. A switch block should be in its **own method** to enable it to be extended.
  - **Long case blocks** are good candidates for being refactored into a class/class hierarchy that has a subclass for each case block. For an example, see the **SalesLineCopyFromSource** class hierarchy.
  - Avoid **default blocks** in switch statements, because they make the method that has the switch block non-extensible.
  - Avoid **throw statements in the default block** of a switch statement, because they make the switch statement non-extensible. One way to handle the throw in the default case is to refactor the switch block to a separate method that is extensible. Alternatively, you can make the whole method replaceable.

    In the following example, **findOrderHeader** is replaceable.

```
private Common findOrderHeader(boolean _forUpdate)
  {
      switch (this.InventTransType)
      {
          case InventTransType::Sales:
              return this.salesTable(_forUpdate);

          default:
              return this.findOrderHeaderDefault(_forUpdate);
      }
  }

  [Replaceable]
  protected Common findOrderHeaderDefault(boolean _forUpdate)
  {
      throw error(Error::wrongUseOfFunction(funcName()));
  }
```

- **While** – Avoid **while** blocks in the middle of methods, because it becomes more difficult to extend the **while** blocks. Ideally, logic in a **while** block should be in a separate method that enables extensions.

  Refactoring logic within a while loop

```
        while select forupdate markupTransOrig
                        where markupTransOrig.TransTableId == origLineUpdate.TableId
                            && markupTransOrig.TransRecId == origLineUpdate.RecId
        {
            markupTransNew.clear();
            markupTransNew.initFromSalesLine(_newLine);
            markupTransNew.initFromMarkupTrans(markupTransOrig);

            markupTransNew.LineNum        = MarkupTrans::lastLineNum(_newLine.TableId, _newLine.RecId) + 1;

            markupTransNew.OrigRecId = origLineUpdate.RecId;
            markupTransNew.OrigTableId = origLineUpdate.TableId;
            markupTransNew = this.initializeNewMarkupTrans(_origLine, _newLine, markupTransOrig);

            if (markupTransOrig.MarkupCategory == MarkupCategory::Fixed)
            {
                markupTransNew.Value = (_newLine.ExpectedRetQty/_origLine.ExpectedRetQty) * markupTransOrig.Value;
                markupTransNew.Value = CurrencyExchangeHelper::price(markupTransNew.Value, markupTransNew.CurrencyCode);
                markupTransOrig.Value -= markupTransNew.Value;
                markupTransOrig.update();
            }
            else
            {
                markupTransNew.Value = markupTransOrig.Value;
            }
```

  Extensible method after refactoring

```
protected MarkupTrans initializeNewMarkupTrans(SalesLine _origLine, SalesLine _newLine, MarkupTrans _markupTransOrig)
{
    MarkupTrans markupTransNew;
    markupTransNew.clear();
    markupTransNew.initFromSalesLine(_newLine);
    markupTransNew.initFromMarkupTrans(_markupTransOrig);

    markupTransNew.LineNum        = MarkupTrans::lastLineNum(_newLine.TableId, _newLine.RecId) + 1;

    markupTransNew.OrigRecId = _markupTransOrig.TransRecId;
    markupTransNew.OrigTableId = _markupTransOrig.TransTableId;

    if (_markupTransOrig.MarkupCategory == MarkupCategory::Fixed)
    {
        markupTransNew.Value = (_newLine.ExpectedRetQty/_origLine.ExpectedRetQty) * _markupTransOrig.Value;
        markupTransNew.Value = CurrencyExchangeHelper::price(markupTransNew.Value, markupTransNew.CurrencyCode);
        _markupTransOrig.Value -= markupTransNew.Value;
    }
    else
    {
        markupTransNew.Value = _markupTransOrig.Value;
    }

    return markupTransNew;
}
```

- If..else statements

- To enable extension of the conditions in an if statement, extract the logic in the if condition into a separate method.
- Avoid nested if..else blocks, because they make it difficult to change the logic in one of the blocks. One way to resolve this issue is to refactor each condition and the logic in each block into a separate method. In this way, you can extend the conditions or the logic in each block.
- When the if..else blocks handle specialization, consider moving the logic into a class hierarchy. For an example, see **SalesLineCopyFromSource**.
- In some scenarios, a throw in an 'else' block of a method (when the method only has an if..else) makes the method non-extensible. One way to handle the throw in the else is to refactor the conditions for the throw into a separate method.

- **Avoid using PrmIsDefault** – When the method is overridden or wrappable, the caller of **super()** or **next()** provides all parameters. Therefore, **prmIsDefault()** always returns false.

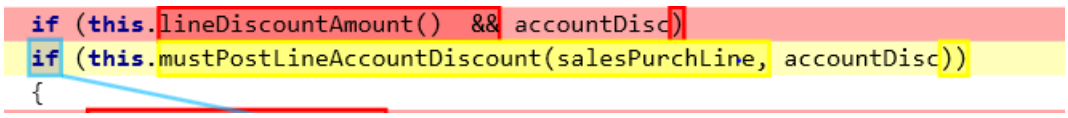
- **Avoid using enumCnt** – At compile time, this method uses a numeric literal of the number of values that an enum has. If the enum is extended or made extensible later, your code will have to be recompiled. Use **DictEnum.values()** instead.

- **Construct methods**
  - Use the **SysExtension** framework to enable easy extensions.
  - Avoid a throw in factory methods. One way to resolve this issue is to extract the conditions for the throw into a separate method that is extensible. For more details, see the guidelines for throw statements later in this list.
- **Static methods** – Static methods can't be extended with extra state. For example, a method extender can introduce properties that can be set by using parameter methods. Use instance methods instead, whenever this approach is possible.

- **Ability to extend part of the logic in a long method** – If it isn't possible to refactor a whole method, but the goal is to make part of the method extensible, apply the extract method refactoring. The new protected method must have a single responsibility, and it must also have a name that conceptually and precisely describes that responsibility. In this way, owners and all extenders can use the method without breaking each other. For example, initialization, insertion, updates to a table record, or instantiation and initialization of a class can be extracted into smaller methods, and each of these smaller methods can be enabled for for extensions. The original method then calls these individual methods. Therefore, the callers to this method aren't broken.

- **Throw statements** – A throw that is added to an existing method that is extensible could break extenders. Consider adding the conditions for the throw in an extensible method. In this way, extenders can take advantage of the method, and you can get rid of the throw.

  If condition refactored out to a protected method



```
if (this.lineDiscountAmount()  && accountDisc)
if (this.mustPostLineAccountDiscount(salesPurchLine, accountDisc))
{
```

  Extensible method after refactoring

```
/// <summary>
/// Determines if the line account discount must be posted.
/// </summary>
/// <param name = "_salesPurchLine">A <c>SalesPurchLine</c> record.</param>
/// <param name = "_accountDisc">A <c>LedgerDimensionDefaultAccount</c> value.</param>
/// <returns>true if the line account discount must be posted; otherwise, false.</returns>
protected boolean mustPostLineAccountDiscount(SalesPurchLine _salesPurchLine, LedgerDimensionDefaultAccount _accountDisc)
{
    return (this.lineDiscountAmount() && _accountDisc);
}
```

- **Create, read, update and delete (CRUD) statements**

- Use Query objects in scenarios where the queries should be extensible. Implement a protected method that builds the query. In addition, you might want to build several separate methods to add joined data sources, ranges, and selection fields. In this way, different parts of the query can be extended individually.
- Use **SysQueryInsertRecordSet** to convert insert_recordset to a query.
- Avoid field lists in select statements. In this way, you enable extenders to retrieve their additional fields without having to extend.
- Use the **in** keyword in query ranges to enable extenders to add more values to the query range. We recommend this approach especially for query ranges that have enum values.

Write extensible forms

2/18/2021 • 2 minutes to read • Edit Online

Methods on forms

- In general, the guidelines for writing extensible methods also apply to form methods.
- Chain of Command (CoC) gives access to the form's non-private members, which are the same as the non-private members for classes.
- CoC is enabled for nested classes. Therefore, methods that are defined in various levels on the form are extensible.

> **NOTE**
>
> One limitation of methods on forms, that for form data source methods only methods that are defined in the kernel are enabled for extensions, i.e. methods defined on the form data source are not extensible. This will be available in an upcoming Platform Update.

Field groups

Consider using field groups whenever possible. In this way, independent software vendors (ISVs) can add their fields for free when they extend a field group.

Form controls

Moving around form controls could potentially cause a break if the controls are made non-extensible by moving.

> **NOTE**
>
> Can you tell us about your documentation language preferences? Take a short survey.
>
> The survey will take about seven minutes. No personal data is collected (privacy statement).

Extended data types

2/18/2021 • 2 minutes to read • Edit Online

Extended data types (EDTs) have a rich extension model that lets extenders change specific behaviors.

To provide an extensible solution, keep the following guidelines in mind when you work with EDTs.

Label/Help text

Labels and Help text properties can be changed by an extension, but only one value can remain. If multiple solutions change the label of the same EDT, the various labels are, in functional terms, mutually exclusive. Therefore, those labels can't all be installed on the same system.

String size

String size can be defined only on root EDTs. The system will use the largest value that is defined across the EDT and its extensions.

For derived EDTs, string size can't be changed by an extension, because the IS-A relationship between the EDTs will be broken.

Assignments to string EDTs will truncate the string to match the defined string size.

Extends

The **extends** property can't be changed by an extension. Any change that is made to this property after release will cause a breaking change. Therefore, you must make sure that the property is set correctly before release.

If you set this property, neither you nor extenders will be able to make changes to the string size later.

Avoid unnecessary dependencies. For example, don't extend generic EDTs such as Name and Description.

Number of decimals

The **Number of decimals** property can't be changed by an extension.

If you set this property to **True**, extenders can change the number of decimal places.

If you set this property to **True**, make sure that the following conditions are met:

- All truncation logic honors the number of decimal places that is specified on the EDT, so that no implicit or hardcoded rounding will occur.
- The value isn't assigned to other incompatible EDTs that don't correctly handle rounding.

Write extensible enums

2/18/2021 • 2 minutes to read • Edit Online

An enumeration (enum) is made extensible by setting the following enum properties:

- Is Extensible = True
- UseEnumValue = No

If you set these properties, downstream implementors can extend the enum with more elements. The values of the elements are determined at deployment time and won't be identical across systems. However, the following behavior is ensured:

- Data upgrade scripts aren't required. Enum values are persisted in the database, regardless of the enum that is extended. Therefore, when an enum is made extensible, the enum values that are used on any system will prevail.
- The first element in the enum gets a value of 0 (zero). Therefore, an extensible enum can still be used with the **not** operator. The only exception is when the first element of the enum had a non-zero value before the enum was made extensible.

Using extensible enums in code

Because enum values are no longer controlled by the developer, there is no certainty about the enum values. When you use extensible enums in code, remember that extensible enums can't be used in comparisons. For example, **MyEnum::Value1 > MyEnum::Value2**.

Also, look for any conversions between integers and enums. For example, modeled ranges in views and queries, and queries that are created from code by using comparisons, such as < and > or by using hardcoded integer values in comparisons.

When the model and all dependent models are compiled, the comparisons and conversions to integers will be detected by the compiler as errors.

Make sure that logic where the enum values are used is extracted in **smaller methods**. In that way, an extension that uses Chain of Command (CoC) can handle the enum values that are added.

For **construct** methods where the instantiation is based on enum values, replace switch blocks with **SysExtension** wherever such a replacement is possible. In other cases, make sure that the default block is extensible. For an example, see the **PurchRFQCaseCopying** class.

If the enum is used in **switch blocks**, avoid having default blocks that either have or don't have throws that aren't extensible. When there are **long switch case blocks** or **if...else blocks** for the enum values, consider creating a class hierarchy to handle specific logic that is related to the enum. For an example, see the **PriceGroupTypeTradeAgreementMapping** class hierarchy.

Use the **in** keyword for query ranges that use the enum values, and make the container that the **in** keyword uses extensible.

Potential issues

Some enums require the elements to have a certain order or value, and cannot be made extensible. This could be status enums, where the values represent a logical progressive sequence, like: Draft, Approved, Completed, or Archived. It could also be enums where the values must have a fixed integral value to match another artifact, like

another enum or a tabpage control's number.

Some enums have many elements. Enums support up to 250 elements. If your enum has many elements, such as more than 100, consider redesigning the solution instead of making the enum extensible. If the enum is extensible, then adding more elements in the future might break customers's combined solution as the addition might exceed the limit.

Delegates

2/18/2021 • 2 minutes to read • Edit Online

Although you can subscribe to existing delegates, don't create new delegates. The Chain of Command (CoC) provides a richer, more robust, and more concise extension mechanism that supersedes delegates.

Instead of creating new delegates, structure your code in small methods that have good names, as described in the guidelines for writing extensible methods.

If you decide to use delegates, consider ensuring no more than one response where applicable. For more information, see EventHandlerResult classes in request or response scenarios.

Write extensible tables

2/18/2021 • 2 minutes to read • Edit Online

Tables have a rich extension model that lets extenders add fields, field groups, indexes, relations, methods, and more.

Unique indexes

Unique indexes can't be changed by an extension. Unique indexes define a table constraint, and they often also define the key of the rows in the tables. You aren't allowed to change unique indexes, because such changes change the nature of the table. Therefore, there is a high risk that the changes will cause logical conflicts with future versions of the solution that defines the table, or with other solutions that consume the table.

Avoid unique indexes that are likely to be changed either now or in the future. For example, don't create a unique index on product dimensions such as color, size, style, and configuration. Instead, create a unique index on a distinct product variant, so that the index doesn't have to be changed if new product dimensions are added.

If you require an extensible uniqueness constraint on multiple columns, consider creating a hash of the column's values. For an example, see the NumberSequenceScope table.

Data events

Tables have many predefined data events that are automatically raised.

Avoid calling **doInsert()**, **doUpdate()**, and **doDelete()**. These methods prevent the data events from being raised and make your table harder to extend. Instead, call **insert()**, **update()**, and **delete()**.

Field groups

Always use field groups to group related fields, and to build forms and reports. By consistently using this approach, you enable the extension to surface additional fields in forms and on reports by extending the field group.

Attributes that make methods extensible

2/18/2021 • 3 minutes to read • Edit Online

This topic describes the various attributes that can be used to control extensibility capabilities for methods.

The following table provides an overview of the default support for extensibility and accessibility on methods. The table also provides guidance on the method signature changes.

	HOOKABLE	WRAPPABLE	REPLACEABLE	ACCESSIBILITY	SIGNATURE
private	No	N/A	N/A	Accessible from within class it is defined in.	Signature can be changed
protected internal	No	Yes, from Platform update 25 onward	No	Accessible from with the class it is defined, from derived classes, and from classes in the same model.	Signature must remain compatible
internal	No	No	No	Accessible in the same model.	Signature can be changed
protected	No	Yes, unless marked final	No	Accessible from with the class it is defined and from derived classes.	Signature must remain compatible
public	Yes	Yes, unless marked final	No	Accessible from within the class it is defined, derived classes, and other classes that have access to the defining class.	Signature must remain compatible

Hookable

If a method is hookable, extenders can subscribe to pre-events and post-events.

For public methods, you can opt out by adding **[Hookable(false)]** to the method.

You can opt in for private and protected methods by adding **[Hookable(true)]** to the method.

If a method is explicitly marked as **[Hookable(false)]**, then it is not wrappable.

Best practices when you write code

When a method is hookable, the compiler generates extra intermediate language (IL) code to enable the method as an extension point. Although the extra code has performance overhead, this overhead is negligible in most cases. However, for performance-critical methods, consider marking the method as non-hookable.

Wrappable

If a method is wrappable, extenders can wrap it by using Chain of Command (CoC). Extenders must call next, because they aren't allowed to break the CoC.

For protected and public methods, you can opt out by adding **[Wrappable(false)]** to the method.

You can't opt in for private methods.

Best practices when you write code

CoC resembles inheritance in many ways. Typically, if you want other people to be able to call your method but not change it, you mark the method as final. Consider marking these methods as non-wrappable or non-hookable.

Replaceable

If a method is replaceable, extenders can wrap it by using CoC, but they don't have to unconditionally call next. Although extenders can break the CoC, the expectation is that they will only conditionally break it. The compiler doesn't enforce calls to next.

To be replaceable, a method must also be wrappable.

For wrappable methods, you can opt in by adding **[Replaceable]** to the method.

Best practices when you write code

When a method is replaceable, it can be extended by using CoC, and the execution of next can be skipped. Before you enable a method to be replaceable, you should thoroughly assess the functional impact if an extender skips the execution of the method.

- **Do** make sure that methods that have **[Replaceable]** have XML documentation that describes the responsibility of the method.
- **Don't** use **[Replaceable]** to let consumers skip the replaced logic and do nothing.
- **Don't** use **[Replaceable]** for factory methods when **SysExtension** can be used instead.
- **Avoid** using **[Replaceable]** when the method changes databases or class state.
- **Avoid** using **[Replaceable]** if the method performs multiple operations and has multiple responsibilities. Instead, refactor the method into separate methods, each of which has a single responsibility, and consider which methods should actually be replaceable.
- **Consider** using **[Replaceable]** to solve transformations.

  Example: Enum conversion that uses a switch statement over enum values, where the default block has a throw.
- **Consider** using **[Replaceable]** to override lookups and jumprefs.

Best practices for extenders

- **Don't** write logic that has a different responsibility than the logic that is being replaced.
- **Do** call the base functionality (call next) when the replacement logic doesn't apply.
- **Avoid** replacing logic completely by not calling the base functionality (call next).

NOTE

Can you tell us about your documentation language preferences? Take a short survey.

The survey will take about seven minutes. No personal data is collected (privacy statement).

Breaking changes

2/18/2021 • 4 minutes to read • Edit Online

When you make your solution extensible, you also help guarantee that you won't break the extension points later. A breaking change is any change that can break a consumer of your code.

This topic lists some of the types of changes that can break your code.

> **IMPORTANT**
> This list isn't exhaustive. Other types of changes that aren't listed here could also be breaking changes.

Data model changes

General

If any data model change requires that a data upgrade script be run, consumers might no longer be able to synchronize their data model, or they might lose access to data.

Data types

- **Changing an enumeration (enum) from extensible to non-extensible** – Consumers might have extensions to the enum.
- **Changing an enum from non-extensible to extensible** – Consumers might be using the enums in comparisons. For more details, see Write extensible enums.
- **Decreasing the decimal precision of an extended data type (EDT) of the real type** – Consumers might have dependencies on the ability to enter data that uses the precision.
- **Decreasing the size of an EDT of the string type** – Consumers might have dependencies on the size of the string.
- **Specializing the EDT by making it extend another EDT** – Consumers might have string length or decimal precision extensions to the EDT.
- **Changing the enum type of an EDT of the enum type when the enum is extensible** – Consumers might have extensions to the enum.

Data model

- **Making a table obsolete and stopping information from being entered in the table** – Consumers might have a dependency on the table that information is entered in.
- **Making a table field obsolete and stopping information from being entered in the field** – Consumers might have a dependency on the field that information is entered in.
- **Renaming a field group** – Consumers might have extensions to field group, or code or metadata dependencies to it.
- **Changing constraints or indexes**
- **Making a table map obsolete and stopping the table map from being used**
- **Make a table map field obsolete**
- **Adding a table map field**
- **Removing a table map field mapping**
- **Making a data entity obsolete**
- **Making a data entity field obsolete**

Code changes

Class members

- **Deleting or renaming public or protected class-level members** – Consumers might be using these members in the extension classes.
- **Changing a class member from public or protected to protected or private** – Consumers might have queried or assigned values to the field.

Classes and interfaces

- **Adding an abstract method to a class** – Consumers might have created a derived type.
- **Adding final to a class** – Consumers might have created a derived type.
- **Adding a method to an interface** – Consumers might have implemented the interface on their own type.
- **Making a public class obsolete and stopping instantiation of the class** – Consumers might have overridden, wrapped, or subscribed to the instance methods.

Methods

- **Changing the access modifier from protected or public to another access modifier** – Consumers might have called, overridden, wrapped, or subscribed to the method.
- **Making a concrete public or protected method abstract** – Consumers might have subclasses to the class, and those subclasses might not have implemented the method, or they might even call super.
- **Renaming method parameters** – Consumers might have dependencies on parameters by name (via arguments or externally from C#, for example).
- **Adding, removing, or changing the type of a method parameter on a protected or public method** – Consumers might have called, overridden, wrapped, or subscribed to the method.
- **Adding or removing a default method parameter on a protected or public method** – Consumers might have wrapped or subscribed to the method.
- **Changing the return type of a method** – Consumers might have called, overridden, wrapped, or subscribed to the method.
- **Adding Hookable(false) to a protected or public method** – Consumers might have wrapped or subscribed to the method.
- **Adding Wrappable(false) to a protected or public method** – Consumers might have wrapped the method.
- **Removing Hookable(true) from a private or protected method** – Consumers might have subscribed to the method.
- **Removing Wrappable(true) from a private method** – Consumers might have wrapped the method.
- **Removing Replaceable(true) from a method** – Consumers might have conditionally wrapped the method.
- **Adding final to a protected or public method** – Consumers might have overridden, wrapped, or subscribed to the method.
- **Changing a method from instance to static or from static to instance** – Consumers might have called, overridden, wrapped, or subscribed to the method.
- **Making a method obsolete and stopping invocation of the method** – Consumers might have called, overridden, wrapped, or subscribed to the method.
- **Changing the responsibility of a method** – Consumers might have called, overridden, wrapped, or subscribed to the method.
- **Removing the reference to a method** – Consumers might have overridden, wrapped, or subscribed to the method, and they might expect their logic to run.

Delegates

- **Making any change in signature** – Consumers might have subscribed dynamically.

- **Removing the reference to a delegate** – Consumers might have subscribed, and they might expect their logic to run.

Label changes

- **Modifying or deleting a label** – Consumers might be using the label in the current context of the label text and the parameters that were passed, and so on. We recommend that, going forward, you add new labels in the event of a label change.

Application element changes

- **Removing any element** – Consumers might have a compile time dependency on the existence of the element.

Metadata extensions

- **Not following the naming guidelines for metadata or augmentation classes** – Consumers might have elements that have the same name.

Compatibility checker tool

2/18/2021 • 4 minutes to read • Edit Online

The compatibility checker tool can detect metadata breaking changes against a specified baseline release or update. In this way, it helps ensure backward compatibility. Microsoft uses the tool to help ensure metadata compatibility.

The compatibility checker tool is available as one of the dev tools in Platform update 34. You can use it to ensure that your solutions are backward-compatible with earlier releases before you install or push updates to customers.

What the tool detects

The tool compares metadata of the current version with metadata of a baseline version. It detects and reports metadata changes that Microsoft has identified as breaking and added to the tool.

For a list of breaking changes that the tool detects, see the List of breaking changes detected by the tool section later in this topic.

> **NOTE**
>
> - The list in this topic doesn't include all the breaking changes that the tool can detect.
> - The tool doesn't detect all breaking changes.

What the tool doesn't detect

The tool detects only breaking changes that can be identified by comparing data. For example, it doesn't detect the following breaking changes that often occur:

- The reference to a protected or public method is removed.
- The responsibility of a method is changed.

Using the tool

You can use the tool to detect metadata compatibility issues that a new version has against the version that it's replacing. Microsoft uses the tool to detect any breaking changes that a new monthly update has against the previous monthly update.

Usage

```
CompatibilityChecker.exe -BaselineDirectory=\<Path to baseline metadata\> -CurrentDirectory=\<Path to
current metadata\> -ModuleName=\<Module name\> -OutputFile=\<Output file path\> -LogFile=\<Log file path\>
```

Example

```
CompatibilityChecker.exe -BaselineDirectory="\\servername\archive\Build1\BaselineMetadata" -
CurrentDirectory="E:\\MyCode\\retail\\amd64\\BaselineMetadata" -ModuleName="Directory"
-OutputFile="E:\\Logs\\Directory\\Diagnostics.xml" -LogFile="E:\\Logs\\Directory\\Checkerlog.txt"
```

Description

The tool identifies breaking changes by comparing the current metadata with specified baseline metadata.

You must specify the following paths:

- **BaselineDirectory** – The path of the baseline metadata.
- **CurrentDirectory** – The path of the current (new) metadata.
- **OutputFile** – The path of the file that contains the list of breaking changes.

The following rules apply:

- You must compile the current metadata before you run the tool.
- The *OutputFile* file contains the list of breaking changes that the tool identifies.
- The *BaselineDirectory* directory must exist and must have the metadata for the specified module and its dependencies (if the module has any dependencies).
- The metadata paths for *BaselineDirectory* and *CurrentDirectory* should have metadata for *StaticMetadata*. This metadata should be present in a folder that is named **StaticMetadata** in the specified paths.
- You can suppress any breaking change that the tool identifies by adding an entry to the model's ignore list. This file is present in the **AxIgnoreDiagnosticList** folder for the model.

List of breaking changes detected by the tool

> **NOTE**
> The tool identifies metadata compatibility changes as breaking changes only if they have been defined as breaking in the tool.

Class members

- **Changing the access modifier of protected or public class members (including making a member read-only)** – Consumers might have read from the field or assigned values to it.
- **Deleting or renaming public or protected class-level members** – Consumers might be using these members in some extension classes.

Methods

- **Changing the method signature of a protected or public method** – Wrappers and callers of the method will be broken.
- **Making a protected or public method obsolete** – Consumers might be wrapping or overriding the methods.

Classes and interfaces

- **Making a class final** – Consumers might have created a derived type.
- **Making a class abstract** – Consumers might be instantiating the class.
- **Adding an abstract method to a class** – Consumers might have created a derived type.
- **Adding a method to an interface** – Consumers might have implemented the interface on their own type.
- **Making a public class obsolete and stopping instantiation of the class** – Consumers might have overridden, wrapped, or subscribed to the instance methods.

Delegates

- **Any change in signature** – Consumers might have subscribed dynamically.

Tables

Any of the following changes will break table extensions and table references to tables and table fields:

- Deleting or renaming table fields, field groups, indexes, table mappings, or table relations

- Modifying these table properties: **Extends**, **SuportInheritance**, **TableType**, **SaveDataPerCompany.Yes**, or **SaveDataPerPartition**
- Modifying these table field properties: **ExtendedDataType**, **Scale**, or **String size**
- Modifying these table index properties: **AllowDuplicates.No** or **IndexType**

Forms

Any of the following changes will break form extensions that reference the controls or methods:

- Deleting or renaming form controls, form data sources, and form data source fields.
- All changes that are breaking for methods are also breaking for form methods.

Enumerations (enums)

- Modifying these properties: **IsExtensible** or **Value**

Extended data types (EDTs)

- Modifying these properties: **Extends**, **EnumType**, or **Scale**

Entities

- All changes that are breaking for tables are also breaking for entities.
- Renaming a public entity.

Labels

- **Modifying or deleting a label** – Consumers might be using the label in the current context of the label text and the parameters that were passed. We recommend that you add new labels instead of changing existing labels.

Application elements

- **Removing any element** – Consumers might have a compile-time dependency on the existence of the element.

Take traces by using Trace parser

2/18/2021 • 2 minutes to read • Edit Online

This tutorial provides guidelines on how to take traces.

In this tutorial, you'll take a tour of how to collect and download traces. The trace analysis tool works largely similar to the Microsoft Dynamics AX 2012 version, but it is not backward compatible and can't be used to analyze AX 2012 traces. The trace parser tool can be found in the PerfSDK folder on your development deployments.

Prerequisites

This tutorial requires that you access the environment as an administrator on the instance. The administrator can also grant rights to other users to take a trace. In this way, you can trace scenarios that can't be reproduced with administrative rights.

Capture the trace

1. Before you trace make sure your scenario is in a warm state, meaning that you have run the scenario you want to trace once before you take the trace. Being in a warm state prevents things like metadata loading and other possible warm-up tasks from being in the trace.
2. In the navigation bar, select **Help**, and then select **Trace**.
3. Name the trace that you are about to capture, and then select **Start trace**.
4. Perform actions that need to be analyzed, for example, opening **Accounts payable > Vendors > All vendors**.
5. When you are finished, select **Stop trace**. Then, you can select one of the following options (for this tutorial, select the second option):

   - **Download trace** – Store the captured trace on a local machine. You can analyze a downloaded trace with the desktop version of Trace Parser.

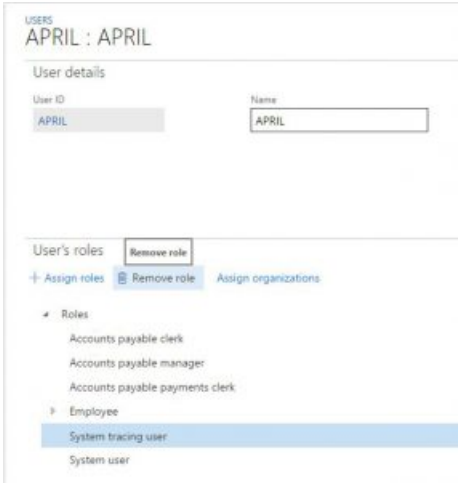
   > **NOTE**
   > If you download a trace it will not be available for later uploading.

   - **Upload trace** – Store the trace in the cloud for later downloading by, for example, the admin, it will be automatically deleted after 7 days and can also be deleted manually from the captured traces form.

> **NOTE**
> If your scenario takes more than 1-2 minutes it is better to try to take multiple smaller traces of 30 seconds each as the trace will likely get too big to be easily analyzed and there is a risk for losing data if the trace gets too big.

Assign trace rights to user

1. To give a user rights to capture a trace, go to **System administration > Users > Users**.
2. Select the user and assign the **System tracing user** role.



Remove the user role again once the user is done with tracing to avoid unwanted tracing.

Open captured trace

1. In the navigation bar, select **Help**, and then select **Trace**.
2. Select Captured traces.

> **NOTE**
> The captured traces button can only be seen by users with administrative rights.

3. Select the trace name to download to open and analyze it with the desktop version of trace parser or
4. Select the user name to get to the user options.
5. Delete the trace if you want. You might do delete the trace if you have downloaded it.

> **NOTE**
> The trace will be deleted after 7 days. For more information about the desktop version of trace parser, see Diagnose issues and analyze performance by using Trace parser.

> **NOTE**
> Can you tell us about your documentation language preferences? Take a short survey.
>
> The survey will take about seven minutes. No personal data is collected (privacy statement).

Single-user testing with Task recorder and the Performance SDK

2/18/2021 • 4 minutes to read • Edit Online

Use the information in this topic to do single-user testing by using Visual Studio and the Performance software development kit (SDK) together with a performance test script that is generated by using Task recorder.

> **IMPORTANT**
> Visual Studio 2019 will be the last version of Visual Studio with web performance and load test features. In the future, we will publish some recommendations for alternative solutions.
>
> - If you are using the Visual Studio and Test Controller/Test Agent for on-premises load testing, Visual Studio 2019 will be the last version. You can continue using it until the end of the support cycle.
> - If you are using the cloud-based load testing service, it will continue to run through March 31, 2020. Until then, you can continue to use all of the experiences powered by this service without interruption. Alternatively, you can switch to on-premises load testing. For more information, see Cloud-based load testing service end of life.

Prerequisites

To complete the steps in this topic, you must have a development environment that has Platform update 21 or later.

> **IMPORTANT**
> Your development must be in Platform Update for 10.0.11 or later if your Finance and Operations apps were deployed in 21Vianet.

Use Task recorder to define and record an end-to-end business scenario

Before you run a single-user test, you must work with your business team to define your end-to-end scenarios and then use Task recorder to create a recording of the steps in each scenario. For more information about how to create a task recording, see Task recorder resources. The scenarios that you should test depend on your customer's business requirements. In this topic, you will use the "Create and confirm a sales order" sample scenario.

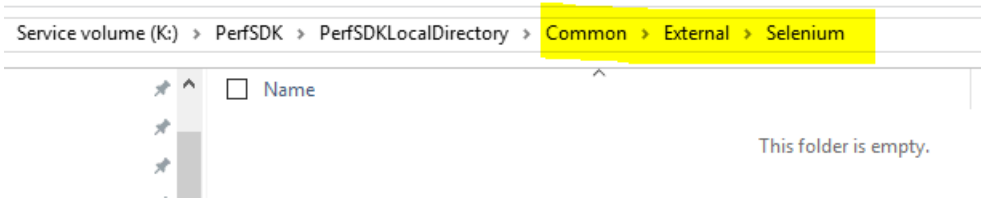
1. Sign in as a Sales persona.
2. Turn on Task recorder, and create and confirm a sales order that includes the following information:
   - Customer account
   - Item number
   - Sales quantity
   - Site
   - Warehouse
   - Sales price
3. When you've finished, select **Save as developer recording** to download the XML file.

Configure a development environment

1. Download the selenium-dotnet-strongnamed-3.13.1.zip and IEDriverServer_Win32_3.13.0.zip files.
2. Unblock and unzip the files.
3. In the **dist** folder, rename the .nupkg files as .zip files, and then unzip them.

ORIGINAL FILE NAME	NEW FILE NAME
Selenium.Support.StrongNamed.3.13.1.nupkg	Selenium.Support.StrongNamed.3.13.1.zip
Selenium.WebDriver.StrongNamed.3.13.1.nupkg	Selenium.WebDriver.StrongNamed.3.13.1.zip

4. Under your **PerfSDK** folder, create a folder that is named **Common\External\Selenium**.

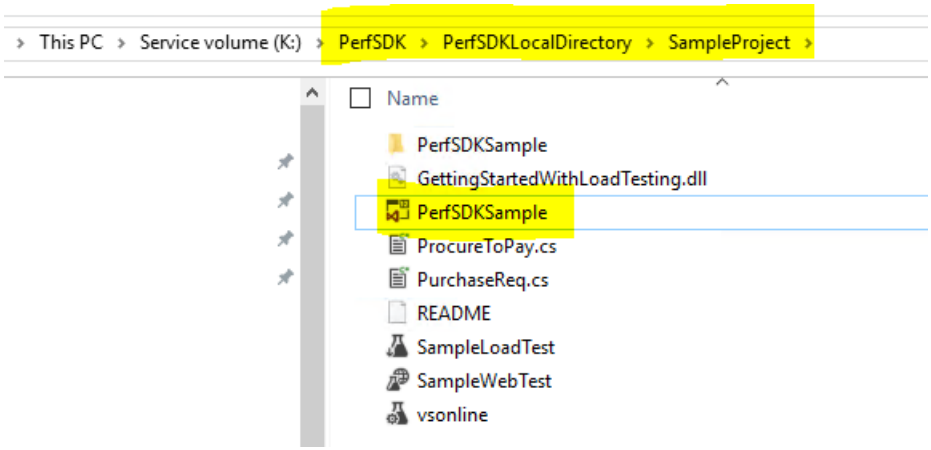


5. Copy the following files, and save them to the folder **Common\External\Selenium** that you created in the previous step:
   - IEDriverServer.exe from the unzipped IEDriverServer_Win32_3.13.0.zip file
   - WebDriver.dll and WebDriver.xml from the lib\net45 folder in the unzipped Selenium.WebDriver.StrongNamed.3.13.1.zip file
   - WebDriver.Support.dll and WebDriver.Support.xml from the lib\net45 folder in the unzipped Selenium.Support.StrongNamed.3.13.1.zip file

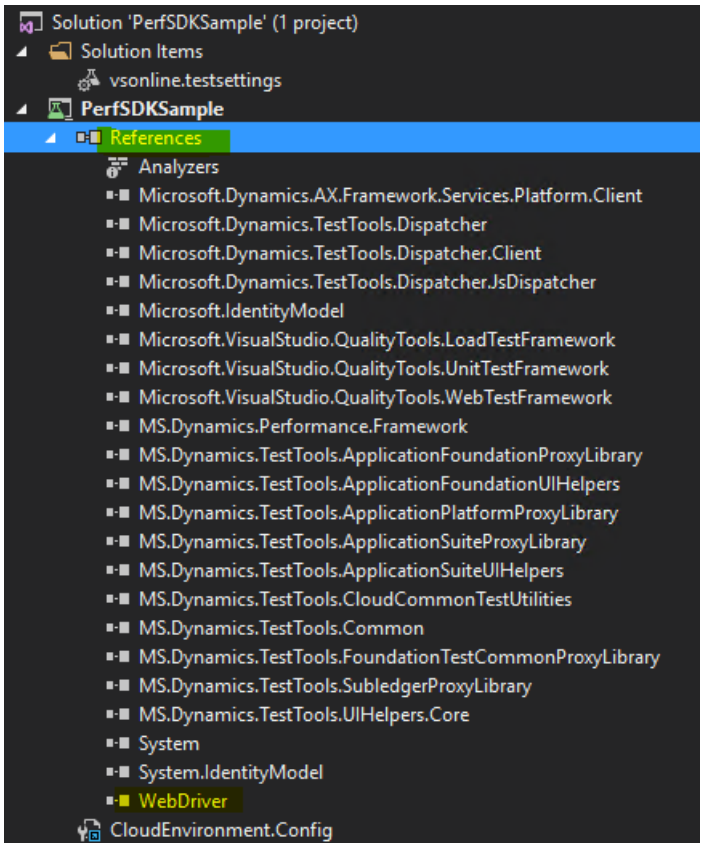
Generate a C# performance test from Task recorder

When you've finished recording the end-to-end scenario, you must generate a C# performance test script that is based the task recording.

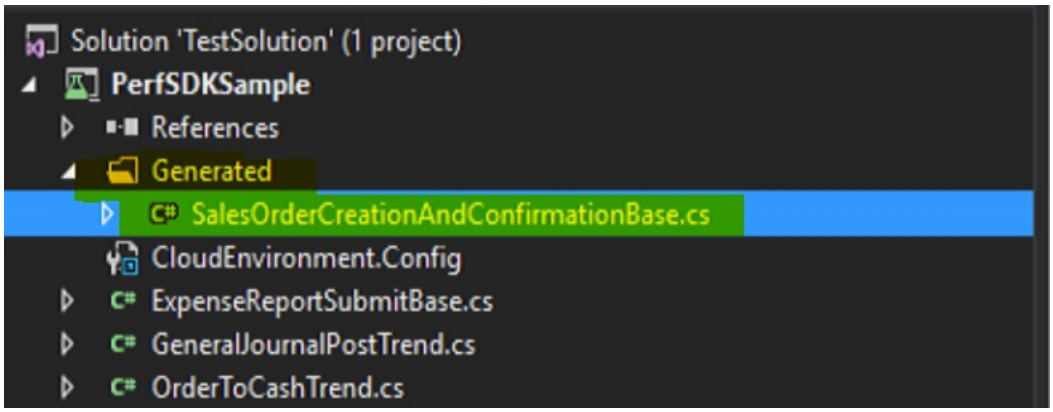
1. In a development environment, open Microsoft Visual Studio as an admin.
2. From your **PerfSDK** folder, open the **PerfSDKSample** solution. In a tier-1 sandbox or a cloud-hosted-environment, the PerfSDK folder is typically in <Service volumne>:\PerfSDK\PerfSDKLocalDirectory.



3. Add a reference to the WebDriver.dll file in the Common\External\Selenium folder.



4. On the **Dynamics 365** menu, point to **Addins**, and then select **Create C# perf test from recording**.
5. In the **Import Task Recording** dialog box, enter the following required details:
   - **Recording path** – The file location of the developer recording of your end-to-end scenario.
   - **Project path** – The location of the PerfSDKSample project. Typically, the path is <Your_PerfSDK_Folder>\SampleProject\PerfSDKSample\PerfSDKSample.csproj.
   - **PerfSDK path** – The location of PerfSDK. Typically, the path is <ServiceVolumeDrive>\PerfSDK\PerfSDKLocalDirectory.
6. When you've finished, select **Import**. A new C# class is created under the **Generated** folder of your PerfSDKSample project.



7. Build the solution.

Run single-user testing by using Test Explorer in Visual Studio

1. Update the **CloudEnvironment.config** file of the PerfSDKSample project in the following ways, so that it reflects the configuration of your environment:
   - Verify that the **HostName** and **SOAPHostName** match your development environment.
   - Verify that the **UserName** for **SelfMintingAdminUser** matches the admin account of your

development environment.

- In each **AuthenticatorConfiguration** element under the **AuthenticatorConfigurationCollection** element, replace **AadAuthenticator** with **SelfMintedTokenAuthenticator**.
- Comment out the **AzureActiveDirectoryConfiguration** and **KeyVaultConfigurations** elements.

```
<?xml version="1.0" encoding="utf-8"?>
<EnvironmentalConfigSettings xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance" xmlns:xsd="http://www.w3.org/2001/XMLSchema">
  <EnvironmentalConfigSettingsCollection>
    <EnvironmentalConfigSetting ConfigName="DEVFABRIC">
      <!-- NOTE: The HostName and SoapHostName value needs to be specified -->
      <ExecutionConfigurations Key="HostName" Value="[redacted]sandbox.ax.dynamics.com" />
      <ExecutionConfigurations Key="SoapHostName" Value="[redacted]ossoap.sandbox.ax.dynamics.com" />

    <KeyVaultConfiguration Key="KeyVaultClientId" Value="" />
    <KeyVaultConfiguration Key="KeyVaultSecretName" Value="" />
  </KeyVaultConfigurations>-->
</EnvironmentalConfigSettings>
```

2. In Visual Studio, on the **Test** menu, point to **Windows**, and then select **Test Explorer**.
3. Right-click your test case, and then select **Run selected tests**.

Tips and tricks

Use the following tips and tricks for single-user testing that uses Task recorder and the Performance SDK:

- Run your business end-to-end scenario first, before you capture it by using Task recorder.
- When you record your scenario by using Task recorder, enter values manually instead of selecting them in drop-down lists.
- Replay your task recording to make sure that everything works as you expect.
- Restart Visual Studio if you don't see your test case after the solution is built.

Troubleshooting

For information about single-user or multi-user testing that uses the Performance SDK, see Troubleshooting guide for single-user or multi-user testing with the Performance SDK.

Multi-user Performance SDK testing with a local test controller

2/18/2021 • 8 minutes to read • Edit Online

IMPORTANT

Visual Studio 2019 will be the last version of Visual Studio with web performance and load test features. In the future, we will publish some recommendations for alternative solutions.

- If you are using the Visual Studio and Test Controller/Test Agent for on-premises load testing, Visual Studio 2019 will be the last version. You can continue using it until the end of the support cycle.
- If you are using the cloud-based load testing service, it will continue to run through March 31, 2020. Until then, you can continue to use all of the experiences powered by this service without interruption. Alternatively, you can switch to on-premises load testing. For more information, see Cloud-based load testing service end of life.

Prerequisites

Before you complete the steps in this topic, verify that the following prerequisites are met:

- You have a development environment that has Platform update 21 or later in your Microsoft Azure subscription.

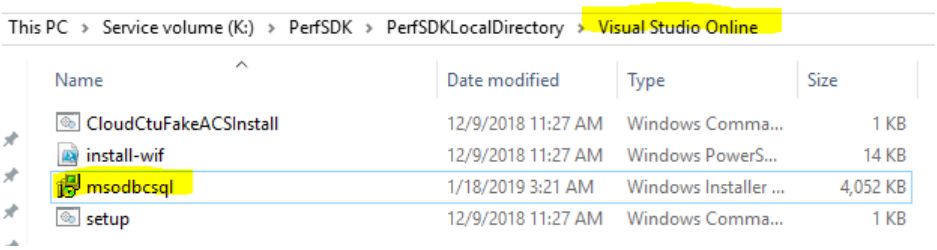
IMPORTANT

If your Finance and Operations apps were deployed in 21Vianet, the platform update of your environment must be Platform Update for 10.0.11 or above.

- You have Microsoft Visual Studio Enterprise edition in a development environment.
- You have a tier-2 or above sandbox environment that has the same release (application version and platform update) as your development environment.
- You've configured your development environment by following the steps in Single-user testing with Task recorder and the Performance SDK.
- C# performance testing classes have been generated for your end-to-end (E2E) scenarios, and you can run a single-user test by following the steps in Single-user testing with Task recorder and the Performance SDK.

Configure a development environment for multi-user testing

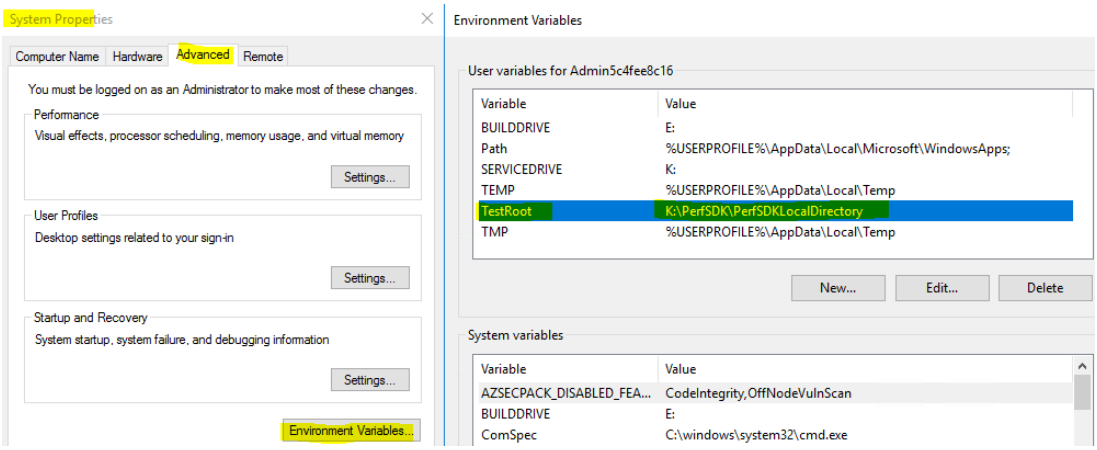
1. Download ODBC Driver 17 for SQL Server, rename the download file **msodbcsql**, and copy it to the **Visual Studio Online** folder under the **PerfSDK** folder.



2. Create an environment variable that is named **TestRoot**, and point it to the **PerfSDK** folder by running the following cmdlet in Microsoft Windows PowerShell.

```
[ENVIRONMENT]::SETENVIRONMENTVARIABLE("TESTROOT", "K:\PERFSDK\PERFSDKLOCALDIRECTORY", "USER")
```

To view the new environment variable, in the **System Properties** dialog box, on the **Advanced** tab, select **Environment Variables**.



3. Open a **Command Prompt** window as an admin, and enter the following commands to generate and install the required certificate. When you're prompted for a private key password, select **None**.

```
"C:\Program Files (x86)\Windows Kits\8.1\bin\x64\makecert" -n "CN=127.0.0.1" -ss Root -sr
LocalMachine -a sha256 -len 2048 -cy end -r -eku 1.3.6.1.5.5.7.3.1 -sv c:\temp\authcert.pvk
c:\temp\authcert.cer

"c:\Program Files (x86)\Windows Kits\8.1\bin\x64\pvk2pfx" -pvk c:\temp\authCert.pvk -spc
c:\temp\authcert.cer -pfx c:\temp\authcert.pfx
```

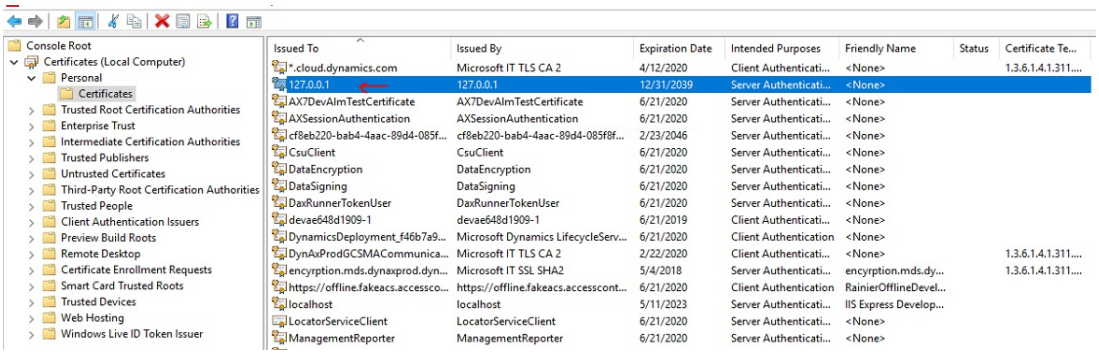
Here is an explanation of the elements in preceding commands:

- **-n "CN=127.0.0.1"** gives a human-readable name to the certificate. It's very important that the name of this certificate be **127.0.0.1**. Otherwise, the single-user tests won't be able to run.
- **-eku 1.3.6.1.5.5.7.3.1** gives the purpose of the certificate. It indicates that the certificate can be used as a Secure Sockets Layer (SSL) server certificate.

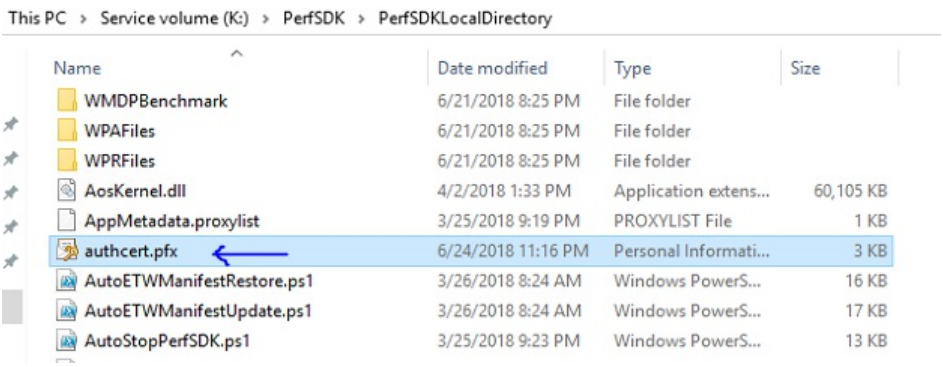
The commands generate the following certificates and save them in C:\Temp:

- Authcert.pvk
- Authcert.cer
- Authcert.pfx

4. Install the **authcert.pfx** and **authcert.cer** certificates in the **Local Machine\Personal** certificate store.



5. Copy the **authcert.pfx** certificate to the **PerfSDK\PerfSDKLocalDirectory** folder.



6. Replace the **setup.md** file in the **Visual Studio Online** folder with the following.

```
setx testroot "%DeploymentDirectory%"
ECHO Installing D365 prerequisites
ECHO MSIEXEC /a %DeploymentDirectory%\msodbcsql /passive /norestart IACCEPTMSODBCSQLLICENSETERMS=YES
MSIEXEC /a %DeploymentDirectory%\msodbcsql /passive /norestart IACCEPTMSODBCSQLLICENSETERMS=YES
%windir%\sysnative\windowspowershell\v1.0\powershell.exe -File %DeploymentDirectory%\install-wif.ps1
Md %DeploymentDirectory%\Common\Team\Foundation\Performance\Framework
%DeploymentDirectory%\CloudCtuFakeACSInstall.cmd %DeploymentDirectory%\authcert.pfx
```

7. In the **Visual Studio Online** folder, in the **CloudCtuFakeACSInstall.cmd** file, remove **%TestCertPassword%** from the **Import** command.

```
set TestCertPath=%1
set TestCertPassword=%2
ECHO Install the CloudCtu test certificate.
set MyStoreInstallCmd="&{$pfxcert = new-object
system.security.cryptography.x509certificates.x509certificate2;$pfxcert.Import('%TestCertPath%', '',
'Exportable,PersistKeySet');$store = new-object
System.Security.Cryptography.X509Certificates.X509Store('My','LocalMachine');$store.open('MaxAllowed');$store.Add(
$pfxcert)}"
ECHO CALL powershell -command %MyStoreInstallCmd%
CALL powershell -command %MyStoreInstallCmd%
```

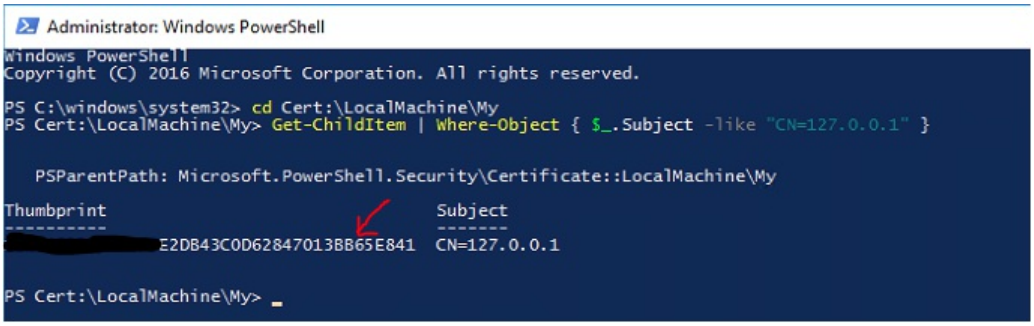
Prepare the PerfSDKSample solution for multi-user testing

1. In Microsoft Visual Studio, on the **Test** menu, point to **Test settings**, point to **Default processor architecture**, and then select **x64**.

2. Retrieve the thumbprint of the **authcert.pfx** certificate in your development environment by running the following cmdlets as an admin. Save the thumbprint somewhere, because you will need it when you configure the tier-2 or above sandbox environment.

```
cd Cert:\LocalMachine\My
Get-ChildItem | Where-Object { $_.Subject -like "CN=127.0.0.1" }
```

The following illustration shows an example of a thumbprint that these cmdlets return.



> **NOTE**
>
> In an environment that has Platform update 21 or later, a certificate that has **127.0.0.1** as the issuer is automatically installed. Verify that you retrieve the thumbprint of the certificate that you generated.

3. Update the **CloudEnvironment.config** file to reflect your configurations. As part of this update, follow these steps:

   - Verify that **HostName** and **SOAPHostName** match your tier-2 or above sandbox environment.

> **NOTE**
>
> If you don't know the **HostName** or **SOAPHostName** of your test environment, you can find it in the web.config file for the AOS server in **Infrastructure.HostUrl** or **Infrastructure.SoapServicesUrl**.

   - Add the thumbprint of the **authcert.pfx** certificate as a value of **SelfSigningCertificateThumbprint**.
   - Update **UserCount** to reflect the number of test users in your case.
   - Update **UserFormat** to reflect your naming convention for test users.

```
<?xml version="1.0" encoding="utf-8"?>
<EnvironmentalConfigSettings xmlns:xsi="http://www.w3.org/2001/XMLSchema-instance" xmlns:xsd="http://www.w3.org/2001/XMLSchema">
  <EnvironmentalConfigSettingsCollection>
    <EnvironmentalConfigSetting ConfigName="DEVFABRIC">
      <!-- NOTE: The HostName and SoapHostName value needs to be specified -->
      <ExecutionConfigurations Key="HostName" Value="d365perftechtalkdev2abc5b5f03e5be852devaos.cloudax.dynamics.com" />
      <ExecutionConfigurations Key="SoapHostName" Value="d365perftechtalkdev2abc5b5f03e5be852devaossoap.cloudax.dynamics.com" />
       <ExecutionConfigurations Key="SelfSigningCertificateThumbprint" Value="01B47080E3C4171E5B6BC667E52870E8A2091759" />

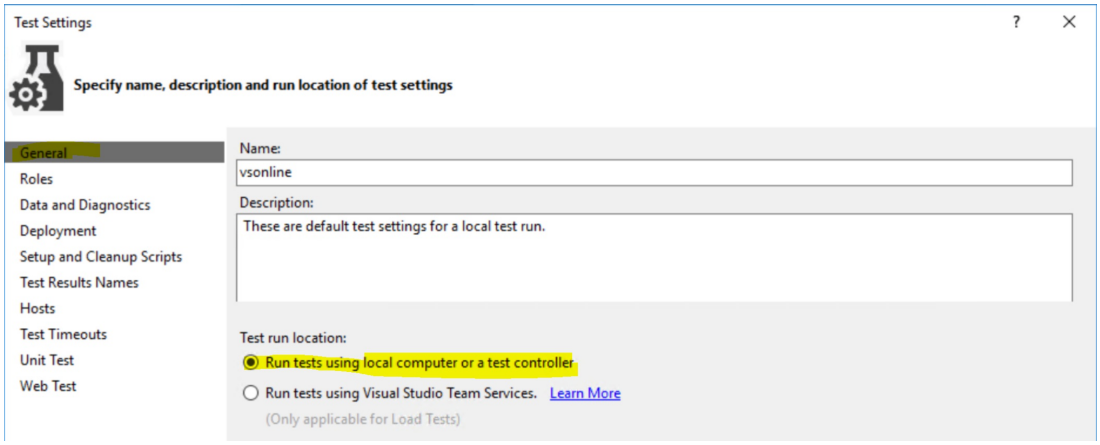
      <ExecutionConfigurations Key="DefaultDispatcher" Value="Microsoft.Dynamics.TestTools.Dispatcher.JsDispatcher, Microsoft.Dynamics.TestTools.Dispatcher.JsDispatcher" />
      <ExecutionConfigurationsNodes ConfigurationName="SVC">
        <ConfigurationSpecificDetails Key="AppConfig" Value="DEVFABRIC.Config" />
      </ExecutionConfigurationsNodes>
      <ExecutionConfigurationsNodes ConfigurationName="PRF">
        <!-- NOTE: Leave IsPerfSdkTest set to true -->
        <ConfigurationSpecificDetails Key="IsPerfSdkTest" Value="True" />
        <ConfigurationSpecificDetails Key="UserCount" Value="5" />
        <!-- NOTE: The UserFormat tenant should match the SelfMintingAdminUser tenant -->
        <ConfigurationSpecificDetails Key="UserFormat" Value="TEST00{0}@axsolutionsarchitecture.com" />
        <ConfigurationSpecificDetails Key="UserRole" Value="-SYSADMIN-" />
        <ConfigurationSpecificDetails Key="ThinkTime" Value="0" />
        <ConfigurationSpecificDetails Key="Company" Value="USMF" />
      </ExecutionConfigurationsNodes>
    </EnvironmentalConfigSetting>
  </EnvironmentalConfigSettingsCollection>
  <AuthenticatorConfigurationCollection>
    <AuthenticatorConfiguration Id="SelfMintingRunnerUser" Class="MS.Dynamics.TestTools.CloudCommonTestUtilities.Authentication.SelfMintedTokenAuthenticator">
      <Credentials IsFromKeyVault="false" Username="daxrunneruser@daxmdsrunner.com" NetworkDomain="urn:Microsoft:Dynamics:Cloud:DaxRunner" />
    </AuthenticatorConfiguration>
    <AuthenticatorConfiguration Id="SelfMintingSysUser" Class="MS.Dynamics.TestTools.CloudCommonTestUtilities.Authentication.SelfMintedTokenAuthenticator">
      <Credentials IsFromKeyVault="false" Username="testuser@microsoft.com" />
    </AuthenticatorConfiguration>
    <!-- NOTE: Specify the PerfSDK user with the System Administrator role -->
    <AuthenticatorConfiguration Id="SelfMintingAdminUser" Class="MS.Dynamics.TestTools.CloudCommonTestUtilities.Authentication.SelfMintedTokenAuthenticator">
      <Credentials IsFromKeyVault="false" Username="sa@axsolutionsarchitecture.com" />
    </AuthenticatorConfiguration>
  </AuthenticatorConfigurationCollection>
  <!-- NOTE: The AAD identity provider and App ID must be specified  -->
  <!--<AzureActiveDirectoryConfiguration IdentityProvider="https://login.windows.net/{Tenant}" ClientAppId="" />-->
  <!-- NOTE: Key vault configuration is optional for tests run locally. If this is not specified, a popup will prompt for the App Authentication key. -->
  <!--<KeyVaultConfigurations>
    <KeyVaultConfiguration Key="KeyVaultUrl" Value="" />
    <KeyVaultConfiguration Key="KeyVaultCertificateThumbprint" Value="" />
    <KeyVaultConfiguration Key="KeyVaultClientId" Value="" />
    <KeyVaultConfiguration Key="KeyVaultSecretName" Value="" />
  </KeyVaultConfigurations>-->
</EnvironmentalConfigSettings>
```

   - If your Finance and Operations apps were deployed in 21Vianet, make sure to specify **NetworkDomain="https://sts.chinacloudapi.cn/"** in **SelfMintingSysUser** and **SelfMintingAdminUser**.

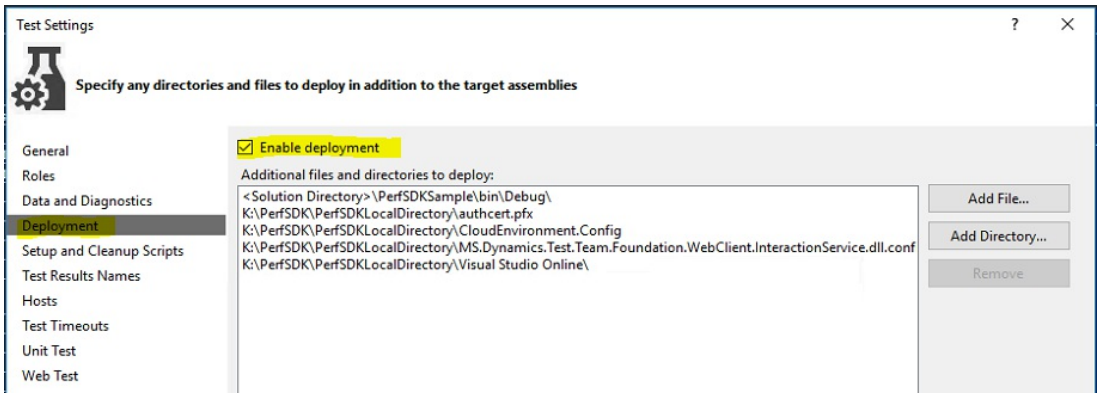
4. Configure **vsonline.testsettings**. In the **Test Settings** dialog box, on the **General** tab, in the **Test run Location** field group, select the **Run tests using local computer or a test controller** option.



> **NOTE**
>
> If you don't see **vsonline.testsettings**, reopen the solution.

5. On the **Deployment** tab, select the **Enable deployment** check box, and then use the **Add Directory** and **Add File** buttons to add the following folders and files to the **Additional files and directories to deploy** field.

   - **K:\PerfSDK\PerfSDKLocalDirectory\SampleProject\PerfSDKSample\bin\Debug** folder
   - **K:\PerfSDK\PerfSDKLocalDirectory\Visual Studio Online** folder
   - **K:\PerfSDK\PerfSDKLocalDirectory\CloudEnvironment.Config** file
   - **K:\PerfSDK\PerfSDKLocalDirectory\authcert.pfx** file
   - **K:\PerfSDK\PerfSDKLocalDirectory\MS.Dynamics.Test.Team.Foundation.WebClient.InteractionService.dll.co** file



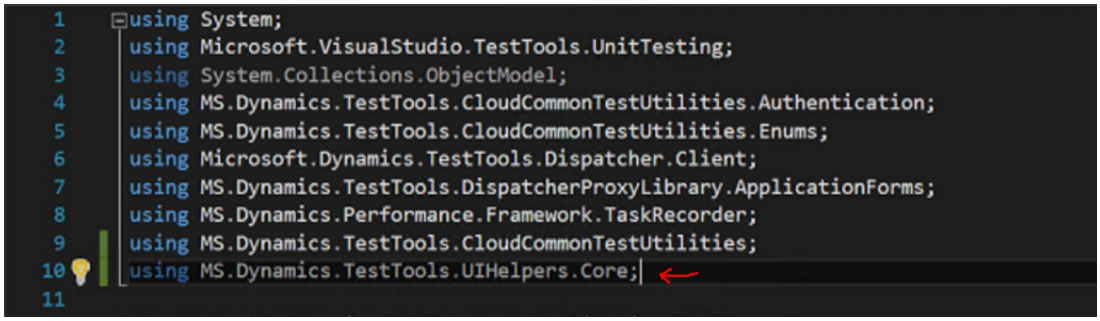
> **NOTE**
>
> When you receive a warning that states, "Deployment item not in solution folder," select **OK** to continue.

6. On the **Hosts** tab, in the **Run tests in 32 bits or 64 bits process** field, select **Run test in 64 bits process on 64 bits machine**.

7. Select **Apply**, and then close the **Test Settings** dialog box.

8. Modify your C# performance class by adding the following statement to your C# performance tests.

```
using MS.Dynamics.TestTools.UIHelpers.Core;
```



9. Modify the **TestSetup** method by adding the following lines to the beginning of the **TestSetup()** method.

```
var testroot = System.Environment.GetEnvironmentVariable("DeploymentDir");
if (string.IsNullOrEmpty(testroot))
{
    testroot = System.IO.Directory.GetCurrentDirectory();
}
Environment.SetEnvironmentVariable("testroot", testroot);
```

```
37          public void TestSetup()
38          {
39              var testroot = System.Environment.GetEnvironmentVariable("DeploymentDir");
40              if (string.IsNullOrEmpty(testroot))
41              {
42                  testroot = System.IO.Directory.GetCurrentDirectory();
43              }
44              Environment.SetEnvironmentVariable("testroot", testroot);
45
46              // For multi-user uncomment following lines
47              //if (this.TestContext != null)
48              //{
49              //    timerProvider = new TimerProvider(this.TestContext);
50              //}
51              SetupData();
52              _userContext = new UserContext(UserManagement.AdminUser);
53              // For multi-user testing use this line
54              // Client = new DispatchedClientHelper().GetClient();
55              Client = DispatchedClient.DefaultInstance;
56              Client.ForceEditMode = false;
57              Client.Company = WellKnownCompanyID.USMF.ToString();
58              Client.Open();
59          }
```

10. In the **TestSetup** method, uncomment lines in the code titled "for multi-user uncomment following lines", and comment out the following line.

```
Client = DispatchedClient.DefaultInstance;
```

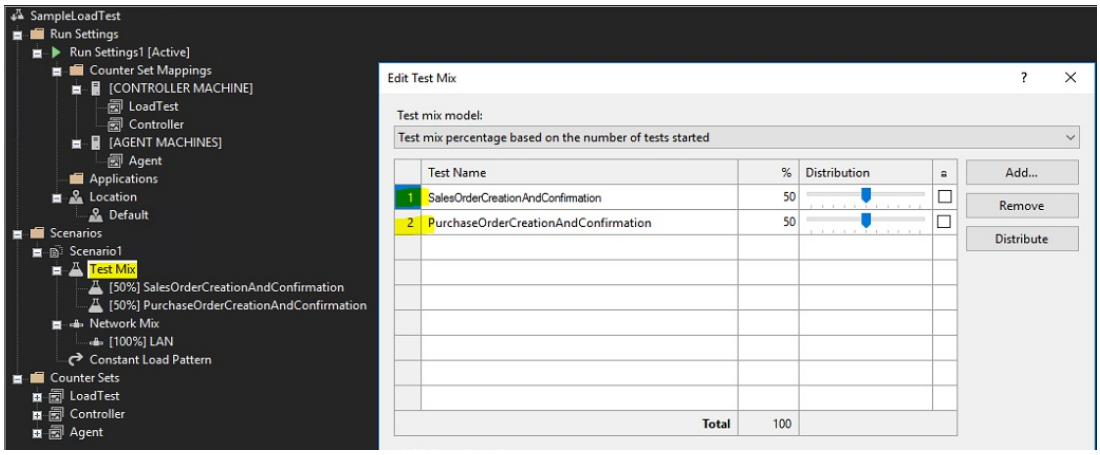
```
public void TestSetup()
{
    var testroot = System.Environment.GetEnvironmentVariable("DeploymentDir");
    if (string.IsNullOrEmpty(testroot))
    {
        testroot = System.IO.Directory.GetCurrentDirectory();
    }
    Environment.SetEnvironmentVariable("testroot", testroot);

    // For multi-user uncomment following lines
    if (this.TestContext != null)
    {
        timerProvider = new TimerProvider(this.TestContext);
    }
    SetupData();
    _userContext = new UserContext(UserManagement.AdminUser);
    // For multi-user testing use this line
    Client = new DispatchedClientHelper().GetClient();
    //Client = DispatchedClient.DefaultInstance;
    Client.ForceEditMode = false;
    Client.Company = WellKnownCompanyID.USMF.ToString();
    Client.Open();
}
```

11. Modify the **TestCleanup** method so that it resembles the following example.

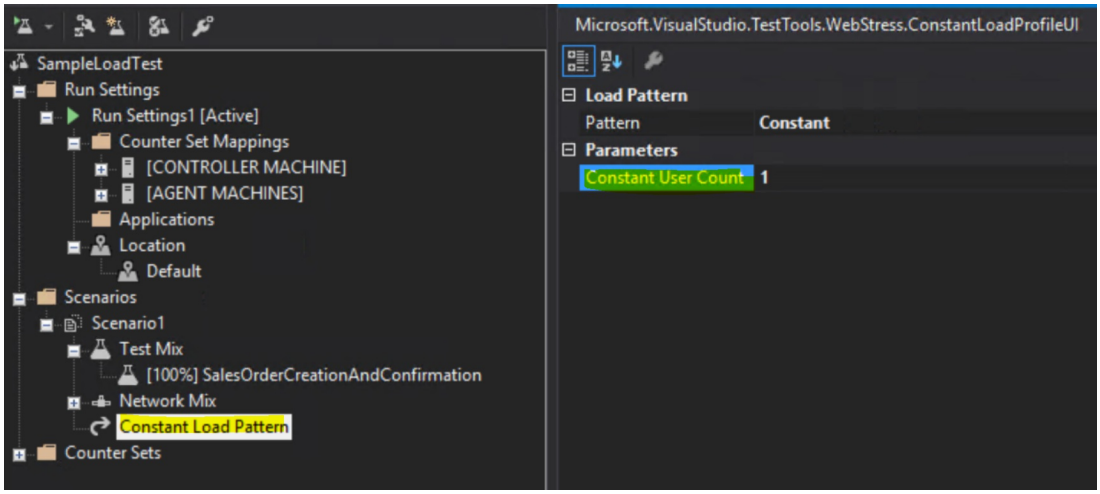
```
public void TestCleanup()
{
    Client.Close();
    Client.Dispose();
    Client = Null;
    //_userContext.Dispose();
}
```

12. Repeat steps 2 through 11 for all the C# performance test classes that you have.
13. When you've finished, build the solution.
14. In **SampleLoadTest.loadtest**, select your test class under **Test Mix**.



15. In **SampleLoadTest.loadtest**, update the **Timing** fields of **Run Settings1 [Active]**. These fields include **Warm-up Duration**, **Run Duration**, and **Cool-down Duration**.

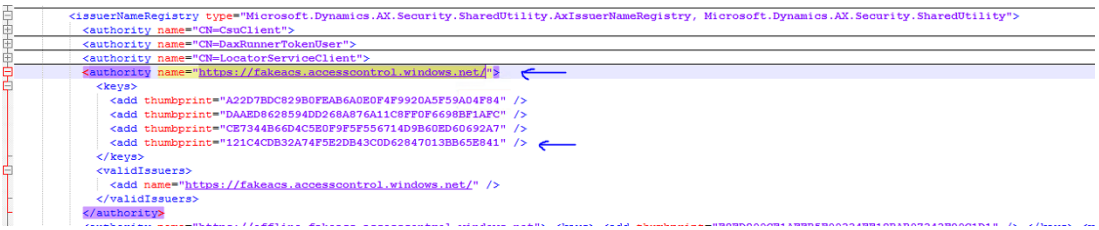
16. In **Constant Load Pattern**, set the **Constant User Count** parameter to the total number of users that you want to use to run the test.



Configure a tier-2 or above sandbox environment for multi-user testing

If your AOS allows Remote Desktop connections

1. Open Microsoft Internet Information Services (IIS) Manager from **Administrative Tools**, and then, under **Sites**, select **AOSService**.
2. On the right, select **Explore in Actions**, and then find the **wif.config** file at the bottom of the window.
3. Add the thumbprint of the **authcert.pfx** certificate to the bottom of the `https://fakeacs.accesscontrol.windows.net/` authority and save the change.



4. Repeat steps 1 through 3 on each AOS computer.

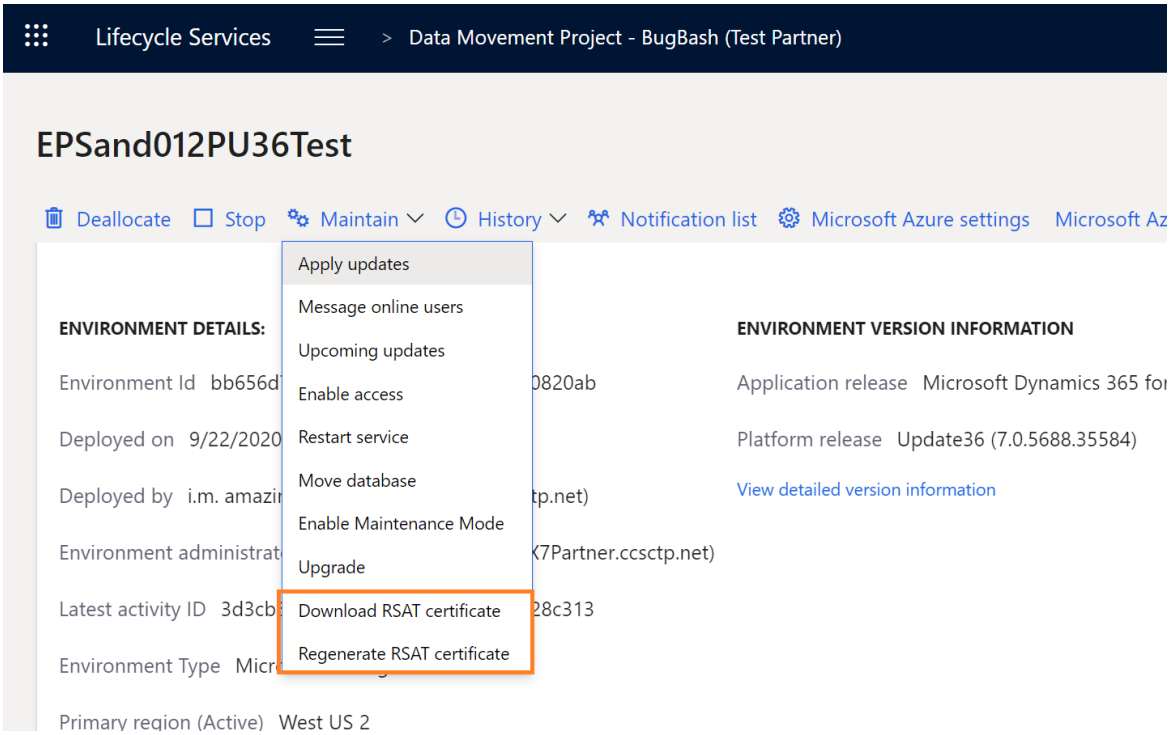
5. Restart all AOS instances.

If you do not have Remote Desktop access to the server

In cases where your Remote Desktop Protocol (RDP) access is removed, such as Microsoft-managed or self-service type sandboxes, Microsoft will generate the certificate for your environment and have it pre-configured. Follow these steps to retrieve the RSAT certificate, which is necessary to use with PerfSDK.

1. Under **Maintain** on your environment details page in Lifecycle Services you'll see two new options.

- Download RSAT certificate
- Regenerate RSAT certificate



Use the **Download** button to retrieve the certificate bundle as a .zip file.

2. You'll receive a warning that a clear-text password will be displayed on your screen. Select **Yes** to continue.

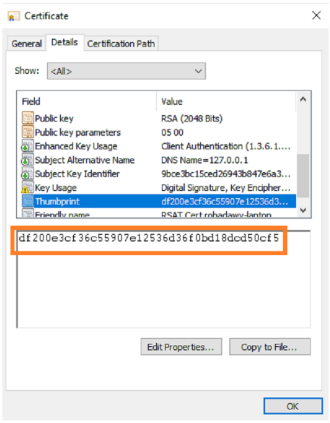
3. Copy the clear-text password for later use. You'll see the .zip file has been downloaded. Inside the .zip file is a certificate (.cer) and a personal information exchange (.pfx) file. Unzip the file.

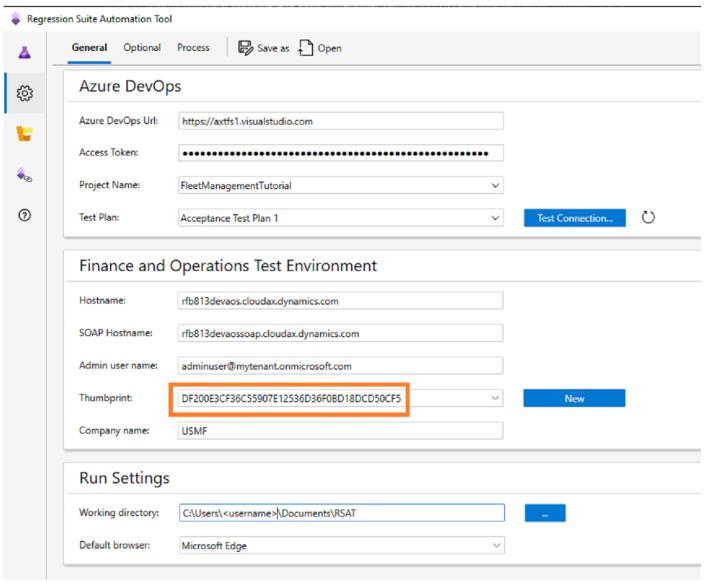
4. Double-click the certificate to open it, and then select **Install**. Install this certificate to your local machine, and then browse to the **Personal** store. Repeat this process for the local machine, and browse specifically to the **Trusted Root Certification Authorities** store.

5. Double-click the personal information exchange (.pfx) file to open it, and select **Install**. Install this certificate to your local machine, enter the password saved in step 2, and browse to the **Personal** store. Repeat this process for the local machine location, enter the password saved in step 2, and browse specifically to the **Trusted Root Certification Authorities** store.

6. Double-click the certificate file to open it. Browse to the **Details** tab, and scroll down until you see the **Thumbprint** section. Select **Thumbprint**, and copy the ID in the text box. Use this thumbprint for RSAT

and to update your PerfSDK **CloudEnvironment.config** thumbprint.

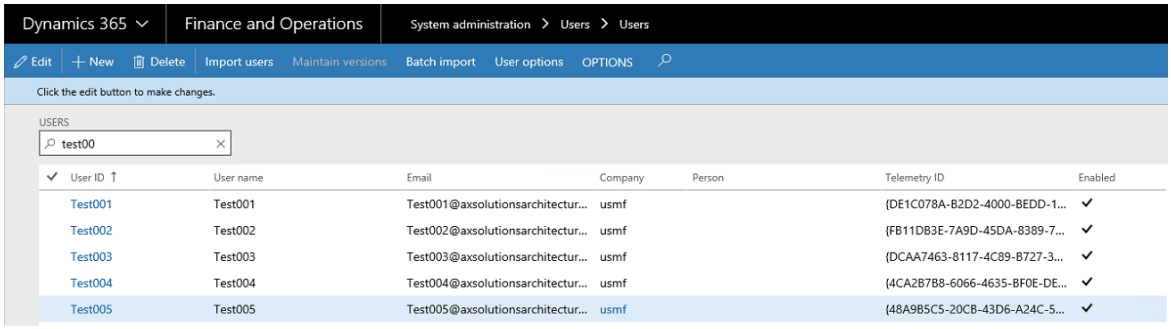




You can now run your tests against the environment using this certificate. The certificate will be auto-rotated by Microsoft before it expires, at which time you will need to download a new version of this certificate starting from step 1 above. For self-service environments this will be rotated every 90 days during a downtime window that is closest to the expiry. These downtime windows include customer initiated package deployment, and database movement operations that target the environment.

Create test users

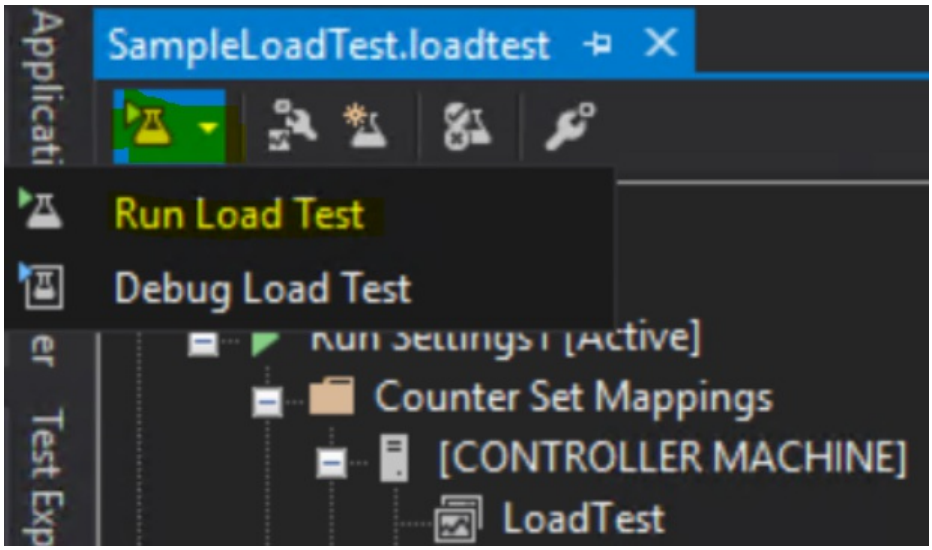
Open the **SampleLoadTest.load** test to create test users and import them into your target environment. Then assign the **System Administrator** security role to each user.



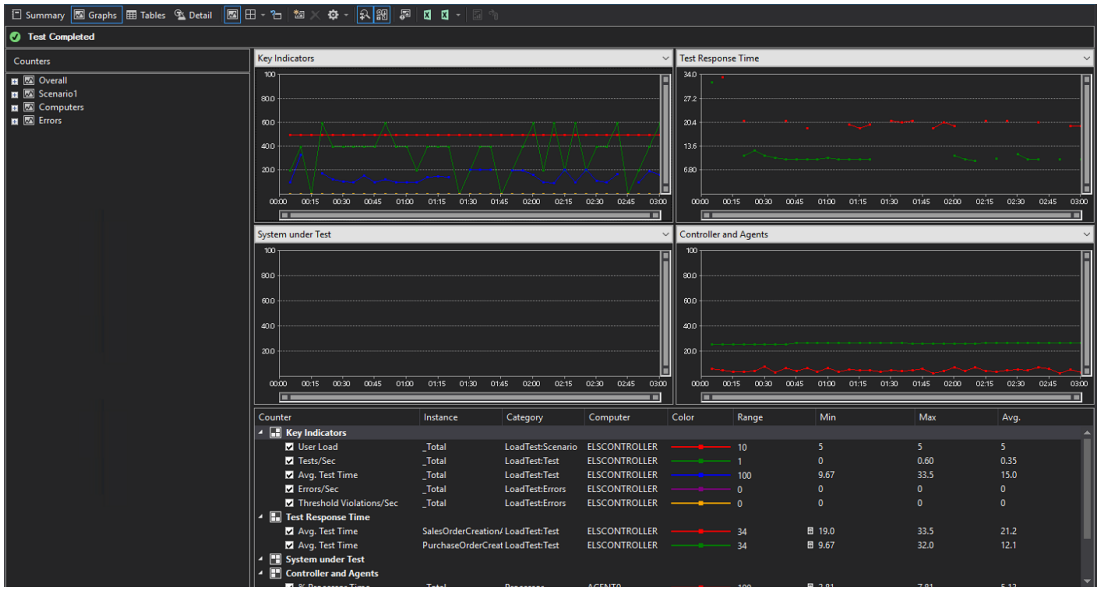
> **NOTE**
>
> You can also create test users by running **MS.Dynamics.Performance.CreateUsers.exe**. In this case, you don't have to use IISRESET.

Run multi-user testing by using a local test controller

1. On the devbox, in Visual Studio, select **Run Load Test**.



2. Review the test output.



Troubleshooting

For information about single-user or multi-user testing that uses the Performance SDK, see Troubleshooting guide for single-user or multi-user testing with the Performance SDK.

Multi-user testing with the Performance SDK and Azure DevOps

2/18/2021 • 2 minutes to read • Edit Online

IMPORTANT

Visual Studio 2019 will be the last version of Visual Studio with web performance and load test features. In the future, we will publish some recommendations for alternative solutions.

- If you are using the Visual Studio and Test Controller/Test Agent for on-premises load testing, Visual Studio 2019 will be the last version. You can continue using it until the end of the support cycle.
- If you are using the cloud-based load testing service, it will continue to run through March 31, 2020. Until then, you can continue to use all of the experiences powered by this service without interruption. Alternatively, you can switch to on-premises load testing. For more information, see Cloud-based load testing service end of life.

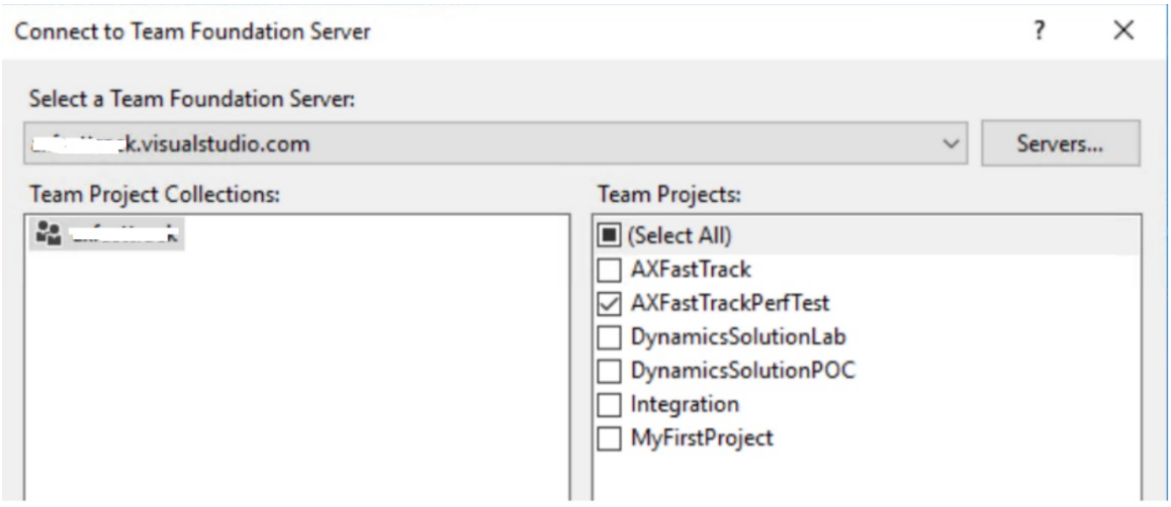
Prerequisites

Before you can complete the steps in this topic, verify that the following prerequisites are met:

- You have a development environment that has platform update 21 or later in own your Microsoft Azure subscription
- You have Microsoft Visual Studio Enterprise edition in a development environment.
- You have a tier-2 or above sandbox that has the same release (application version and platform update) as your development environment.
- You've completed all the steps in Single-user testing with Task recorder and the Performance SDK and all the steps except "Run multi-user testing with local test controller" in Multi-user testing with the Performance SDK and a local test controller.

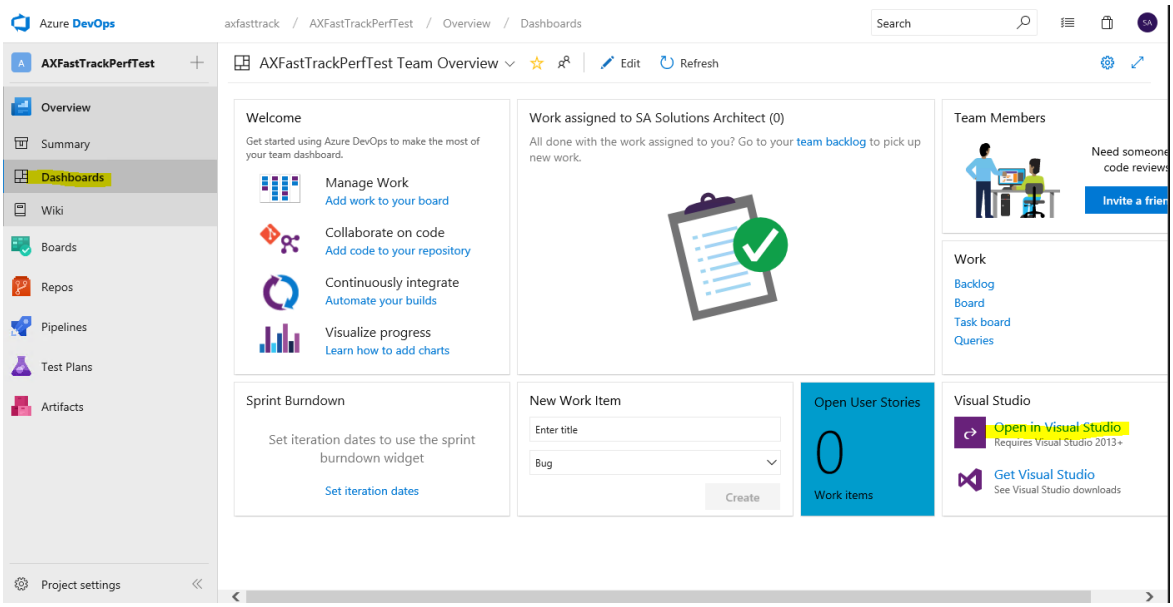
Prepare the PerfSDKSample solution for multi-user testing

1. Connect Microsoft Visual Studio in a development environment to an Azure DevOps project.



> **NOTE**
>
> When you add the Azure DevOps server, use **https://<YourAzureDevOpsAccount>.visualstudio.com**.

2. On your Azure DevOps project dashboard, select **Open in Visual Studio**, and then select **Allow in prompted window**.

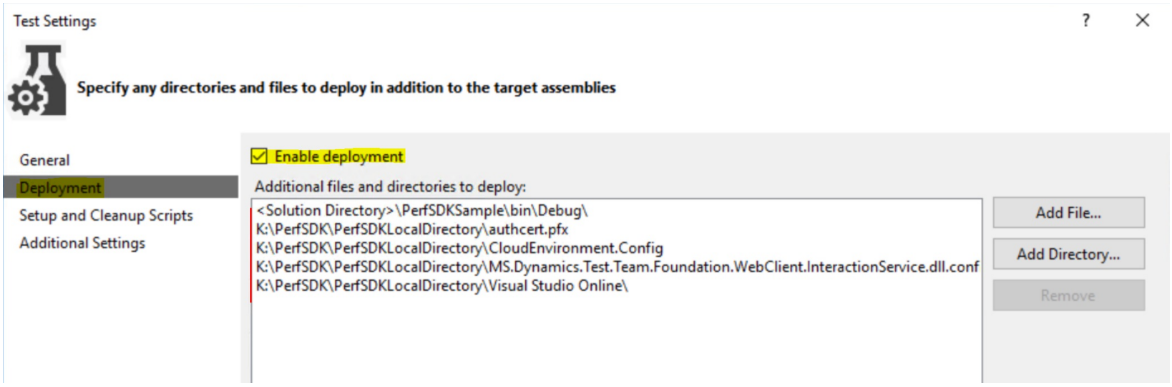


3. After Visual Studio is opened, verify that you're running it as an admin. If you aren't, close it, and then reopen it as an admin.

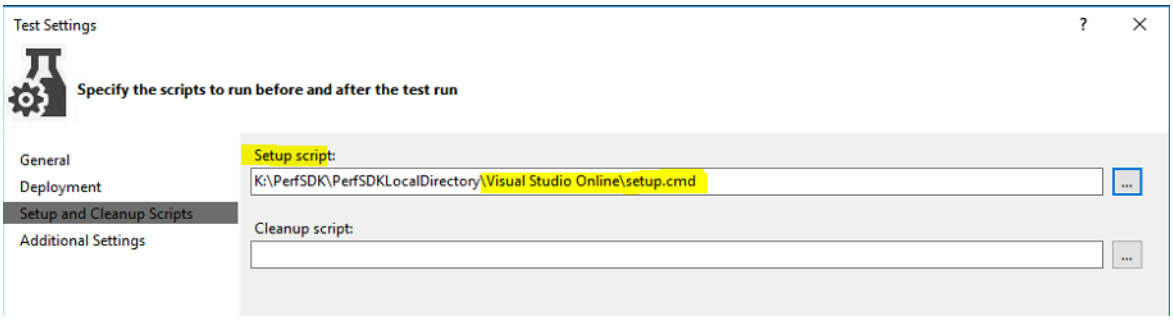
4. Go to K:\PerfSDK\PerfSDKLocalDirectory\SampleProject, and change the file, **vsonline.testsettings**.

5. In the **Test Settings** dialog box, on the **General** tab, select the **Run tests using Visual Studio Team Services** option.

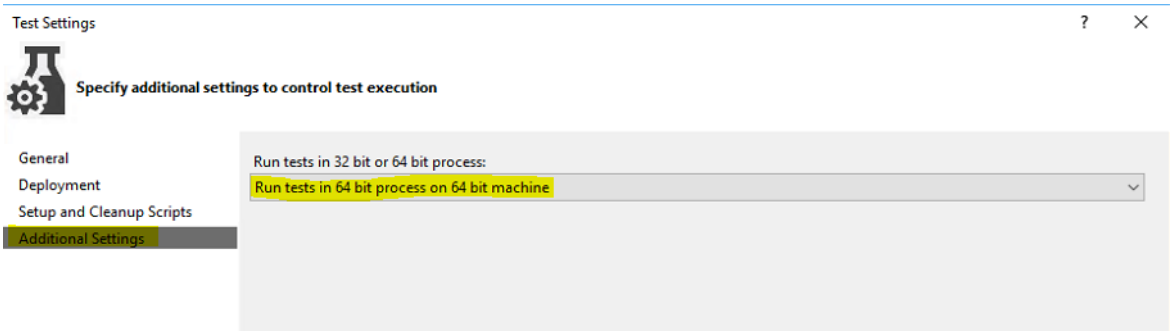
6. On the **Deployment** tab, leave all the fields set as they were set in Multi-user testing with the Performance SDK and a local test controller.



7. On the **Setup and Cleanup Scripts** tab, point the **Setup script** field to the **setup.cmd** file under the **Visual Studio Online** folder.



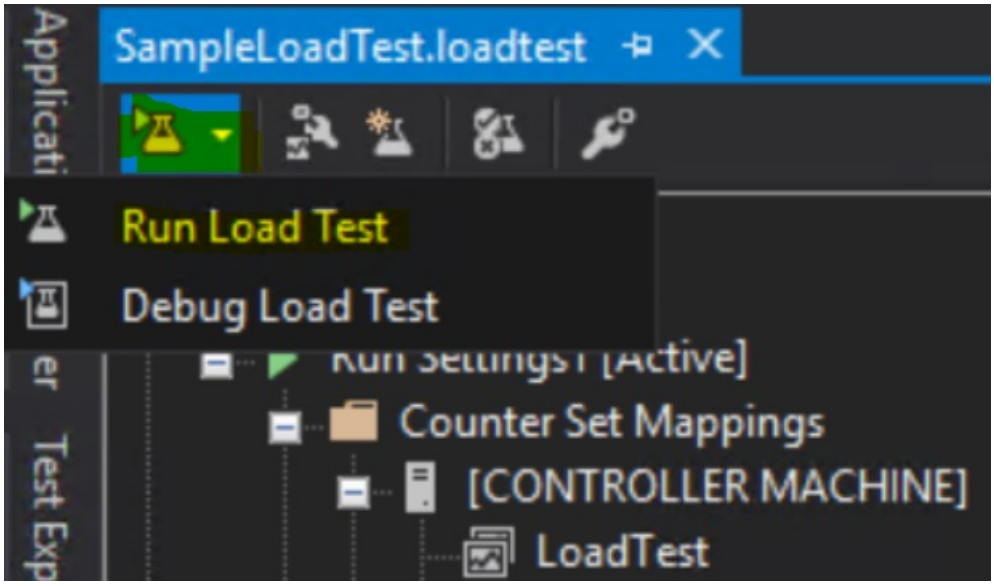
8. On the **Additional Settings** tab, leave all the fields set as they were set in Multi-user testing with the Performance SDK and a local test controller.



9. Select **Apply and Close**.

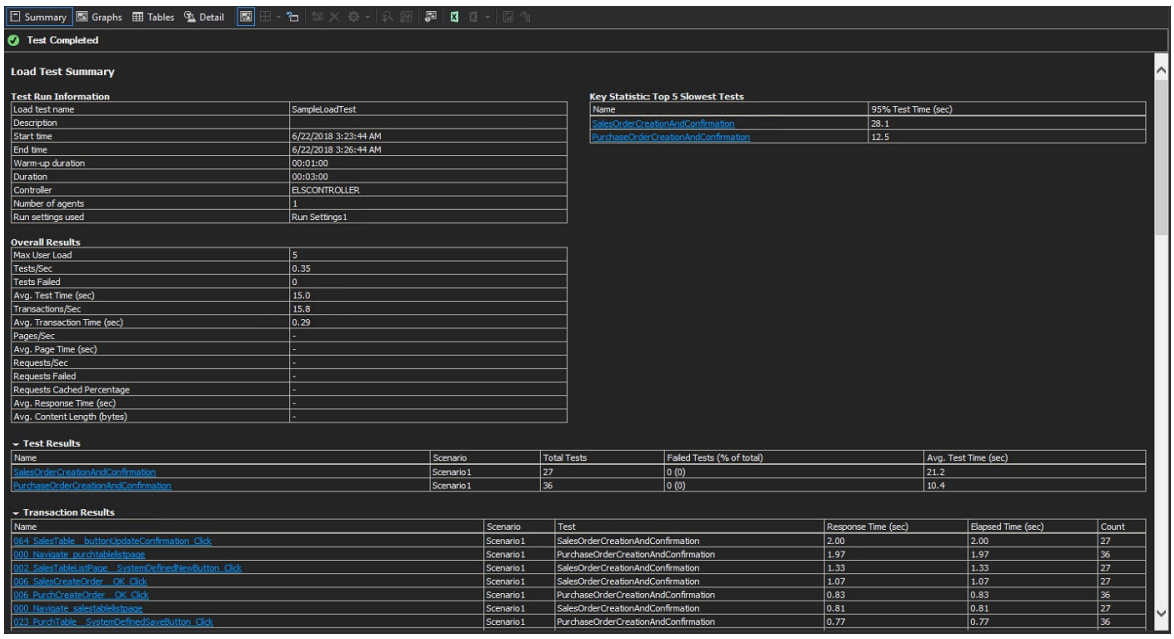
Run multi-user testing by using Azure DevOps

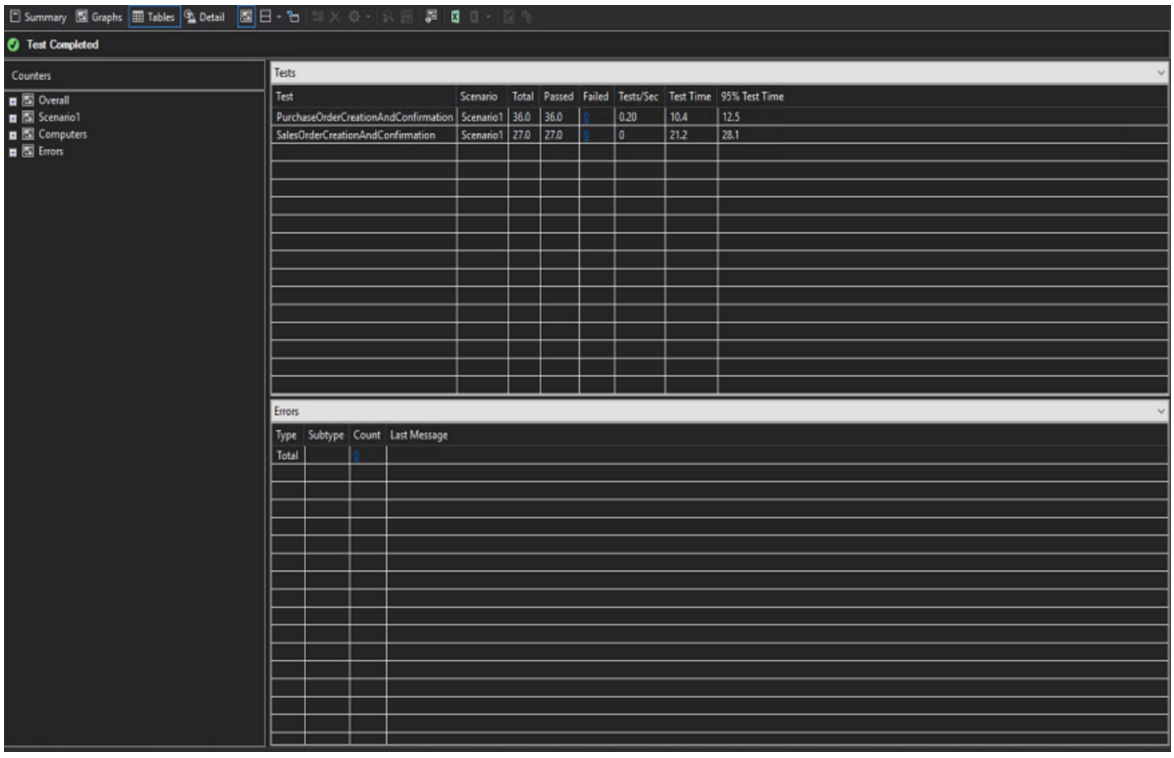
1. In Visual Studio, open **SampleLoadTest.loadtest**.
2. Select **Run Load Test**.

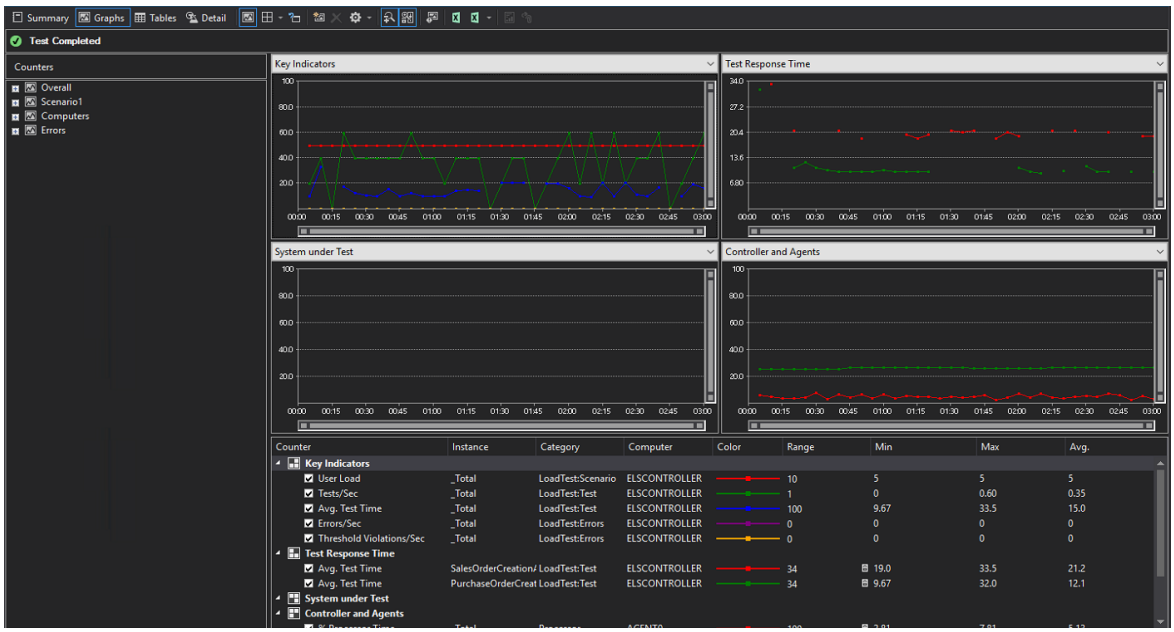


The load test is run, and a chart shows its progress.

3. Review the test output.







Tips

To switch multi-user testing between the local test controller and Azure DevOps, create a copy of **testsettings** for each, and then select the copy that you want as **Active Test Settings**.

Troubleshooting

For information about single-user or multi-user testing that uses the Performance SDK, see Troubleshooting guide for single-user or multi-user testing with the Performance SDK.

Troubleshooting guide for testing with the Performance SDK

2/18/2021 • 13 minutes to read • Edit Online

No client was opened in the time-out period

This issue affects only single-user tests. When the test is running, a web client is opened, but a website is never loaded. Instead, there is an empty web client that has a white background. The following message appears at the top of the page, "This is the initial start page for the WebDriver server." The test eventually times out and fails, and an error message is shown.

Error - No client was opened in the time-out period

> Initialization method <Test class name>.TestSetup threw an exception. System.TimeoutException: System.TimeoutException: No client was opened in the timeout period.

Solution

See Multi-user testing with the Performance SDK and a local test controller. That topic explains how to create a correct certificate for this type of test. It also explains how to add the thumbprint of the certificate to the wif.config file.

Zoom factor

This issue affects only single-user tests.

Error - Zoom factor

> Initialization method <Test class name>.TestSetup threw exception. System.InvalidOperationException: System.InvalidOperationException: Unexpected error launching Internet Explorer. Browser zoom level was set to 200%. It should be set to 100% (NoSuchDriver).

Solution - Zoom factor

In Internet Explorer, you can change the zoom factor to 100 percent by changing the following registry keys:

- Computer\HKEY_CURRENT_USER\SOFTWARE\Microsoft\Internet Explorer\Zoom\ResetZoomOnStartup = 0
- Computer\HKEY_CURRENT_USER\SOFTWARE\Microsoft\Internet Explorer\Zoom\ResetZoomOnStartup2 = 0
- Computer\HKEY_CURRENT_USER\SOFTWARE\Microsoft\Internet Explorer\Zoom\Zoomfactor = 80000

Depending on the version of the local machine that is used, before you start the Remote Desktop Protocol (RDP) session, you might have to select **Change the size of text, apps and other items**. This field is available in **Display settings** in Microsoft Windows.
